The spectrum of energies for the different categories of electrons that are emitted from a surface exposed to an energetic beam of incident electrons is summarized schematically in Fig. 3. Because inelastic scattering processes may involve a range of different energies and because a given electron may be subject to several different scattering events, the spectrum is continuous--ranging from zero to the energy of the incident beam. By convention, the term "secondary electrons" is often used to refer to emitted electrons with energies less than or equal to 50 eV, and the term "backscattered electrons" is applied to electrons that leave the surface with energies greater than 50 eV, including high-energy secondary electrons, Auger electrons, low-loss electrons, and elastically scattered electrons. Many of the electrons that leave the surface have undergone multiple scattering by several different processes.

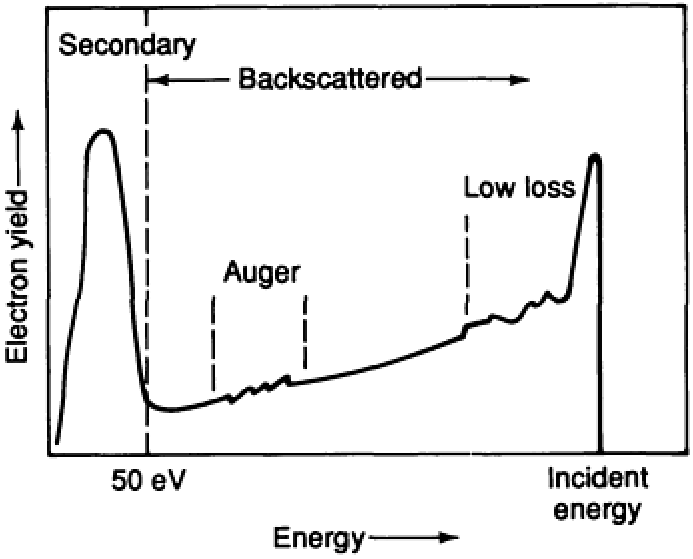

Fig. 3 Energy spectrum of emitted electrons

X-rays are produced by two processes. "Bremsstrallung" x-rays are generated by the deceleration of energetic electrons in the potential field of the specimen and have a continuous range of energies. Characteristic x-rays, as mentioned earlier, result from the relaxation of atoms ionized by the loss of an inner-shell electron and have discrete energies characteristic of the atoms in the specimen. A characteristic x-ray emitted as a result of an electron transition to a vacant K-shell site is referred to as a K-series x-ray. More specifically, $K\alpha$ x-rays are associated with the L- to K-shell transition and $K\beta$ x-rays with the M- to K-shell transition. Similarly, such series exist for other shells. Practically speaking, only the K, L, and M series give rise to x-rays that have sufficient energy to be useful in SEM- and TEM-based analysis systems.

Cathodoluminescence refers to the emission of light (infrared, visible, and ultraviolet) due to irradiation by electrons. A ubiquitous example of cathodoluminescence is the visible light emitted by the phosphor of a cathode-ray tube (CRT)

under the action of its internal electron beam. Semiconductors, various other inorganic materials and certain organic materials exhibit cathodoluminescence. Metals are only weakly cathodoluminescent. The most extensive application of the cathodoluminescent signal has been in connection with the study of semiconductors. In semiconductors, the emission of light occurs as a result of the recombination of electron-hole pairs either intrinsically between the valence and conduction band or extrinsically because of the presence of donor and acceptor sites. Discussions of cathodoluminescence can be found in Ref 8, 9, and 11.

Specimen current, I_c, originates from the absorption of electrons in the specimen. Thus, referring to Fig. 2, the specimen current is given by:

$$I_c = I_i - (I_{bs} + I_s + I_t + I_{diff}) \qquad \textbf{(Eq 1)}$$

where I_i is the incident-beam current, I_{bs} is the backscattered current, I_s is the emitted secondary electron current, I_t is the transmitted electron current, and I_{diff} is the diffracted-beam current. For a bulk specimen, I_t and I_{diff} are zero.

Finally, the electron beam gives rise to heating. This thermal signal is not used directly, but has been exploited in connection with thermal wave imaging, whereby an acoustic signal resulting from the expansion caused by heating is detected.

An important concept in connection with the beam-specimen interaction process is that of the interaction volume. This is the volume of material penetrated by the incident beam and includes elastically and inelastically scattered electrons. For specimens of low atomic number, the volume has a teardrop shape, as shown schematically in Fig. 4. The volume becomes more hemispherical in shape for materials of higher atomic number. The relative depths from which the various signals may escape to the surface are indicated in Fig. 4.

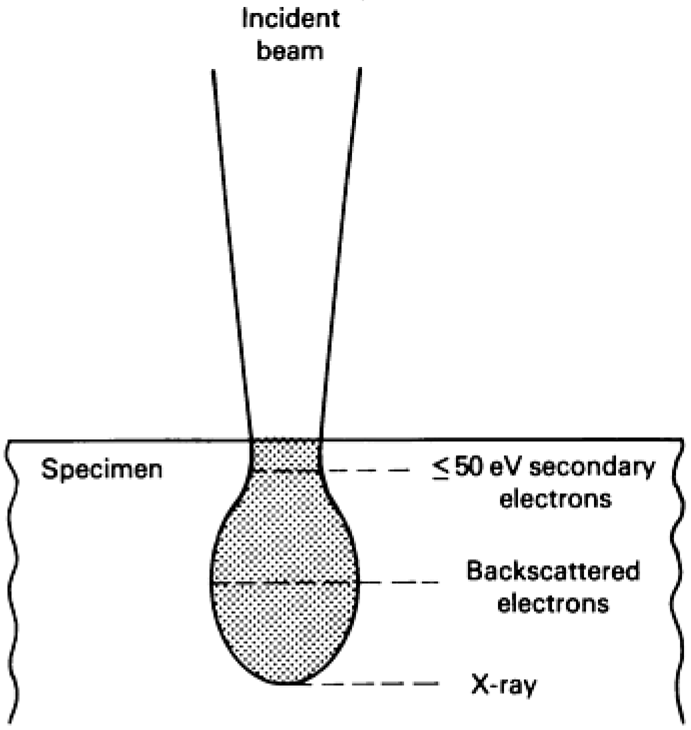

Fig. 4 Electron-specimen interaction volume

SEM and TEM Instruments

The first transmission electron microscopes were designed solely to extract information from transmitted and diffracted electrons beams, and the first scanning electron microscopes utilized secondary and/or backscattered electrons. Modern

TEMs and SEMs continue to be optimized for these signals; however, they also make extensive use of several other signals shown in Fig. 2. For instance, both microscope make use of the emitted x-ray spectrum to obtain information on composition, greatly enhancing their analytical capabilities.

Schematic drawings illustrating the basic configurations of SEM and TEM instruments are shown in Fig. 5(a) and (b), respectively. Both instruments employ an illumination system consisting of an electron gun and subsequently electromagnetic lenses to project an appropriately focused and/or collimated beam of electrons onto the specimen. In the TEM, additional lenses below the specimen are provided for image formation and magnification. Suitably located apertures are employed to defined the beam, along with coils for beam alignment, astigmatism correction, and beam scanning. A vacuum environment is required for both microscopes to limit scattering by gas molecules.

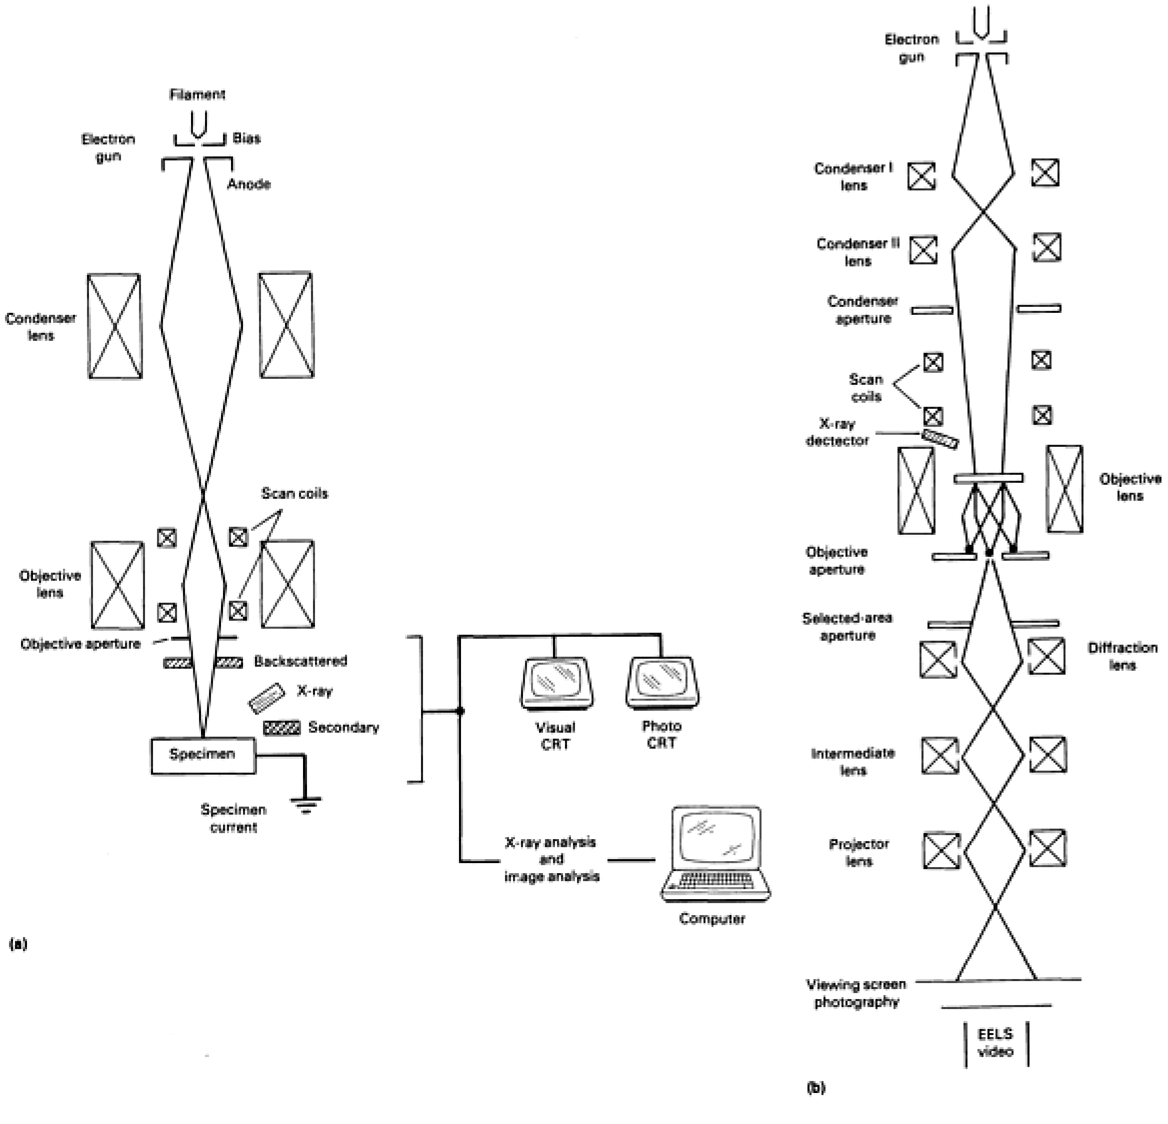

Fig. 5 Basic configuration of (a) SEM and (b) TEM

The most common source of electrons in both instruments is a heated tungsten filament, although single-crystal lanthanum hexaboride (LaB_6) emitters and tungsten field emission tips are gaining in popularity. These two sources are substantially brighter than the tungsten filament, as much as 10^2 times for the LaB_6 source and 10^4 for the tungsten field emission source. In general, they provide improved resolution and analytical capabilities. Their operational life is also greater, but cost is higher and a more sophisticated vacuum system is required.

The electrons are accelerated through a potential that is established by an applied voltage between the filament and anode. SEM accelerating voltages typically range from about 100 V to 30 kV. Higher accelerating voltages are not ordinarily

used with the SEM, because this instrument is applied primarily to the study of surface features of bulk specimens. In general, as will be discussed later, an accelerating voltage is selected that best suits the application at hand.

Transmission electron microscopes are available in three different accelerating voltage ranges. The most commonly used instruments operate at a maximum of 120 kV, but allow the selection of voltages as low as 20 kV. With so-called intermediate-voltage microscopes, the maximum voltage is typically 200 to 400 kV. High-voltage instruments are capable of operating at 10^6 V and higher.

In general, a higher accelerating voltage permits penetration of thicker specimens and provides improved resolution. However, the gain in going from the intermediate-voltage range to the high-voltage range is relatively small for all but the most specialized applications and is achieved at a very substantial increase in cost. Intermediate-voltage instruments allow routine observation of the atomic structure of all classes of crystalline materials. This, together with increased penetration, improved EELS capabilities, and the fact that specially constructed laboratory facilities (necessary for high-voltage instruments) are not required, has led to an increase in the popularity of intermediate-voltage instruments.

In the SEM, the specimen is normally located below the final lens in the illumination system. For improved resolution, however, some instruments provide a second position within the final lens. The electron beam is focussed to a small spot and scanned serially over the specimen to form a rectangular raster. Secondary electrons (or one of the other sources in Fig. 2) are collected to provide a signal that is amplified and used to modulate the intensity of the electron beam in a CRT, The CRT beam is scanned in synchronism with the electron beam incident on the specimen, resulting in an observable image. The magnification of the image is determined by the ratio of the distance scanned on the specimen to the corresponding distance displayed on the CRT, the latter generally being kept constant. Thus, when the scanned area on the specimen is small, the magnification is high, and when the scanned area is large, the magnification is low.

Resolution in the SEM is determined to a first approximation by the diameter of the beam incident on the specimen. In practice, the diameter of the beam is controlled by the type of filament, the excitation of the condenser lenses, the final aperture size, and the position of the specimen with respect to the final lens. The latter distance is referred to as the working distance. A critical factor limiting the useful probe size is the available beam current. Increasing the excitation of the condenser lenses or reducing the size of the final aperture results in a small electron probe diameter; however, the probe current is also reduced. This in turn reduces the strength of the signal available for amplification, so that the usable minimum probe size is limited by the capacity of the signal amplifier, that is, the signal-to-noise ratio of the amplifier. With a heated tungsten filament, the probe diameter is limited to about 5 nm; with LaB_6 and field emission sources, diameters of about 3 nm and 1 nm, respectively, are achievable.

In actual operation, the nature of the specimen and the signal source (secondary electrons, x-rays, and so on) usually play a limiting role in determining resolution. If the features of interest result in only a small difference in the signal, then an increased probe current and correspondingly larger probe size are required, thereby reducing resolution.

The TEM in its conventional mode of operation differs significantly from the SEM. The specimen is illuminated by a relatively broad, nearly parallel, stationary beam of electrons. Transmitted and diffracted electrons that have lost little or no energy and that do not deviate too far from the optical axis are focused by the objective lens. Subsequent lenses provide additional magnification and allow observation of either the image or a diffraction pattern. The image and diffraction pattern can be viewed directly on a fluorescent screen, photographed, or displayed by means of a TV system.

As an additional enhancement, TEMs have also been adapted for operation in a scanning mode, similar to the SEM. For this purpose, the illuminating beam is focused to a small probe. Detectors are included to sense transmitted and diffracted electrons, as well as secondary and backscattered electrons as in the SEM. A transmission electron microscope designed to function either in the conventional stationary illumination mode or in the scanning mode is commonly referred to as a scanning transmission electron microscope (STEM). The acronym CTEM is often used to refer to a conventional transmission electron microscope without STEM capability, or simply to operation in the conventional mode. Transmission electron microscopes are available that have been designed and optimized to operate only in the scanning mode; such instruments are usually referred to as "dedicated" STEMs. Finally, a TEM equipped with x-ray detectors, and perhaps with electron energy loss spectrometers as well, is frequently referred to as an analytical electron microscope, or AEM.

Originally, SEM and TEM instruments were essentially analog in operation. X-ray analysis systems designed as separate attachments to SEMs and later to TEMs incorporated digital technology. As development has progressed, these systems have become capable not only of processing x-ray data but also of controlling the position of the beam on the specimen.

Thus, composition maps can be acquired and stored in computer memory. With suitable programming, the stored data can be used, for example, to provide information on the proportion of each compositionally different phase in the sample or to count particles having a particular composition. In essence, the x-ray analysis system has also become an image analysis system. Accommodating other signals in the system, such as secondary and backscattered electron signals, is a fairly easy step. Thus, image analysis can be done directly with these signals, eliminating the need for indirect analysis of photographs and separate image analysis equipment.

Recent TEM and SEM instrument designs rely heavily on digital technology and computer control, incorporating keyboards and computer CRT screens. The operator interacts with a software program rather than directly manipulating an array of knobs, buttons, and switches. The image can be digitized and sent directly to computer memory or stored in a nonvolatile memory medium, such as a hard disk. As a result, image analysis and x-ray analysis capabilities are directly incorporated in the instrument.

Finally, it should be mentioned that the SEM is not merely a passive instrument for examining wear-related specimens; it may also incorporate a wear testing device for *in situ* observation of wear processes. A number of important results have been obtained in this way (Ref 28, 29, 30, 31, 32, 33).

Specimen Preparation

Scanning Electron Microscopy

An important advantage of the SEM is that a specimen can be examined with little need for special preparation beyond that required for the optical microscope. This does not imply that the condition and nature of the specimen do not have a significant bearing on the quality of the image and the information obtained. Indeed, revealing the desired information may require considerable effort with respect to sectioning, polishing, and etching.

For a specimen to be suitable for examination, it must be free of volatile matter that might interfere with the attainment of an operational vacuum level or result in the contamination of apertures and other components, thus degrading the performance of the instrument. A contaminant film that hides the surface features of interest is certainly unacceptable. Even a thin deposit of oil may lead to the rapid appearance of a dark film over the area scanned by the electron beam. This is especially noticeable when focusing is carried out at a higher magnification, leaving a telltale dark square in the lower magnification field. Solvent cleaning or low-temperature vacuum bakeout for porous specimens may be required. The surface should also be free of extraneous dust particles, which may charge or otherwise detract from the image. Specimen cleaning is discussed in Ref 8 and 12.

Before adopting a particular cleaning method, careful consideration should be given to the effect of the procedure on surface films and attached wear debris. Wear debris and triboreaction films almost always yield important information regarding wear processes. If necessary, loose films and debris may be removed for separate analysis, using methods discussed later, freeing the underlying surface for examination.

A second requirement is that the specimen must have adequate electrical conductivity to allow electrons to flow to ground or to the specimen current amplifier connector without charging. For metal and some semiconducting specimens, the inherent conductivity is sufficient, and it is necessary only that the specimen make good electrical contact with the mounting device that attaches to the microscope stage. Specimens that are poor conductors or insulators must be coated with a conductive layer, usually a heavy metal such as gold or a gold-palladium alloy.

Alternatively, if compositional or crystal structure studies are to be made, interference may be minimized by a carbon coating, assuming that carbon itself is not one of the constituents in the specimen of interest. The coating should not obscure the details of the microstructure and topography being examined. This becomes especially important in high-resolution studies, where care in the selection of coating material and coating method is of critical importance. Materials and methods for coating are discussed in several general references (Ref 8, 9, 10, 12).

In addition to the direct observation of worn surfaces in the SEM, a replica of the surface may be prepared for examination. This approach is required when the component of interest is too large to be accommodated by the SEM or cannot be sectioned, or when it is not desirable or feasible to remove the component from its system. One method for preparing a replica is to employ the cellulose acetate tape used to prepare TEM replicas. A piece of the tape is moistened with acetone and pressed against the component surface. After a suitable drying time, the tape is stripped from the surface and coated for examination in the SEM. Rough surfaces may require use of a different replicating material (Ref 12, 20). It

should be noted that the replica method is limited in its ability to provide an accurate representation of the surface. This is especially true in connection with cracks and holes, neither of which may be easily recognized using a replica. Also, a lip of folded-over material can often be identified by direct surface observation in the SEM, but usually not with a replica.

Although much can be learned by direct examination of the worn surface, the subsurface is also an important source of information. Oxide layers, films, compacted debris, cracks, deformed layers, and transformed regions may be poorly revealed or not revealed at all when the outer worn surface is studied. Examination of the subsurface requires the preparation of a section through the specimen. It is common practice to prepare a cross section perpendicular to the surface. Moreover, because relative motion between the contacting bodies usually occurs along a specific direction on the surface, it is best to prepare two sections, one parallel and the other perpendicular to the direction of motion.

In general, more information is obtained from the parallel section. The majority of material flow usually occurs in the direction of sliding, and the parallel section is best suited to reveal its pattern. If grain boundaries or other suitable microstructural features are present, it may be possible to measure the strain as a function of depth by the amount of bending or microstructural distortion (Ref 34, 35). Tensile cracks oriented with their plane roughly normal to the direction of sliding are also best observed in the parallel section.

Preparation of cross sections requires considerable care and skill. Soft materials and specimens with fragile or poorly adherent films are probably the most difficult candidates. Figure 6 is an example of a section through the wear track on a copper surface. The specimen was electroplated with a layer of copper before sectioning parallel to the direction of sliding. The deformed region below the track is clearly visible. Dislocation cells and an annealing twin are displayed as a result of channeling contrast (discussed below).

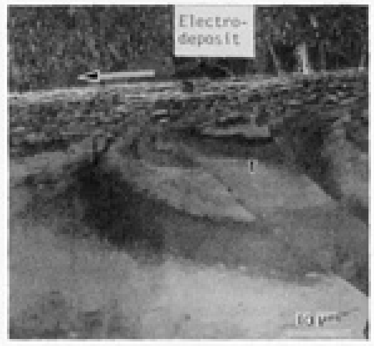

Fig. 6 Cross section through wear track on a copper surface parallel to sliding direction. T, annealing twin, and arrow indicate direction of motion with respect to counterface. Source: Ref 27

A taper section may also be prepared through the worn surface (Ref 36). This method makes it possible to obtain what is in effect a magnified view of linear and planar features on the surface, such as scratches and films, respectively. The length of the scratch or width of the film in the taper plane, together with the known taper angle, allows the scratch depth or film thickness to be determined. Note that scratches or ridges must not be parallel to the line of intersection of the taper plane and the surface and preferably should be perpendicular to that line. Furthermore, for an accurate determination, the feature of interest should be uniform in thickness or depth over the length of the taper plane.

There are a number of methods for collecting and preparing debris specimens for examination in the SEM. When oil and other volatile materials are not present, loose debris remaining on the worn surface can be studied directly be placing the component in the SEM. If the component is too large or cannot be removed from its system, the debris must be removed by stripping it away with adhesive tape or by brushing it onto the tape. Double-sided adhesive tape facilities attachment to the specimen mount. Although conductive tape may be used, it is usually necessary to apply a coating for conductivity.

The surface replica methods described above may also be used to remove debris for examination. When the debris is present in oil, a small amount may be placed in a suitable solvent, such as hexane. The oil can be eliminated by centrifuging and replacing the contaminated solvent with fresh solvent. Ultimately, a drop of debris-containing solvent is placed on a specimen mount for examination in the SEM. An alternative approach involves washing the solvent-oil-debris mixture through a porous membrane filter, which is then coated for examination in the SEM. Finally, it should also be

mentioned that debris distributed on ferrography slides (see the article "Lubricant Analysis" in this Volume) can be examined in the SEM (Ref 37).

Transmission Electron Microscopy

In contrast to specimen preparation for the SEM, specimen preparation for TEM examination almost always involves considerable effort. Because specimen preparation plays such an important role, several volumes have been written that are devoted entirely to the subject (Ref 38, 39, 40, 41).

The discussion that follows will first consider the preparation of specimens from bulk materials, including both thin sections and surface replicas. Methods used to prepare specimens from debris particles will then be reviewed.

Specimens from Worn Surfaces. The main challenge in preparing TEM specimens from bulk materials is to obtain a section that contains a region approximately 100 μm^2 or more in area with a thickness of 5 to 500 nm. Moreover, the surface of the thinned area should be smooth and free of contamination, and the internal structure should not be altered by the preparation process. For the study of defect structures, a thickness of approximately 200 nm is suitable, although thicker specimens may be acceptable for materials of low atomic number and thinner specimens would be favored for materials of high atomic number. Operation at high accelerating voltages will extend the maximum usable thickness. For high-resolution studies, the specimen should be no thicker than 40 nm; the optimum value depends on the material and the nature of the study to be performed. Because most preparation methods result in a wedge-shaped section, achieving the desired thickness is not that difficult; at some location within the wedge, a suitable thickness can usually be found.

The only distinction between TEM specimen preparation methods for tribological studies and TEM specimen preparation methods in general concerns the strong emphasis placed by the former on surface and near-surface material. However, tribology is not the only field where interest is focused on the surface. The study of corrosion, of semiconductor devices, and of surface treatment processes, such as nitriding, ion implantation, and so on, have promoted the development of methods for preparing specimens from the surface region.

A thin section may be taken parallel to the worn surface, or perhaps a sequence of several sections prepared in order to study the structure as a function of depth. If material immediately at the surface is to be studied, a soluble coating may be necessary to protect the surface during preparation. The parallel section approach to examining the immediate surface is feasible only if the worn surface is quite smooth. Otherwise, a cross section normal to the surface must be prepared. As discussed in connection with SEM specimen preparation, the orientation of the section may be chosen either parallel to a characteristic direction, such as the sliding direction, or perpendicular to that direction. An electrodeposited layer (for metal specimens) or a thick coating of cement (for example, epoxy) is usually applied to the surface for protection during sectioning and thinning. A technique commonly employed for semiconductor devices is to cement together a pair of specimens face to face (or a stack of several specimens, in the case of thin semiconductors) (Ref 42). Not only is protection provided, but having more than one specimen also improves the chances for success.

A general scheme that is often followed in preparing TEM specimens from the bulk is illustrated in Fig. 7. It is assumed that the specimen is a cross section and that the worn surface has been protected by a thick coating layer (>1.5 mm). First, a thin section is cut, with care being taken that the section is thick enough that damage from the cutting process does not extend into the region of actual study. For hardened steels and ceramics, a thickness of 01.1 to 0.2 mm may be acceptable. For soft, annealed metals, 1 mm or larger may be required. A low-speed diamond saw or, for conductive materials, an electric discharge machine (EDM) is frequently used for cutting.

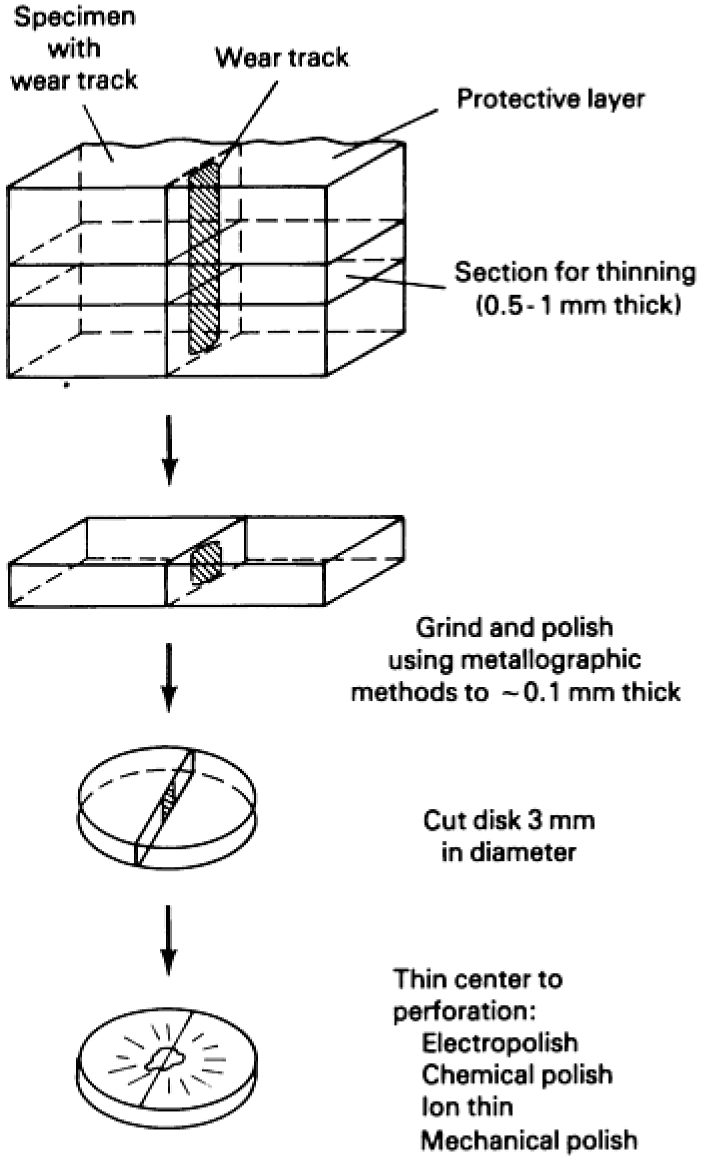

Fig. 7 Schematic showing steps required to prepare TEM cross section specimen

Then the thickness of the section must be reduced to about 0.1 mm. Conventional abrasive grinding, lapping, and polishing methods are usually employed (Ref 43). One or more disks 3 mm in diameter are cut from the thin section. Because this is a cross section, the line of intersection demarcating the worn surface is placed at the center of the disk. The disk may be cut with a hollow or tubular-shaped tool having an inside diameter of about 3 mm. One of several different cutting methods may be used, depending on the material--for example, core drilling with a tool impregnated with diamond grit, abrasive slurry core drilling, ultrasonic abrasive impact machining, or EDM.

The final step is to reduce the thickness of the center region of the disk until it becomes thin enough to be electron transparent. In practice, thinning is usually continued until perforation occurs. When successful, some of the area around the perforation will be thin enough for electron transmission. Thinning may be accomplished by electropolishing, chemical polishing, ion beam milling, possibly mechanical polishing, and combinations of these processes. Alternative methods and approaches for preparing specimens, as well as additional details, can be found in Ref 37, 38, 39, 40, 41, 42.

Surface replicas have already been discussed in connection with the preparation of specimens for SEM study. As was mentioned, a technique that is often used involves pressing a thin section of cellulose acetate film moistened with acetone onto the surface. After a short time is allowed for drying, the film is stripped from the surface. For TEM study, the acetate replica is coated (shadowed) at oblique incidence with a heavy metal such as palladium-gold or chromium. The shadow

produced by the heavy metal absorbs or scatters electrons, enabling the topography to be revealed by transmitted electrons.

After shadowing, a uniform layer of carbon, 10 to 20 nm thick, is deposited--in effect generating a carbon replica of the acetate film surface. Deposition of the shadowing metal and the carbon support film is usually done in vacuum evaporator. The shadowed and carbon-coated acetate film is cut into pieces 3 mm square. One of the squares may then be placed on a TEM support grid and the cellulose acetate film dissolved with acetone--leaving the shadowed carbon replica, suitable for examination in the TEM. This describes only briefly one of many different methods (Ref 20, 37), for preparing replicas. The same cautionary note made with respect to accurate surface representation in reference to SEM replicas is also true for TEM replicas.

Debris Specimens. Wear debris particles that are thin enough to be electron transparent can be studied directly in the TEM. In this case, preparation consists of collection, dispersion, and mounting the particles on a suitable support film. Specimen grids covered with a 10 to 20 nm thick film of carbon or silicon monoxide are often used for this purpose. If the particles are in the form of a dry powder, they can be brushed or blown such that some fall onto the support film.

Alternatively, the particles may be dispersed in a volatile solvent and deposited as a small drop or sprayed onto the support film. Particles in-oil or grease can be extracted by solvent washing through an appropriate membrane filter or by repeated centrifuging in a solvent and decanting until the particles are free of contaminants, as discussed in connection with SEM specimen preparation. When a membrane filter is employed, it is treated like a replica; that is, the filter surface is coated with a layer of carbon to support the particles, and the filter material is dissolved away.

When the wear debris particles are too thick to be electron transparent, they are usually embedded in mounting material (epoxy, for example) to form a composite, which is then sectioned and thinned like a bulk specimen (Ref 44), or they may be incorporated in a thick plating which is subsequently thinned. Additional information on particle specimen preparation can be found in texts dealing with particle analysis in general (Ref 45, for example).

Imaging and Analysis in the SEM

The most important signals that are employed for analysis in the SEM and the information that each provides are summarized in Table 1. Each signal requires an appropriate detector (except for specimen current, where the specimen itself is the detector) and an amplifier. In the case of x-rays for quantitative studies, a complete computer-based analysis system in necessary.

Table 1 SEM signals

Signal	Information	Special requirements
Secondary electron	Topography; some crystallography; some composition	None
Backscattered electron	Composition; topography; crystallography; magnetic domains	None
Specimen current	Similar to secondary and backscattered electrons	None
X-ray	Composition	Smooth surface for quantitative analysis
Cathodoluminescent	Composition	Used for materials that exhibit cathodoluminescence
Thermal wave	Subsurface defects	Smooth surface

Secondary Electron Signal

The main application of SEM is the investigation of surface topography, and the low-energy secondary electron signal ($\leqslant$50 eV) is the primary source of this information. Secondary electron emission is strongly influenced by surface orientation and varies approximately as the secant of the angle of incidence of the electron beam. An element of surface that is inclined to the beam appears brighter than one that is normal to the electron beam. Enhanced brightness is seen at sharp edges, small particles, and fine-scale roughness because of the larger area from which secondary electrons can escape. With increased penetration at higher accelerating voltages, the area also increases, so that more detailed and sharper images of fine surface features are more often obtained at lower accelerating voltages ($\sim$5 to 10 kV) than at higher voltages.

The observed contrast is also influenced by the position of the secondary electron detector, which is usually located to one side and at about the same level as the specimen. More electrons are received by the detector from an element with its surface inclined toward the detector than from an element tilted away from the detector. The visual effect is to make the image appear as though the specimen were illuminated by a source located at the detector.

Although secondary electrons are created throughout the interaction volume (Fig. 4), because of their low energies only secondary electrons originating close to the surface are able to escape and contribute to the image. The maximum escape depth ranges from about 1 to 10 nm for high- and low-density materials, respectively. Thus, the specimen surface immediately under the incident beam is the source of directly generated secondary electrons. If this were the only source of secondary electrons, the image resolution would be closely determined by the beam or spot size. However, secondary electrons are also generated by backscattered electrons as they leave the surface or strike the SEM polepiece and specimen chamber walls. Backscattered electrons have a large range and may exit the surface some distance from the location of the incident beam. This effectively increases the source size and decreases resolution.

In general, the fraction of secondary electrons emitted is relatively insensitive to the atomic number, *Z,* although some compounds do have a significant effect on emission (Ref 8). However, the number of backscattered electrons generated is quite sensitive to *Z* (discussed below). Thus, secondary electron emission is indirectly, affected by *Z* through its influence on backscattered electron emission. For this season, phases with different average atomic numbers can be distinguished in secondary electron images. Similarly, the emission of secondary electrons is not directly sensitive to crystallographic orientation, but, because backscattered electron emission is influenced, differences in orientation produce contrast in secondary electron images. A notable example is the variation in contrast exhibited by different grains in the image of a carefully polished polycrystalline sample; these grains exhibit channelling contrast. This effect can be seen in Fig. 6, where an annealing twin is visible and dislocation cells with only slight differences in orientation can be distinguished. Moreover, grains in the electrodeposited layer of copper can be seen.

Further examples of images obtained in the secondary electron imaging mode are shown in Fig. 8. The specimen is the worn sealing face of a diesel engine valve. The valve was titled at a large angle to the incident electron beam in order to display the lip of material that resulted from plastic flow. It is only because of the tremendous depth of field associated with the small angular aperture of the SEM objective lens, assisted by the dynamic focusing capability with which most SEM instruments are equipped, that such an image can be obtained. (Dynamic focus refers to the programmed change in focus as a function of raster position as the beam is scanned across the specimen.) In addition to the images in this article, secondary electron SEM images of worn surfaces can be found elsewhere in this Volume. Note especially those in the article "Surface Damage."

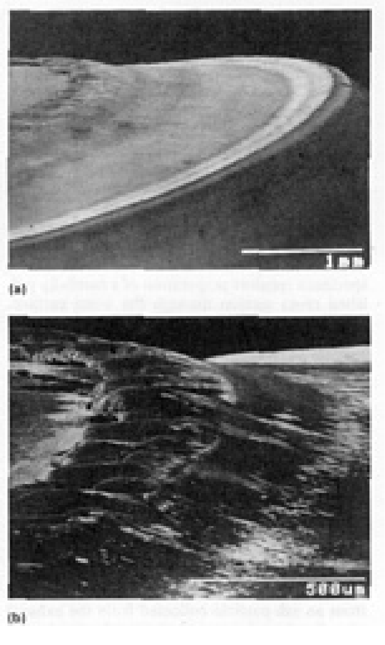

Fig. 8 Secondary electron image of the sealing face of a diesel engine valve. (a) Low magnification. (b) Higher magnification of flowed lip. Note dark contrast at carbonaceous deposit.

Other sources of contrast in addition to those discussed above are electric and magnetic fields. Both can strongly influence the number of secondary electrons collected. This permits the imaging of magnetic domains and is the basis for voltage contrast in semiconducting devices (Ref 9).

Finally, the ability to carry out stereomicroscopy using secondary electron images can be of considerable value in the examination of surface topography. Stereopairs are produced by photographing the surface at two different angles of tilt, usually at a separation of 5° to 10°. A stereoviewer can be used to observe differences in height visually, or the difference in distance between corresponding pairs of points in the two images can be measured and the height difference obtained quantitatively by simple geometry utilizing the known tilt angle and magnification.

Backscattered Electron Images

Backscattered electrons are those electrons that leaves the specimen with energies greater than 50 eV (Fig. 3) and have a component of direction opposite to that of the incident beam. This includes inelastically scattered electrons and, at the high-energy limit, primary electrons that have undergone elastic scattering with almost no loss in energy. The majority of backscattered electrons have energies from 0.5 to 0.9 of the incident beam energy.

As mentioned above, the efficiency with which backscattered electrons are generated is strongly dependent on the atomic number of the scattering atoms. This dependence is depicted schematically in Fig. 9, which shows that the scattering efficiency for light elements is less than that for heavy elements. The distribution of backscattered electrons is also a function of the beam orientation with respect to the specimen surface. Figures 10(a) and 10(b) illustrate the effect of surface orientation on distribution for normal and oblique incidence. Because of these dependencies, the backscattered electron signal carries both topographic and compositional information.

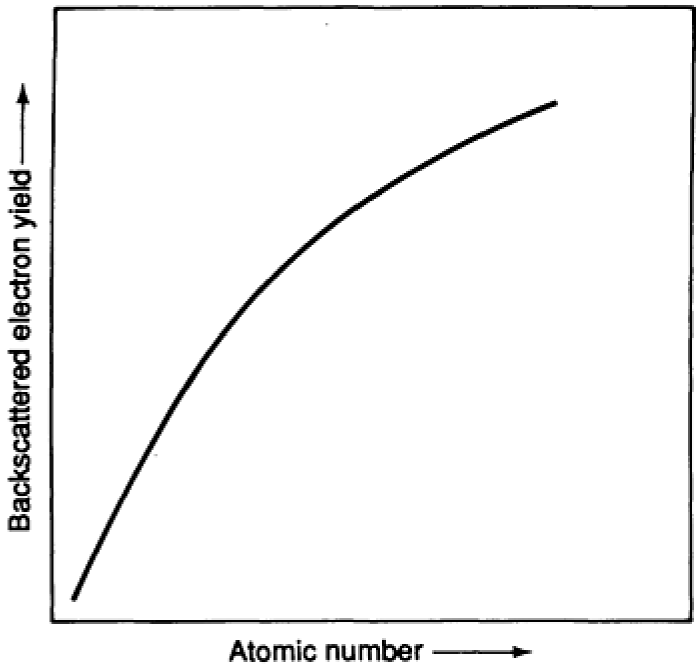

Fig. 9 Backscattered electron yield dependence on atomic number

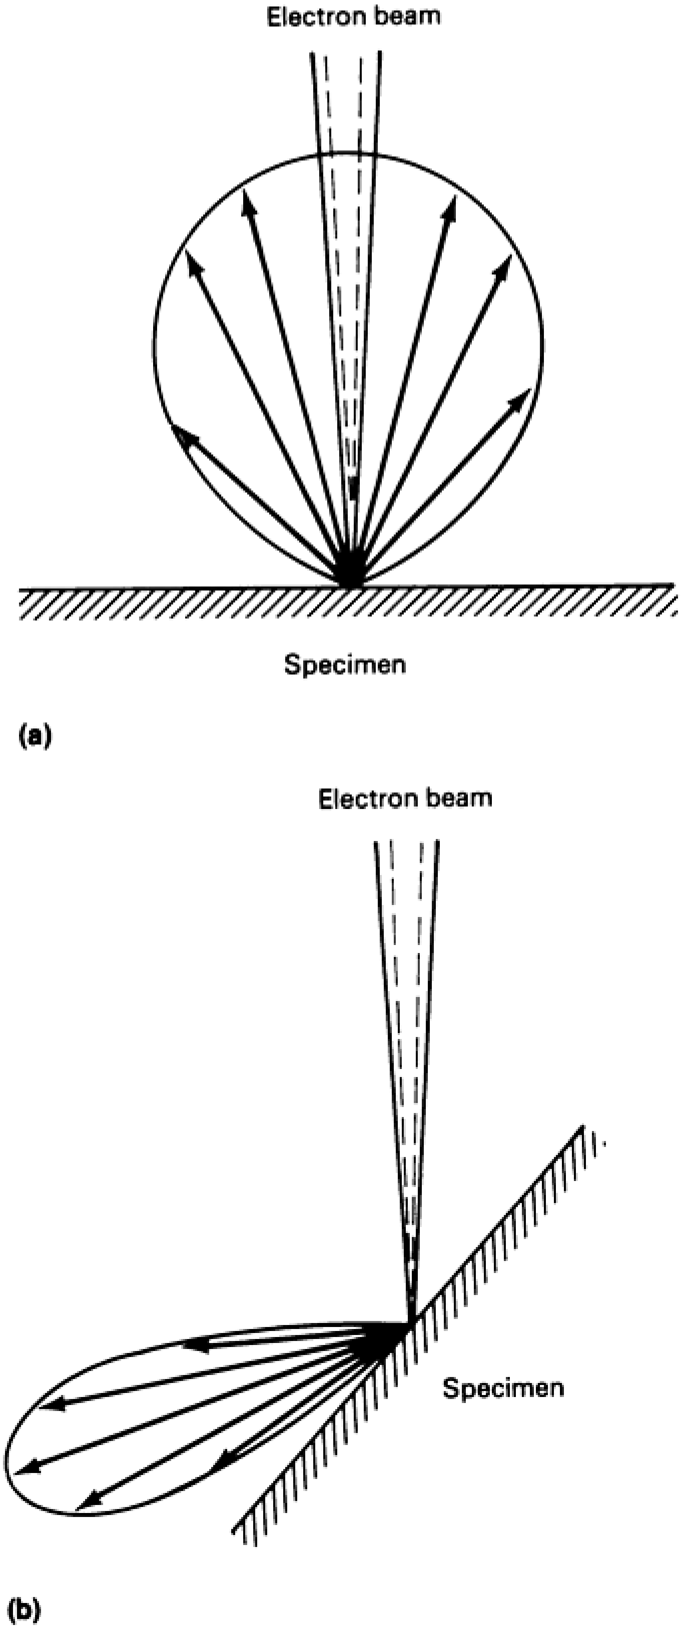

Fig. 10 Angular distribution of backscattered electrons. (a) Incident beam normal to surface. (b) Incident beam inclined to surface

The backscattered electron detector is often designed to detect electrons from several (usually four) separate locations around the specimen. The signals from each of these different quadrants may be individually selected, and added or subtracted. This feature allows the selective emphasis of atomic number contrast or topographic contrast. When the

electrons from all directions are collected and summed, the contrast is less sensitive to topography, and atomic number differences are emphasized. If the surface is very smooth, extremely small differences in composition can be detected, and the contrast is a sensitive means of mapping variations in average atomic number. Alternatively, by selecting signals from different quadrants, or adding and subtracting signals, topographic contrast can be enhanced, while atomic number contrast is suppressed. Figure 11(a) is an example of a backscattered electron image emphasizing atomic number contrast. The light features are silver transferred on a copper surface when a silver pin was slid on a copper flat. Some topographic contrast is evident along with the atomic number contrast. For comparison, the secondary electron image is shown in Fig. 11(b). In the latter image the contrast is primarily topographic.

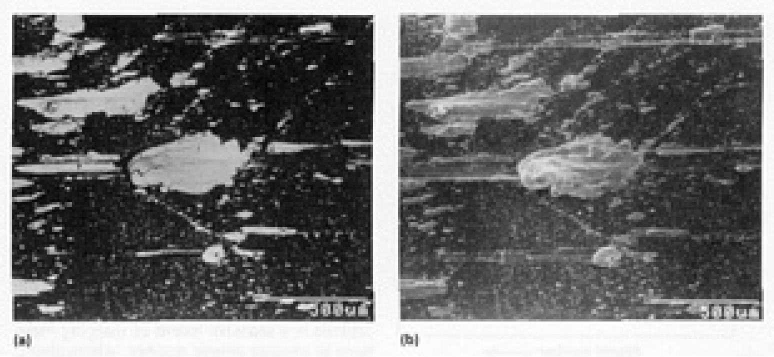

Fig. 11 Transferred patches of silver on a copper specimen surface. (a) Backscattered electron image in which silver (light contrast) with a higher atomic number yields more backscattered electrons than copper. (b) Secondary electron image of the same area

The propagation of electron waves in crystalline materials is strongly orientation dependent. This gives rise to an effect known as electron channeling (Ref 14, 15, 16, 17, 18, 19, 20, 21, 22), which relates to the enhanced flow of electrons along crystallographic planes. There is a corresponding effect on the intensity of emitted backscattered electrons. As mentioned earlier, this gives rise to the variation in contrast that distinguishes grains of different orientation at the surface of a carefully polished polycrystalline specimen.

By rocking the electron beam about a stationary point on the specimen, this same effect can be utilized to produce an electron channeling pattern (ECP). The pattern consists of light and dark bands corresponding to the crystalline planes of the material at the location of the beam. SEMs equipped to obtain ECPs are capable of generating crystal orientation lattice parameter information from areas as small as 1 μm in diameter. The quality of the ECP is influenced in a systematic way by the amount of strain in the material, and this fact has been exploited as a means of measuring strain (Ref 9). Ruff (Ref 46) has employed this method to determine the strain in the vicinity of wear tracks. If the specimen surface is heavily strained or is covered by a thick film, an ECP will not be formed.

X-ray Microanalysis and Mapping

Utilization of emitted x-rays to determine specimen composition is an extremely important capability of the SEM. The description of the method as being one of microanalysis is justified by the small volume from which information is obtained and the sensitivity of the technique. For a smooth specimen surface, the x-ray source volume is represented by a region on the order of 1 μm in diameter, about the size of the interaction volume in Fig. 4. The size can be increased by the fact that x-rays generated within the interaction volume may fluoresce additional x-rays outside the volume before reaching the surface. For fluorescence to occur, the exiting x-ray must exceed the ionization energy of the shell to which the fluoresced x-ray belongs.

Two types of x-ray spectrometers are employed. The wavelength-dispersive spectrometer (WDS) separates the emitted x-rays according to wavelength. X-rays that enter the spectrometer are Bragg diffracted by an appropriate single crystal, and the intensity is measured by means of a proportional counter. By appropriately rotating and moving the diffracting crystal and the counter, the spectrum of emitted x-rays can be scanned in serial fashion. To cover the complete spectral range, however, may require more than one crystal. The minimum concentration of an element that can be detected can be as low as 0.01% under favorable conditions.

The second type of x-ray spectrometer separates the emitted x-rays according to energy and is thus referred to as an energy-dispersive spectrometer (EDS). A semiconductor diode, most often silicon into which lithium has been diffused (called a lithium-drifted silicon detector), is used to measure the x-rays. Some application is also made of a germanium base because of its greater sensitivity to low-energy x-rays. In either case, electron-hole pairs produced by an absorbed x-ray photon result in a charge pulse proportional to the energy of the photon. The pulses are amplified, shaped, and sorted according to energy by means of the succeeding components of the analysis system. The number of pulses, or counts, is a direct indication of the emitted x-ray intensity at the given energy. The net result is a spectrum of x-ray intensity that can be displayed as a function of energy. In contrast to the WDS system, the EDS system detects x-rays of all energies as they are delivered to the detector--that is, effectively in parallel, rather than serially--resulting in an acquisition process that is much more rapid. On the other hand, EDS resolution of nearby x-ray lines (~150 eV) is (~20 eV).

The EDS detector crystal must be maintained at approximately liquid nitrogen temperature in a high vacuum. Protection from the external environment is provided by a window. The window is usually constructed from a thin film of beryllium, but polymer and diamond films are being increasingly used. Absorption in the window decreases the sensitivity of the detector to low-energy x-rays. Thus, a detector equipped with a beryllium window is limited to the detection of elements with atomic numbers equal to or greater than that of sodium (Z = 11). Carbon (Z = 6) and even boron (Z = 5) can be detected when polymer and diamond windows are used.

Windowless detectors are also available. A vacuum-tight cover is closed to prevent exposure of the detector crystal to atmosphere or poor vacuum conditions. The operating microscope environment must of course be relatively free of condensable vapors. Even in the absence of a window, absorption of low-energy x-rays takes place in the thin (~20 nm) gold layer that must be deposited on the detector surface for conductivity and in an inactive (dead) layer of silicon present on the detector crystal. This absorption, coupled with the low inherent yield of characteristic x-rays by light elements, means that the sensitivity for light elements is much less than for heavy elements.

EDS systems are simpler and less expensive than WDS systems and are the predominant type of spectrometer utilized with SEMs. In more sophisticated installations, however, both types of spectrometers may be employed with the same instrument.

Both WDS and EDS systems use computers for control of data acquisition, display, and processing. Processing involves the identification of elements represented by observed characteristic peaks and the determination of their concentrations according to the size of the peaks. Identification is relatively straightforward for large, well-separated peaks. Small peaks only slightly above background, or which overlap for different elements, make identification more difficult. In some investigations, only the identification of the elements present is sought. In other cases, quantitative concentration values are required.

In general, the theory and associated computations for determining concentrations are quite complex (Ref 8, 47). Accurate results require that the specimen surface be smooth and that the analyzed volume of the specimen be homogeneous throughout. A relatively rough wear surface covered with a film of unknown thickness does not satisfy this criterion. A more acceptable specimen requires preparation of a carefully polished cross section through the won surface. The limited spatial resolution (~1 μm^3 volume) may still restrict accuracy, especially in the presence of a transferred layer or reaction film 100 nm or less in thickness. This may be resolved by applying TEM methods (see the section "Imaging and Analysis in the TEM" in this article).

The analysis itself may be semiquantitative (without reference standards) or quantitative (with standards). In the latter case, prior collection of spectra from pure specimens of each element present or from alloys of known concentrations is required. Fortunately, the computations are done quickly and efficiently by the system software, and the process is relatively transparent to the operator. An x-ray spectrum obtained from an ash particle collected from the exhaust of a diesel engine operated on pulverized coal-fuel is shown in Fig. 12 (Ref 48). Due to the small size and complicated shape of the particle, element identification only was carried out in this case.

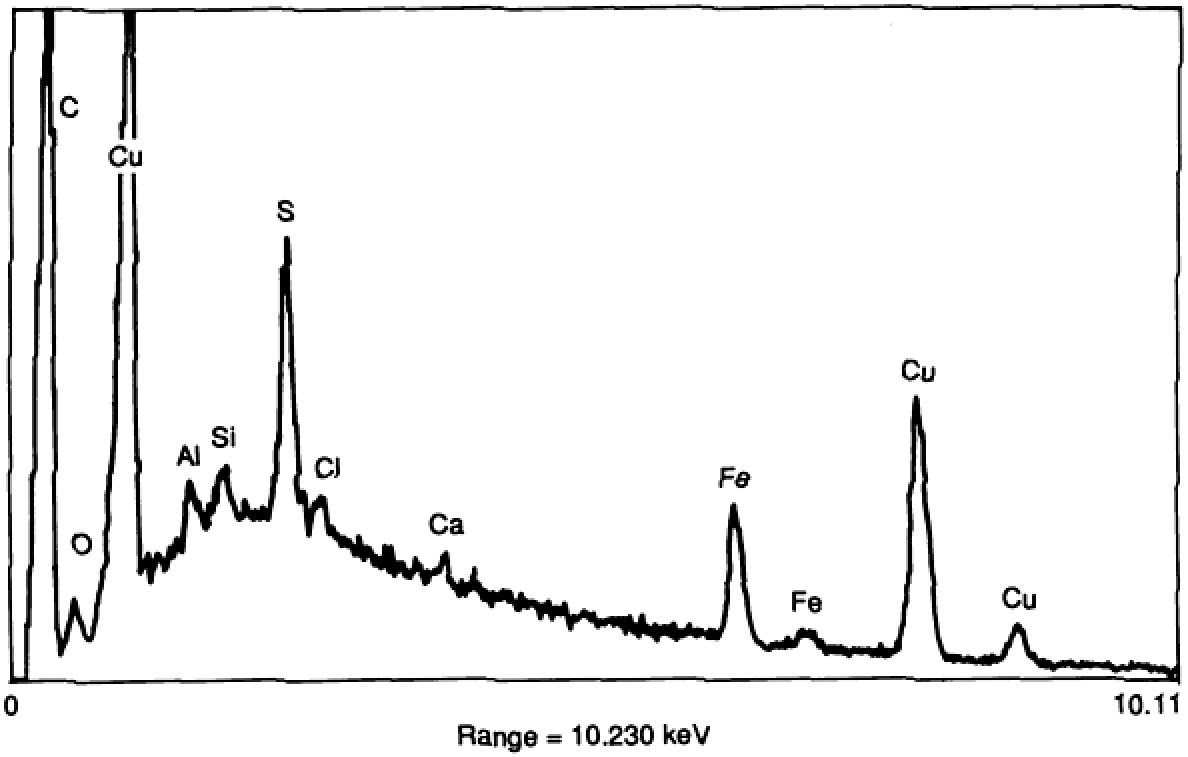

Fig. 12 X-ray spectrum from coal-fueled diesel engine exhaust particle. Copper mount is source of copper peaks. Source: Ref 48

In addition to determining the local composition of a specimen, the x-ray signal can generate a map showing the distribution of elements over a scanned area of the specimen surface. The procedure involves selecting a region of window in the x-ray spectrum that includes the elemental peak of interest and using the signal to modulate the intensity of the SEM CRT as the electron beam is scanned across the specimen. Because each x-ray photon is recorded as a pulse, the resulting image consists of a pattern of bright dots, and is usually referred to as a dot map. When the x-ray analysis system is equipped to control the position of the electron beam of the SEM (digital beam control), the map can be fully quantified at each picture element and stored directly in the analyzer computer. An example of a dot map is shown in Fig. 13(a). The specimen (the same as that shown in Fig. 11) was copper with silver transferred during sliding. The bright dots correspond to silver. A secondary electron image from the same area is shown in Fig. 13(b).

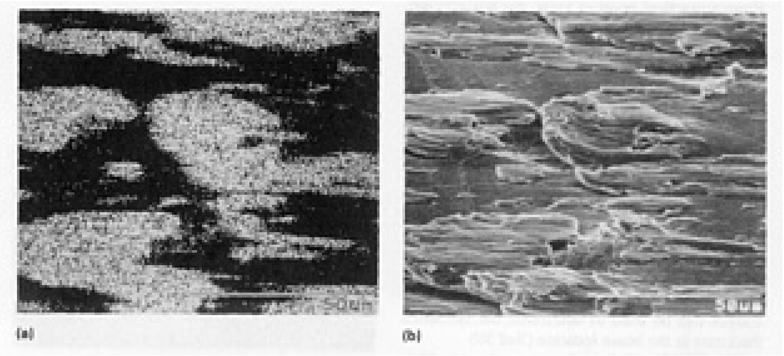

Fig. 13 Transferred patches of silver on a copper specimen surface. (a) X-ray dot map of silver. (b) Secondary electron image of same area

Other Imaging Modes

Specimen current images bear a complementary relationship to the secondary and backscattered signals (Eq 1) and can be exploited to reveal topographic, compositional, crystallographic, and magnetic information. At the extremely small currents available, especially when the probe size is made small for higher-resolution studies, the limited bandwidth of the required high-impedance, high-gain, direct-current amplifier limits observation and recording to very slow scan rates. In practice, relatively little use is made of the specimen current imaging mode.

Many minerals, semiconductors, and organic compounds exhibit relatively strong cathodoluminescence signals. Cathodoluminescence is sensitive not only to the presence of such materials but also to their properties. For example, it can be exploited to study defects in semiconductors. Relatively little use appears to have been made of cathodoluminescence in tribology studies.

The last imaging mode that will be discussed is thermal wave imaging. This mode requires a modification to the SEM that allows the electron beam to be interrupted or "chopped" at a high frequency. Heating of the specimen by the electron beam occurs at a corresponding high frequency resulting in a thermal wave. Thermal expansion causes an associated acoustic wave that can be detected by a transducer attached to the specimen. The signal is influenced by the thermal properties and microstructure of the specimen. Thus, different phases and subsurface defects such as cracks and voids can be detected. An example of an application of thermal wave imaging to wear can be found in the work of Blau and Olson (Ref 49).

Imaging and Analysis in the TEM

Basic Imaging and Diffraction Modes

Electrons incident on sufficiently thin regions of the specimen may be transmitted. The fraction of transmitted electrons depends on the accelerating voltage and on the characteristics of the specimen, including thickness, composition, density, and crystallographic orientation. Transmitted electrons that have not been scattered, elastically scattered electrons (especially diffracted electrons), and inelastically scattered electrons that have lost only a small amount of energy may be utilized to form an image. Focusing and magnification are accomplished by a series of electromagnetic lenses (Fig. 5b). The lens design is such that electrons scattered by more than a few degrees from the optical axis will not be brought to focus. The mode of operation is determined by the current that is used to energize each lens and the selected apertures. In modern instruments, the lens currents are preprogrammed according to the chosen imaging or diffraction mode. Adjustments required of the operator are mainly those associated with focusing, illumination, and magnification. A simple ray diagram construction is commonly used to represent the path of the electrons and the function of the various lenses and apertures in the different modes of operation (Ref 19) (see Fig. 14).

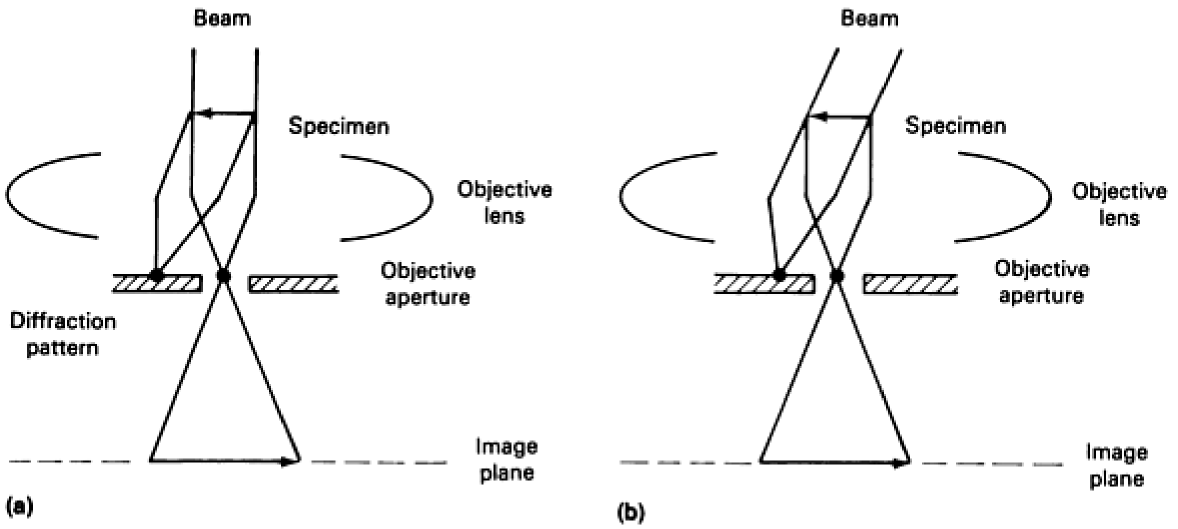

Fig. 14 TEM ray diagram illustrating (a) bright-field and (b) dark-field imaging modes

As in the optical microscope, the most critical lens in the TEM is the objective lens, which produces a magnified and focused image of the specimen. The design and quality of this lens determines the resolution of the instrument. The focal length of the objective lens is very small, 1 to 3 mm, and the specimen is immersed in the magnetic field of the lens. In achieving the desired lens characteristics, rather severe restrictions are imposed on the size of the specimen holder and the specimen that it must accommodate. The holder is usually designed to accept a specimen disk with a diameter of 3 mm, although 2.3 mm is sometimes employed. The maximum thickness of the disk is usually limited to approximately 0.5 mm or less. Precise translation, tilting, and rotation are necessary capabilities of the specimen holder and its associated stage.

Lenses following the objective lens are used to control magnification and to switch between the imaging and diffraction modes. Both the image and the diffraction pattern are observable on a fluorescent screen below the final lens. Photographic film exposed directly to the beam can be used to provide a permanent record of the image. Alternatively, a TV imaging system can be used. A combination of TV imaging and image intensification facilitates the achievement of precise instrument alignment and focusing required in high-resolution work. Also, through connection to a video recorder, the time sequence of a dynamic experiment can be recorded.

Before TEM image contrast is discussed, electron diffraction should be considered. Electron diffraction is not only a means of determining crystal structure and orientation but is also closely associated with the process of image formation.

Electron Diffraction

A transmission diffraction pattern of the illuminated specimen region is always present in the back focal plane of the objective lens. When this plane rather than the image plane is brought into focus by the first intermediate or diffraction lens (the terminology varies with manufacturer), the diffraction pattern rather than the image is displayed. Operationally, switching between imaging and diffraction is accomplished by little more than the press of a button. There are several different operating modes for obtaining a diffraction pattern; these are briefly discussed below. Greater detail can be found in Ref 19. The references should also be consulted for full details on diffraction theory and such closely related and very important topics as crystallography and crystal structure determination.

Under conventional imaging conditions--that is, when the specimen is illuminated by a large-diameter, nearly parallel beam of electrons--the area of the specimen from which the diffraction pattern is obtained is determined by an aperture introduced into the image plane of the first intermediate or diffraction lens. This mode of diffraction is referred to as selected-area diffraction (SAD). SAD patterns are shown in Fig. 15(a) and 15(b). The selected area in Fig. 15(a) included only a single grain, while many grains with different orientations are included in Fig. 15(b), giving rise to spots in rings. For these patterns, the angle 2θ between the incident beam (the center spot) and each of the diffracted beams is given by Bragg's equation:

$$2d \sin \theta = n\lambda \qquad \textbf{(Eq 2)}$$

where d is the lattice spacing, λ is the electron wavelength, and n is the order of diffraction.

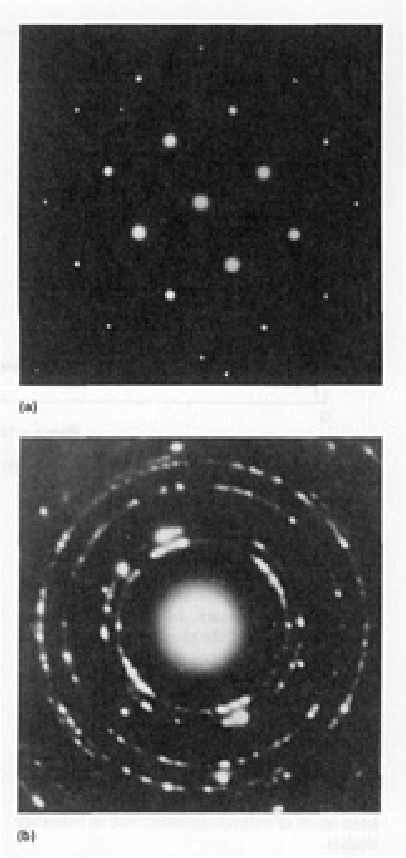

Fig. 15 Selected-area diffraction patterns. (a) Single-crystallite aluminum, (100) orientation. (b) Many crystallites near abraded copper surface. Source: Ref 27

Due to spherical aberration of the objective lens, as well as any focusing error, material slightly outside the region defined by the area-selecting aperture also contributes to the diffraction pattern. In practice, this error is not a problem unless the diffracting region must be known to high precision or the region to be selected is very small. Then the error limits the minimum selectable area to a diameter of about 1 or 0.5 μm at 100 or 300 kV, respectively.

For smaller areas, one of the so-called microdiffraction modes must be used (Ref 19). One method employs very small condenser apertures to limit the size of the beam. A second method requires an electron lens system similar to that in instruments capable of STEM operation to produce a very narrow and intense but still parallel beam of electrons. In both cases, the illuminating beam itself defines the area from which the diffraction pattern is obtained. This makes it possible to obtain spot patterns similar to those in the SAD mode from a specimen area less than one tenth of that possible in SAD.

In addition to spot or Laue-type patterns obtained by diffraction of the incident electron beam, a pattern of lines or bands referred to as a Kikuchi pattern may be observed (Fig. 16). To obtain a well-defined Kikuchi pattern, the illuminated specimen region must be relatively free of strain and not too thin. The lines occur because of the diffraction of electrons that have been subject to previous inelastic scattering within the specimen. As pointed out earlier, only inelastically scattered electrons that have lost relatively little energy can be brought to focus and are thus able to contribute to the pattern. In the absence of diffraction, these inelastically scattered electrons would form a uniform background with diminishing intensity at increasing distance from the central beam. Diffraction of these electrons by a given set of planes produces bright lines. Because these diffracted electrons are now lost from the background, there is an accompanying dark or deficiency line at 2θ distance from the bright line according to Bragg's law. Because the electrons that give rise to the Kikuchi pattern originate within the specimen, when the specimen is tilted the lines move or sweep across the field of view as though they were attached to the specimen. From a practical point of view, the Kikuchi pattern gives a more precise indication of the specimen orientation than the spot pattern. Most importantly, it allows the specimen to be oriented exactly as required for imaging and for the analysis of dislocations and other lattice defects.

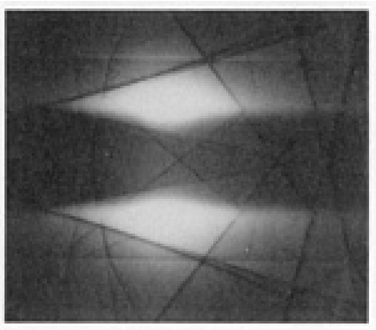

Fig. 16 Kikuchi diffraction pattern

If the specimen is illuminated with a focused converging beam instead of a parallel beam of electrons, a convergent-beam electron diffraction (CBED) pattern is formed. The size of the diffraction spots is increased substantially and internal contrast is visible (Fig. 17). If the illuminated specimen region is relatively free of defects and strain, "pendellosung" fringes may be observed within the spots. The spacing of these fringes can be used to determine the specimen thickness at the beam location (Ref 50).

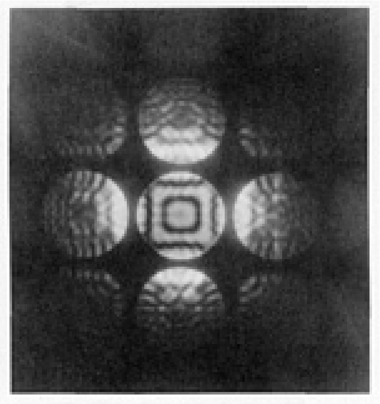

Fig. 17 CBED pattern for aluminum with (100) orientation

The CBED technique is extremely powerful. Because a focused probe is used, only the illuminated region contributes to the diffraction pattern; thus, this also qualifies as a microdiffraction mode. Also of great significance is the fact that the CBED technique allows the determination of crystal symmetry and crystal structure (Ref 19). By comparison, only limited symmetry information can be determined from SAD patterns. The procedure involves tilting the specimen so that the beam is along a low-index zone axis. From the detailed symmetry of such zone axis patterns (ZAPs), crystal structure information is obtained. The CBED method, coupled with compositional analysis by means of EDS and EELS, provides an extremely powerful method for the complete identification of small particles, precipitates, and microconstituents in a variety of materials.

To the three modes of diffraction (SAD, microdiffraction, and CBED) described above, reflection electron diffraction and several STEM modes of diffraction may be added. Reflection diffraction requires a smooth, nearly flat surface and a special holder or mount that allow the specimen to be oriented with its surface nearly parallel to the beam. In this case, the specimen need not be thin, because only the surface is involved. Reflection diffraction can be used to analyze thin films or to determine the orientation of a near-surface layer. Several different diffraction modes are available in STEM and will be discussed in a later section.

Image Contrast

Contrast in a TEM image can arise from almost any variation in the specimen material being examined. In general, these can be categorized as differences or variations in:

- Thickness
- Crystal structure
- Defects in the crystalline structure
- Crystal orientation
- Composition
- Strain
- Magnetic properties

More specifically, the observed contrast may be associated with different phases, which may be present in the form of precipitates, inclusions, atomic clusters, or embedded particles; lattice defects, such as dislocations, stacking faults, domain boundaries, and grain boundaries; strain associated with bending; crystal lattice planes and crystal structure; individual atoms under certain conditions; overlapping crystal that produce moiré patterns; and magnetic domains.

The size of the observable features can range from millimeters (that is, the dimensions of the viewable specimen) when the microscope is operated at its lowest magnification to the atomic scale at the highest magnifications. The origin of the contrast is often quite complex. A detailed quantitative explanation of the contrast lies very much in the realm of solid-state physics and quantum mechanics. Fortunately, most of the analyses have been worked out, and once the principles are understood, much of the interpretation can be carried out without recourse to theoretical details and computations. Examples of such analyses include the determination of dislocation Burgers vectors and the characterization of stacking faults. Exceptions where detailed compilations are required to exist, however. In particular, the analysis of high-resolution images to determine the details of atomic structure usually must be carried out in conjunction with computer simulation to verify any hypothesized interpretation (Ref 51).

Type of Contrast

In general, there are two ways in which contrast can be formed in the image: amplitude contrast and phase contrast.

Amplitude contrast arises from the variation in the number of electrons that leave the back surface of the specimen and reach the image. This is determined not only by scattering processes in the specimen but also by the fact that only electrons within a small angular range of the electron-optic axis can be brought to focus. In fact, the objective aperture is used to determine this angle and therefore to control contrast. If only the primary beam is allowed to pass through the aperture, a bright-field image results. Diffracted electrons are stopped by the objective aperture and do not contribute directly to the image. If more electrons are diffracted from one region of the specimen than from another, the former region will appear dark in the bright-field image. Similarly, inelastically scattered electrons that fall outside the objective aperture do not contribute, and a region where inelastic scattering is strong will appear dark. Contrast that is produced by inelastic scattering of this type is referred to as absorption contrast. Those inelastically scattered electrons that do enter the aperture produce a diffuse background.

If only diffracted electrons are allowed to pass through the objective aperture, a dark-field image results. Specimen regions contributing most to the diffracted beam will appear bright in the image. Small precipitates, for example, can be identified in this way. Ray diagrams illustrating the bright- and dark-field modes are shown in Fig. 14.

Phase Contrast. A phase contrast image results from the interference between two or more transmitted beams that have left the specimen. These interfering beams must of course pass through the objective aperture. The most notable application of this mode of imaging is in the formation of lattice images and crystal structure images (Ref 51).

Diffraction Contrast

Crystalline materials probably constitute the majority of the specimens of interest to tribologists. Diffraction contrast is the primary means by which the microstructures of crystalline materials are revealed. An example of diffraction contrast is shown in Fig. 18. The specimen is a polycrystalline aluminum alloy thinned by electropolishing. A bright-field image is shown. Because of differences in crystallographic orientation, there are in some cases marked differences in contrast

among the grains. By tilting the specimen--that is, by changing the diffracting conditions--grain that are dark could be made to appear bright and vice versa.

Fig. 18 Bright-field image of a polycrystalline aluminum alloy

Alternatively, one of the diffracted beams could have been selected for imaging to obtain a dark-field image. This is best accomplished by tilting the illuminating beam (Fig. 14) while observing the diffraction pattern. The diffraction spot of interest is brought to the center of the screen. An objective aperture is then introduced, excluding other spots, and the instrument is switched to the imaging mode. Another alternative would be simply to move the objective aperture to the diffraction spot of interest, but this results in a blurred image because of the spherical aberration of the objective lens. In any case, grains that do not contribute to the selected diffraction spot will appear dark.

Diffraction contrast provides the means of revealing and characterizing lattice defects, such as dislocations and stacking faults, and for observing precipitates and other second-phase particles. To explain the origin of the observed contrast, consideration must be given to the manner in which electrons propagate through the specimen material. Fundamentally, this involves the determination of the wave function of the electron as it encounters the potential field associated with the assembly of atoms constituting the specimen. The wave function is obtained by solving Schrödinger's equation. This approach is referred to as the dynamic theory. The theory is considerably simplified if only two beams are considered--specifically, the primary beam and one diffracted beam. Realization of this condition is accomplished by tilting the specimen so that only the primary beam and one diffracted beam are strongly excited in the diffraction pattern.

At high accelerating voltages (>300 kV) and for materials with large lattice spacings, it may not be possible to obtain a single strongly excited diffracted beam without strongly exciting other reflections in a systematic row (for example, exciting the 111 reflection without exciting the 222 and 333 reflections). Accurate computation of image contrast under these circumstances requires the so-called many-beam theory.

The kinematic theory, which is much simpler than the dynamic theory, can sometimes be employed to determine contrast. Strictly speaking, the kinematic theory is valid only for very thin specimens and when the diffracted beams is weak compared with the primary beam. The theory is essentially a geometric optics approach. The scattering of electrons by an array of atoms is treated like the scattering of light by a grating. A number of interference and diffraction effects can be demonstrated by this approach.

An important result of the two-beam dynamical theory is the relationship describing the intensity of the diffracted beam, *I*(D), and of the transmitted primary beam, *I*(T):

$$\begin{aligned} I(\mathrm{D}) &= 1 - I(\mathrm{T}) \\ &= \frac{1}{1+w^2} \sin^2 \left(\pi \sqrt{1+w^2}\frac{t}{\xi_g} \right) \end{aligned} \quad \textbf{(Eq 3)}$$

where t is the thickness of the specimen normal to the beam ξ_g is the extinction distance, and $w = s\xi_g$. The parameter s is a measure of the deviation from the exact orientation for Bragg diffraction: $s = 0$ indicates that the specimen is oriented so that the Bragg condition (Eq 2) is exactly satisfied. Also, the total transmitted intensity, $I(T) + I(D)$, is normalized to 1.

The extinction distance, ξ, is an extremely important parameter in this relationship. It accounts for the periodic variation in intensity that occurs as a function of specimen thickness, an effect that is most obviously demonstrated by the bright and dark fringes seen at the edge of thin, wedge-shaped specimens. Physically, this effect is explained by the fact that rediffraction occurs between the transmitted and diffracted beams. Thus, intensity is built up in the diffracted beam, reaches a peak, and is then returned to the transmitted beam, and so forth. The distance between peaks is the extinction distance. The extinction distance also affects the contrast seen at dislocations, stacking faults, bend contours, grain boundaries, and second-phase particles.

To describe the contrast that occurs at various features (dislocations, stacking faults, precipitates, and so on), the column approximation is usually employed (Ref 13). As illustrated in Fig. 19, a slab of material containing the feature of interest is divided into equal-size columns parallel to the beam. Each column is assumed to be large enough in cross section to contain both the transmitted and diffracted beams, but to be sufficiently small that variations caused by the feature across the column can be ignored. The amplitudes of the coupled transmitted and diffracted waves are integrated down the column. The contributions of all columns then gives the image.

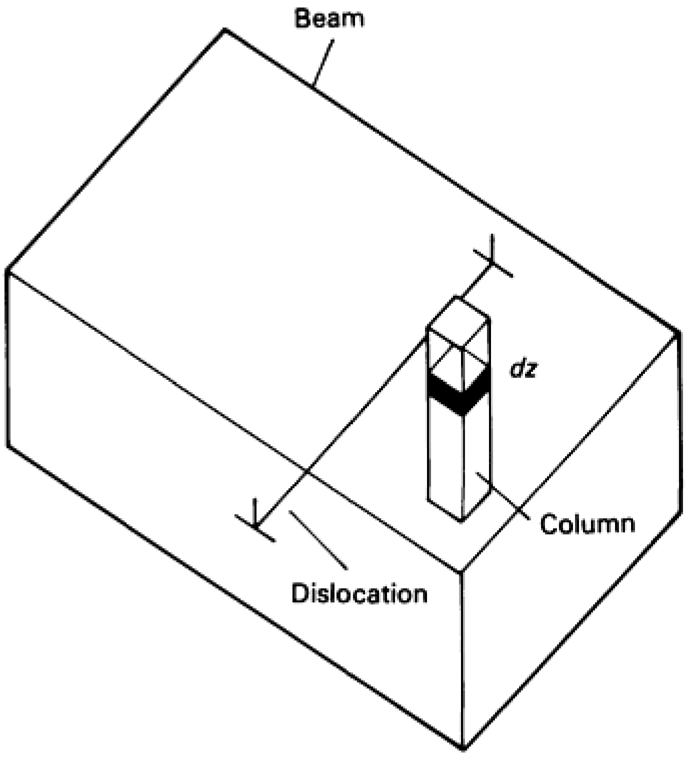

Fig. 19 Illustration of column approximation used to calculate contrast near lattice defects

Maps of intensity associated with various defects have been determined by computer methods (Ref 19), although in many cases one or a few computed profiles of intensity across the feature are suitable to establish the required identification.

For many metals and alloys where the nature of the possible lattice defects is already known, and even in some cases where it may not be, such detailed computations are not required. Rather, all that are needed for identification are the relatively simple relationships between the diffracting condition, which is determined by the orientation of the specimen, and parameters characterizing the feature, such as the possible Burgers vector of a dislocation or the displacement vector of a stacking fault.

Figure 20 illustrates schematically the means by which diffraction contrast can give rise to the image of a distortion, in this case an edge dislocation. Strain caused by the presence of the dislocation is accommodated by the local tilting of the lattice planes. Planes perpendicular to the Burgers vector are most affected. It is assumed that the specimen has already been tilted to a two-beam condition and that these planes are the diffracting planes. Furthermore, it is assumed that the Bragg condition is not quite satisfied for planes distant from and therefore little affected by, the presence of the dislocation. This is tantamount to the parameter *s* in Eq 3 having a value slightly different from zero. As a consequence, less than the maximum intensity will be carried by the diffracted beam, except in the vicinity of the dislocation, where planes, at least on one side of the dislocation, may be oriented for exact Bragg diffraction . For these planes, $s = 0$ and the maximum intensity can appear in the diffracted beam. As a result, the dislocation will be displayed, at least nominally, as a dark line of contrast under bright-field conditions and as a bright line under dark-field conditions.

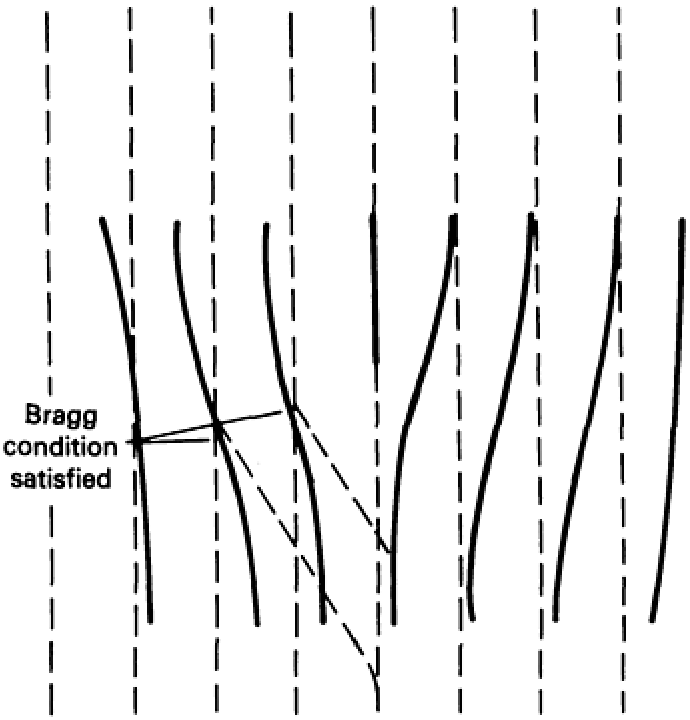

Fig. 20 Schematic showing origin of diffraction contrast from edge dislocation

If the specimen is oriented so that only planes parallel to the Burgers vector are diffracting, almost no contrast will be seen, because the diffracting planes are now only slightly affected by the presence of the dislocation. This result is expressed by the relation:

$$\mathbf{g} \cdot \mathbf{b} = 0 \qquad \textbf{(Eq 4)}$$

where **g** is a vector perpendicular to the diffracting lattice planes and **b** is the Burgers vector of the dislocation. Thus, by experimenting with different diffracting conditions (that is, by selecting various **g** vectors), the direction of the Burgers vector of the dislocation can be determined.

Under conventional two-beam diffraction contrast conditions, where **g** refers to the lowest index set of planes in the series (the diffraction spot in the systematic row that is closest to the center of the pattern), the images of dislocations are 10 to 20 nm in width. Much narrower images and therefore greatly improved resolution can be achieved by utilizing a higher-order **g** vector. Thus, for example, it is possible to resolve individual partial dislocations in copper that are separated by approximately 2.3 nm. This method is referred to as weak beam imaging (Ref 14, 19).

An example of dislocations observed in a worn specimen is shown in Fig. 21. The specimen is relatively pure copper that was subjected to solid particle erosion. The dislocations are arranged in a cell structure, and, in fact, the size of the cells is

an indication of the amount of strain in the material. In the study from which this example was taken, cross sections were prepared perpendicular to the worn surface and the cell size measured as a function of distance below the surface. From this, the relationship between the amount of strain and depth below the worn surface was determined. Additional discussion of the relationship between cell size and strain at worn surfaces, together with illustrative TEM images, can be found in Ref 35.

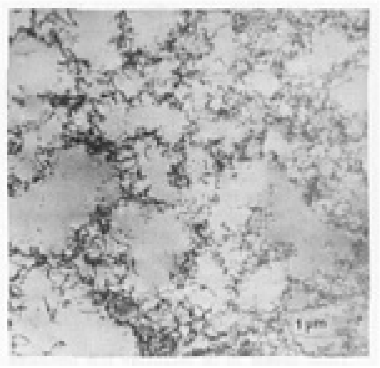

Fig. 21 TEM micrograph of cross section through an eroded copper surface showing dislocation cell structure. Source: Ref 52

Deformation and the associated presence of dislocations also play an important role in the response of nonmetallic materials to tribological contacts. In sliding wear experiments, the dislocation structure near the worn surface of an alumina (Al_2O_3) doped with MgO) specimen exhibited a transition from low wear to high, severe wear (Ref 53). The transition was attributed to strain-induced cracking at grain boundaries. The strain arose from the accumulation of dislocations during the low wear regime. The specimen from which Fig. 22 was obtained has been exposed to prolonged wear in the low wear regime. Prior to exposure to wear, the grains were essentially free of dislocations.

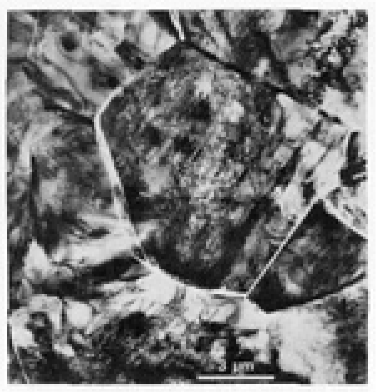

Fig. 22 Accumulation of dislocations near grain boundaries caused by sliding contact. The material is Al_2O_3 doped with MgO. Source: Ref 53

In addition to imaging dislocations, other lattice defects, such as stacking faults, grain boundaries, and boundaries between ordered and disordered regions, can be revealed in the TEM. Many examples, together with detailed discussions of the analysis schemes for characterizing these defects, can be found in Ref 13, 14, 15, 16.

An investigation of wear will usually involve the study of one or more materials, and each material may consist of several phases. Identification and characterization of these materials and phases can play a critical role in understanding the wear process and perhaps in selecting or developing improved materials. Commercial alloys typically consist of more than one phase. Depending on composition and processing method, the phase morphology can range from relatively large grains to extremely small, coherent precipitates. All are subject to change under the influence of a tribological contact. The

thermal, mechanical, and chemical effects associated with the tribological contact may modify an original structure or create an entirely new structure. The conditions in the contact can be assessed on the basis of the presence of a particular phase, which might occur only if, for example, a specific temperature had or had not been exceeded. Oxide and other films formed by chemical reaction of the surface with the surrounding environment and perhaps a lubricant require characterization. Wear debris may form a mechanically alloyed layer on the surface (Ref 35, 54) and should be analyzed.

An interesting example where TEM was used together with SEM and light optical microscopy to reveal changes in the microstructure of AISI 52100 bearing steel as a result of rolling contact fatigue can be found in an investigation by Osterlund and Vingsbo (Ref 55). The microstructure of AISI 52100 when heat treated for bearing applications consists primarily of tempered lath martensite, with a small amount of retained austenite and a dispersion of small (~1 μm diam) carbides throughout. Depending on load, after about 10^7 cycles, the martensite begins to decay in the region below the contact surface that experiences the maximum Hertzian stress. Evidence of the change can be observed on carefully etched sections by light optical and SEM examination. Detailed characterization of the changes, however, requires TEM analysis. The change essentially involves the transformation of martensite to ferrite and the formation of carbide precipitates (Ref 55). Excellent TEM micrographs illustrating the decay process can also be found in an earlier paper by Swahn *et al.* (Ref 56).

Phase Contrast Imaging

Phase contrast imaging has become an increasingly important imaging mode. The primary application has probably been the study of the atomic-scale crystal structure of electronic materials and devices, but the technique is also being used extensively to study structural ceramics, composites, cermets, intermetallics, and metal alloys. The field of electron microscopy devoted to the study of structure on the atomic scale is generally referred to as high-resolution electron microscopy (HREM). For a full discussion of HREM, see Ref 51.

High-resolution studies require a suitable TEM, such as intermediate-voltage instruments capable of 0.17 to 0.2 nm resolution or high-voltage instruments that provide even better resolution. Considerable operator skill as well as a sound knowledge of the basic principles involved are prerequisites for most high-resolution studies. Moreover, specimen requirements are quite stringent. For crystal structure images, the thickness should generally be no greater than about 40 nm.

Obtaining a lattice image requires that at least two beams (the primary and one diffracted beam, for example) enter the objective aperture. Interference due to the phase difference between the two beams results in periodic fringes corresponding to the lattice planes. Phase changes also are introduced by the spherical aberration of the objective lens and objective lens defocus. Adjusting the focus of the objective lens allows an optimum image to be obtained; this is referred to as the Scherzer focus. The capability of the objective lens to produce this type of contrast is expressed in terms of the so-called contrast transfer function of the lens.

When reflections from different, noncoplanar sets of planes enter the objective aperture and interfere, the positions of atom rows can be imaged. Interpretation of the actual crystal structure, that is, assigning specific atoms to the rows, is complicated by the fact that the contrast is sensitive to a number of different factors, including the specimen thickness and the contrast transfer function of the objective lens. In practice, a structure is hypothesized and a simulated image is computed by employing the appropriate variables. When the computer-generated and observed images are the same, it can be assumed that the hypothesized structure is valid.

HREM can be used to study the structure of triboreaction films and solid lubricants and, of course, the detailed changes in tribocomponent materials. Martin *et al.* (Ref 57) used HREM to observe lattice fringes of iron-rich crystallites in triboreaction film debris fragments generated by sliding AISI 52100 steel against cast iron lubricated with oil containing the additive zinc diisopropyldithiophosphate. In another investigation, Ganapathi and Rigney (Ref 58) studied the mechanically mixed layer that formed on a copper block slid on type 440 stainless steel in argon. TEM showed that the structure at the surface consisted of extremely small "nanosize" grains. High-resolution lattice images were used to study the detailed structure of these nanocrystalline grains and the associated grain boundaries.

EDS Analysis in the TEM

Energy-dispersive x-ray analysis is conjunction with TEM is conducted in essentially the same way as with SEM. The same types of detector and analysis systems are employed with both microscopes. The main differences lie in the much higher accelerating voltages and thin, electron-transparent specimens that are typical of TEM applications. This

combination can have significant advantages. For sufficiently thin specimens, absorption and fluorescence corrections are not necessary, resulting in a considerable simplification in the quantitative determination of composition. The maximum allowable specimen thickness for this condition to hold depends on the material and the accelerating voltage (Ref 51). The maximum thickness is increased for low-atomic-number materials and higher accelerating voltages.

Thin specimens also result in a significant improvement in spatial resolution. In analyzing a bulk sample in the SEM, the volume from which x-rays are collected is on the order of 1 μm in diameter. In the TEM, with a sufficiently thin specimen, the volume may be little greater than that established by the beam diameter and the specimen thickness. With a beam diameter that may be as small as 1 nm and a specimen thickness as small as a few nm, this represents an extremely small volume indeed. As a result of this high spatial resolution, accurate compositional analyses can be obtained for small precipitates and other second-phase particles. Also, composition profiles in the vicinity of interfaces and grain boundaries can be determined precisely.

Electron Energy Loss Spectrometry

Electron energy loss spectrometry in the TEM is most important in connection with the analysis of light elements, where the application of EDS is limited, and in the determination of atomic bonding information, which is not available from x-ray spectra. Thus, EELS is capable not only of determining the elemental composition of a specimen but also of assessing its full chemical identity. A thorough discussion of EELS can be found in Ref 18, 19, and 59.

An energy loss spectrum is schematically depicted in Fig. 23, where the difference between the energy of the incident and scattered electrons--that is, the amount of energy lost--is plotted as a function of intensity. The spectrum, as illustrated in Fig. 23, is usually separated into two parts: the low-loss region and the high-loss region. The low-loss region ranges from approximately 0 eV (no energy loss) to about 50 eV, and the high-loss region extends beyond 50 eV. On average, the intensity falls off rapidly with increasing energy loss and becomes very small in the high-loss region. In order to show the details of both the low- and high-loss regions in the same graph, as is customary, the high-loss region is displayed at an increased gain.

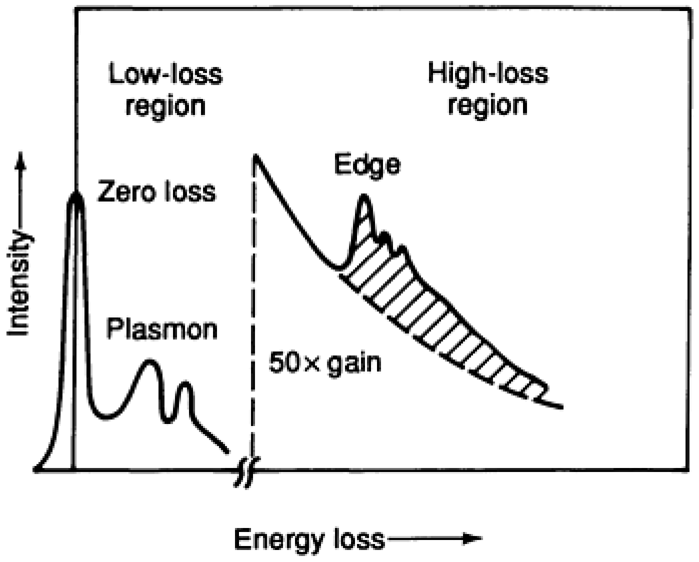

Fig. 23 Schematic illustration of EELS spectrum

In Fig. 23, the first and largest peak in the low-loss region is the zero-loss peak. This peak consists primarily of incident beam electrons that have passed through the specimen without being scattered and of electrons that have been scattered without losing energy (elastically scattered electrons). The incident electrons beam is not monochromatic, but has a small energy spread. This, together with the finite resolution of the spectrometer, results in the measurable width of the zero-loss peak.

The relatively broad peaks following the zero-loss peak result from collective, or plasmon, interactions with conduction and/or valence band electrons. By comparing the integrated intensity of these plasmon peaks with that of the zero-loss peak, it is possible to obtain information on specimen thickness.

The high-loss region of the spectrum is by far the most important. It is from this region that most of the information about specimen chemistry is obtained. The ejection of an inner-shell atomic electron (that is, ionization of the atom) results in a characteristic absorption edge that can be used to determine the elemental composition of the specimen. (It may be recalled that the emission of x-rays during decay of the ionized atom is the basis of EDS analysis.) In addition, the shape immediately following the onset of the edge, the so-called energy-loss near-edge structure (ELNES), provides information about the atomic environment around the atomic species responsible for the edge.

The most commonly used EELS spectrometer is positioned on the optical axis at the base of the microscope, below the viewing screen. Electrons passing through the entrance slit of the spectrometer are energy dispersed by a magnetic field. The dispersed electrons can be detected either serially by being scanned across a single detector or in parallel by an array of detectors. The latter method takes much less time to acquire a spectrum. The signal associated with the detected electrons is amplified and sent to an analysis system for processing and display. The same analysis system used for EDS can be used for EELS.

By positioning a particular area in the specimen image over the entrance aperture of the spectrometer, the energy loss spectrum from that area and the features within can be collected and analyzed. The size of the analyzed area is defined by the entrance aperture and can be controlled by adjusting the image magnification. Alternatively, a diffraction spot can be placed over the entrance aperture and the entire specimen region contribution to that spot subjected to analysis. In the STEM mode of operation, it is possible to map the composition of the specimen or to obtain an energy-filtered image.

There are several limitations to EELS analysis. The specimen must be quite thin, generally less than 50 nm, to avoid multiple scattering events as the electron passes through the material. Multiple scattering results in a rapid increase in background level, which eventually overcomes the spectral features of interest. In addition, the application of EELS to specimens containing more than a few elements may be severely limited because of extensive peak overlap. Also, the quantitative determination of concentrations is less well developed in EELS than in EDS.

There appear to be relatively few instances where EELS has been applied directly to the study of wear. One example concerning the analysis of boundary lubrication films can be found in Ref 57.

Scanning Transmission Electron Microscopy

Many TEMs are designed to operate in the STEM mode as well as in the stationary-beam CTEM mode. The desired mode of operation is selected according to the requirements of the particular investigation and to some extent by the preferences of the operator. The conventional operating mode is probably most convenient for routine examination of microstructure, diffraction contrast studies of defect structures, crystal structure studies using electron diffraction, and for EDS and EELS analyses of specific features. Also, only when the microscope is equipped with a field emission source does resolution in the STEM mode approach that in the CTEM mode. Thus, the CTEM mode is generally employed for high-resolution studies.

The STEM mode has three extremely important and the useful capabilities not available in the CTEM mode, or available only to a limited extent. First, virtually any emitted signal for which a detector is available can be used to produce an image in the STEM mode. Second, the electronic signal is easily processed and enhanced to control contrast and brightness for suitable viewing and photography. Third, digital beam control and image digitization are relatively easy steps, allowing the direct application of computer processing and analysis to the image. For example, with digital beam control, all particles meeting a certain size or shape criterion might be selected for further compositional analysis, which would then proceed automatically.

Once in the STEM mode, the microscope functions essentially as an SEM. CRTs are available for visual observation and photography. Alternatively, with a modern digital instrument, a computer screen replaces the visual CRT. Bright- and dark-field detectors are basic equipment in the STEM system. According to the principle of reciprocity (Ref 19). STEM bright-field and dark-field transmission images are similar to CTEM bright- and dark-field images, or at least can be made similar by the selection of appropriate aperture angles. Thus, the rules regarding image contrast interpretation in CTEM carry over to STEM images.

STEM offers several different methods for obtaining a diffraction pattern. The incident beam can be rocked about a point on the specimen surface, whereby the diffraction pattern is scanned across the detector and displayed on the CRT monitor. Alternatively, the incident beam can be kept stationary and the transmitted beam scanned over the detector, or both the incident and transmitted beams can be deflected in synchronism to generate the diffraction pattern. By using the image analysis capabilities inherent in the STEM mode, analysis of the diffraction pattern can be carried out directly in conjunction with appropriate computer software.

In addition to bright- and dark-field detectors, an array of other detectors is also available, including secondary electron, backscattered electron, and emitted light (cathodoluminescence) detectors. These detectors are used to examine the specimen surface and allow direct comparison of surface topography and internal structure revealed by transmission detectors. When equipped with EDS and EELS systems, signals detected by these systems may also be used for image generation to produce composition maps. As already discussed in the sections on EDS and EELS in the TEM, the thin, electron-transparent specimen results in a significant improvement in spatial resolution compared with bulk analysis in the SEM by EDS.

Summary and Future Outlook

A detailed understanding of wear processes and mechanisms will, in general, require comprehensive information on the response of the materials involved. Surface topography, reaction films, subsurface microstructure, and wear debris all require characterization. The SEM has become the primary tool in such investigations. Ease of operation, an extremely large magnification range, high resolution, great depth of field, and lack of restrictive specimen preparation requirements, together with the ability to determine elemental composition with associated x-ray analysis facilities, are responsible for this status. With the continued improvement in capabilities, particularly in connection with the development of computer-based instruments with more extensive compositional mapping and quantitative image analysis capabilities, it seems likely that the SEM will be of even greater value in tribological studies in the future.

The TEM has not been as extensively used in the study of wear as the SEM, but nevertheless has made significant contributions to the understanding of wear processes. Specimen preparation for TEM analyses, in general, requires considerable effort. Image interpretation is more demanding and may require a substantial understanding of the physics of electron-specimen interactions. The TEM is capable of providing detailed information on the microstructure and composition of materials, even at the atomic scale of resolution in some cases. The nature and arrangement of dislocations resulting from tribological contact, thermal and stress-induced phase changes, the composition and microstructure of triboreaction films, and the properties of wear debris can all be characterized by means of TEM.

Scanning Tunneling Microscopy

Yip-Wah Chung and T.S. Sriram, Northwestern University

Introduction

THE SCANNING TUNNELING MICROSCOPE (STM) represents a microscopy technique that enables high-resolution imaging of surfaces over a relatively large dynamic range, both in the horizontal and vertical directions. Even more significantly, this high resolution is achieved in vacuum, air, and liquid environments, which makes this new technique convenient to use for practical specimens.

This article describes the STM technique in the context of surface topography measurements, although applications in other areas are described, as well. To bring the subject into perspective, its history is described first, followed by a brief discussion of its physical basis. The technical details of the design and operation of the microscope are then discussed, followed by several examples of its applications. Finally, limitations and variants of the basic STM are described.

Historical Perspective

The theory of quantum mechanical tunneling was first developed in the early 1920s. An early triumph of this theory was its correct explanation of the strong dependence of the half-lives of radioactive nuclides on kinetic energies of emitted α particles. Leo Esaki was the first to exploit tunneling in a real solid-state device while working at the IBM Yorktown Heights Thomas J. Watson Research Center. In 1972, he received the Nobel Prize in physics for this invention. At about that time, Russell Young and his coworkers at the National Bureau of Standards (now the National Institute of Standards and Technology) described an instrument called the topografiner (Ref 1, 2), which in many ways is the predecessor of the modern STM. The topografiner operates in the field emission mode, with a horizontal resolution of about 20 nm and a vertical resolution of about 0.3 nm. Vibration and tip instabilities are the probable reasons that resolution was somewhat limited at this stage.

The concept of the STM was first described in a patent disclosure in mid-1979 by Heinrich Rohrer and his research staff assistant, Gerd Binnig. The next few years were spent solving problems related to vibration isolation and both coarse and fine motion control in all three axes. Their first success occurred in 1981, when images resolving monatomic steps on the surface of a calcium-iridium-tin crystal were obtained. However, the corresponding paper was rejected, because one referee found it "not interesting enough." What caught the attention of the scientific community in 1982 was the paper written by these researchers that described their success in imaging the famous Si(111)-(7 × 7) surface (Ref 3). Although this surface structure was first observed in the 1960s, its complexity precluded a structural solution until this work in 1982. In 1986, Binnig and Rohrer were awarded the Nobel Prize in physics for their STM work.

Since then, many STMs have been built and developed around the world. Commercial versions that operate both in air and in ultrahigh vacuum are also becoming available. Variants, such as the atomic force microscope and the scanning capacitance microscope, the expand the functionalities of the basic STM have also been developed. Applications cover many disciplines in physics, chemistry, biology, materials science, and engineering. Reports of using the STM for additive and subtractive lithography in the nanometer scale are emerging (Ref 4, 5, 6).

Principle of STM Imaging

Consider a sharp conducting tip brought to within 1 nm (0.04 μin.) of a specimen surface (Fig. 1). Typically, a bias ranging from 0.01 to 1 V is applied between the tip and the specimen. Under these conditions, the tip-surface spacing, *s*, is sufficiently small that electrons can tunnel from the tip to the specimen or vice versa. As a result, a current, *I*, flows across this gap and can be shown to vary with *s* as follows (Ref 7):

$$I \sim \exp(-10.25 \quad) \qquad \textbf{(Eq 1)}$$

where ϕ is the effective work function in eV (for most systems, this is on the order of a few eV) and *s* is in nm. One can see that if the tip-surface spacing is increased (decreased) by 0.1 nm, then the tunneling current will decrease (increase) by a factor of

$$\exp(1.025\sqrt{\phi}) \qquad \textbf{(Eq 2)}$$

or about a factor of 10 for an effective work function of 4 eV.

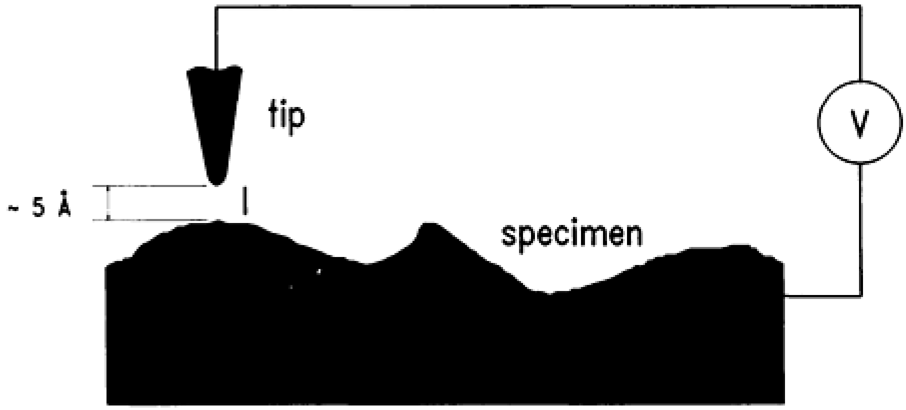

Fig. 1 Electron tunneling across gap between tip and specimen under an applied bias voltage

One can then exploit this sensitive dependence of *I* on the tip-surface spacing for topographic imaging, as described below. In scanning the tip horizontally across the specimen, any change in the tip-surface spacing results in a large change in *I*. One can use some feedback mechanism to move the tip up or down to maintain a constant value of *I*. According to Eq 1, this implies that one is maintaining a constant tip-surface spacing (the effective work function may change with position, because of surface heterogeneity, but its variation is ignored in this discussion). In other words, the up-and-down motion of the tip traces out the topography of the surface, analogous to the conventional technique of stylus profilometry, except that the tip never touches the surface in STM. This is known as constant current imaging, the most common imaging mode used in scanning tunneling microscopy.

Now the discussion returns to the situation where the effective work function varies with position. In the constant current imaging mode, one maintains a constant value during scanning. Therefore, for an absolutely flat surface with an effective work function of (4 ± 1) eV (a substantial surface heterogeneity) and a nominal tip-surface spacing of 0.5 nm, the STM topograph would reveal an apparent height variation of less than 0.1 nm, because of such surface heterogeneities. Hence, for surface roughness variations that exceed 0.1 nm, STM images obtained in the constant current mode reveal primarily surface topography.

To separately map such surface heterogeneities, one can modulate the vertical position of the tip in sinusoidal manner, for example, at a rate faster than the feedback response of the system. In this case, the tunneling current is also modulated. From Eq 1, one can readily show that:

$$\frac{d(\ln i)}{ds} \sim -\sqrt{\phi} \qquad \textbf{(Eq 3)}$$

from which the work function variation can be imaged.

Because of the proximity of the tip to the surface and the nature of tunneling, the tunneling electron beam diameter can be very small, and is given by (Ref 8):

$$\sqrt{0.2\,(R+s)} \qquad \textbf{(Eq 4)}$$

for an effective work function of 4 eV, where *R* is the radius of the tip, and *s* is the tip-surface spacing, both in units of nm. Therefore, for *R* = 0.2 nm and *s* = 0.5 nm, the electron beam diameter is on the order of 0.4 nm.

It is important to note that the STM works in vacuum, as well as in air and under liquids (Ref 9, 10). The reason is that the tip is so close to the surface (0.5 nm) that the volume through which the tunneling current flows is on the order of 0.1 nm^3. In a normal air environment, there is less than 0.003 air molecule contained in this volume. In water, the corresponding number is about 3. Therefore, the tunneling electrons flow more or less unaffected by ambient molecules.

Motion Control

To bring the tip to within tunneling range, it must be moved over macroscopic distances (hundreds of microns). During tunneling and feedback control, the tip must be positioned with precision better than 0.1 nm. The task is usually segregated into coarse and fine motion control.

Coarse motion control employs several methods. As described in their original work, Binnig and Rohrer used a piezoelectric inch-worm (piezoelectric materials are further described later). More recent designs are based on purely mechanical means, all using fine-thread screws (for example, Ref 11). Figure 2 depicts one type. Consider a conventional 80-pitch screw, that is, the screw advances by 25 mm (1 in.) after 80 turns. This translates into a motion advance of about 880 nm for 1° of screw rotation. Using a cantilever beam with a mechanical advantage of 10, as shown in Fig. 2, a precision of 88 nm (for 1° of screw rotation) can be achieved.

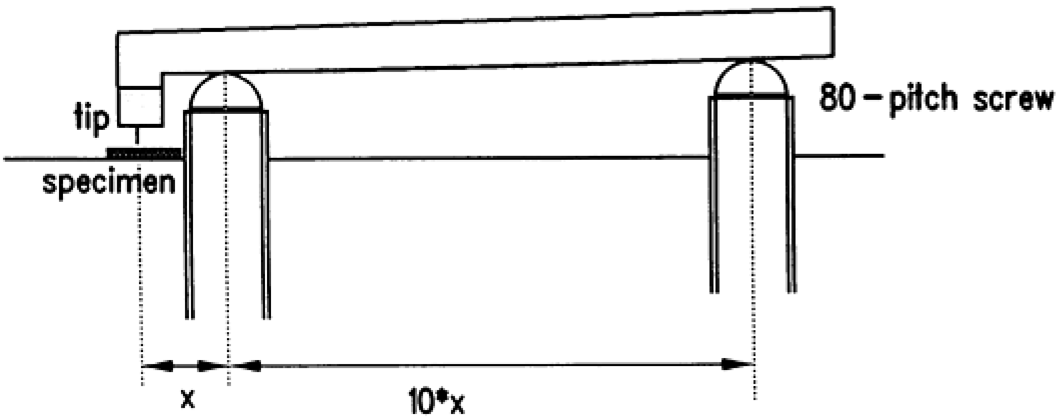

Fig. 2 Example of coarse approach using fine-thread screws and mechanical advantage of a cantilever beam

Fine Motion Control. During tunneling and feedback control, the precision required for tip positioning relative to the specimen surface must be better than 0.1 nm. This is achieved by using piezoelectric positioners. Piezoelectric materials expand or contract upon the application of an electric field (Fig. 3). Lead zirconium titanate (PZT) is the material of choice in the STM community. Most STMs are designed with a response of 1 to 10 nm/V, although a response of up to 500 nm/V can be achieved for large-scale scanning. Because voltages can be easily controlled and monitored in the submillivolt level, subnanometer control can be readily attained.

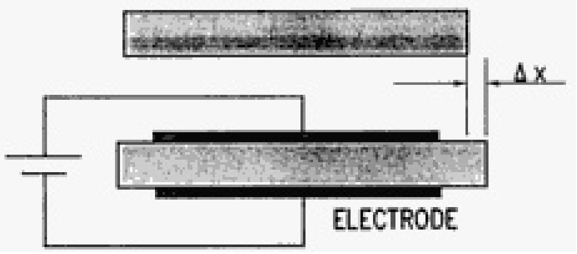

Fig. 3 Piezoelectric effect

In the initial development of STMs, three-axis control was accomplished using three separate pieces of piezoelectric bars held together in an orthogonal arrangement. To improve rigidity, especially for long-range scanners, most researchers opt for a design based on a piezoelectric tube scanner, shown in Fig. 4 (Ref 12). The inside of the piezoelectric tube is completely metal-coated, whereas the outside is metal-coated, in four separate quadrants. By applying appropriate voltages to one pair of diametrically opposite quadrants, one causes the piezoelectric tube to bend along that direction, thus achieving *x* or *y* scanning motion. Application of voltage to the inner surface causes the tube to expand or contract (*z*-axis motion). Therefore, three-axis motion can be attained with a single tube.

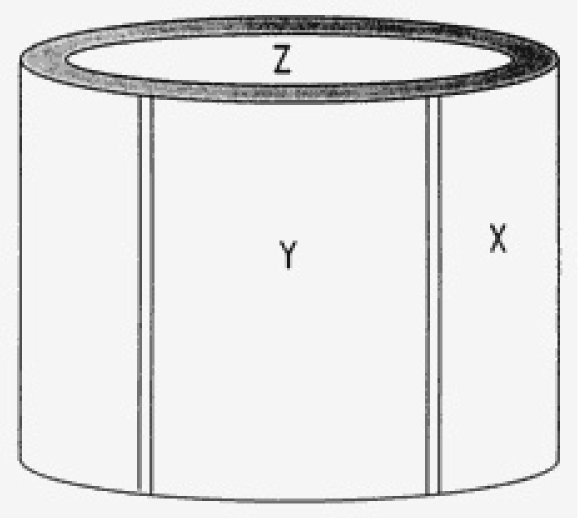

Fig. 4 Typical piezoelectric tube scanner used for STM work

The lowest resonance frequency of such a structure can be made to exceed 10 kHz easily (compared to, typically, 1 kHz for the orthogonal tripod). This higher resonance frequency allows electronic feedback and scanning to be performed at higher rates without setting the microscope into resonance or without crashing the tip onto the specimen surface. Therefore, a tube-based STM is inherently capable of acquiring topographical data rapidly. The major disadvantage of the tube scanner is the possibility of crosstalk among the three axes.

Vibration Isolation

The first tunneling microscope was supported using superconducting levitation for vibration isolation. More recent designs use damped springs, air tables, and stacked stainless steel plates separated by viton dampers. The goal of all these designs is to keep the tip-surface spacing immune to external vibration.

Assume that the STM sits on a platform that is coupled to the outside world via a spring with resonance frequency, *f*, and that the lowest resonance frequency of the STM is *F*, which is much greater than *f* (Fig. 5). The external vibration has a

frequency, f', and amplitude A. With such a system, the vibration amplitude transmitted to the STM depends on the frequency f' of the vibration. There are four regimes to consider.

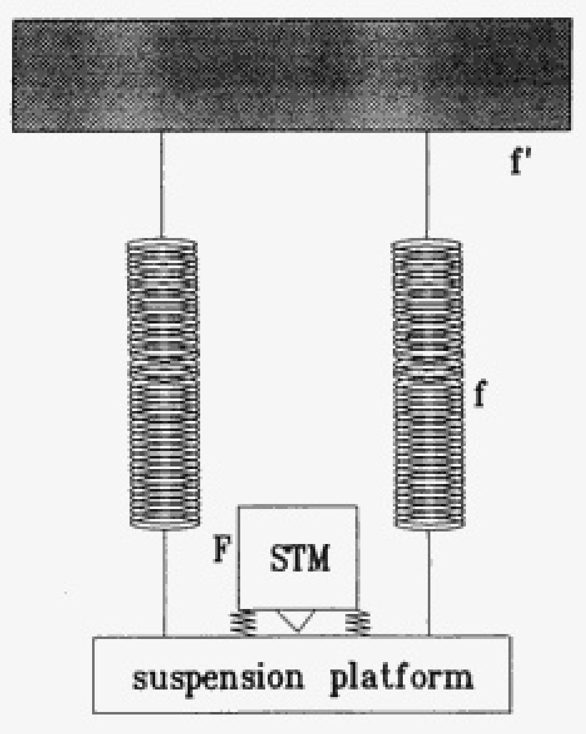

Fig. 5 Vibration isolation for an STM using a suspension platform. Source: Ref 11

The first regime is $f' < f$. The platform spring does nothing to attenuate the external vibration. The vibration amplitude entering into the microscope causes a tip-surface spacing change given by

$$a = A\,(f'/F)^2 \qquad \textbf{(Eq 5)}$$

The second regime is $f' \sim f$. The vibration amplitude entering into the microscope is actually amplified, depending on the amount of damping in the platform spring.

The third regime is $f \ll f' \ll F$, where the vibration amplitude, a, entering into the microscope is independent of f' and is given by

$$a = A\,(f/F)^2 \qquad \textbf{(Eq 6)}$$

In the fourth regime, $f' \gg F$, only the platform spring does the attenuation and the transmitted vibration amplitude, a, is given by

$$a = A\,(f/f')^2 \qquad \textbf{(Eq 7)}$$

In examining these four cases, it becomes clear that one should support the STM on a soft platform (small f value) and design a microscope with high rigidity (large F value). For example, for the third regime, with $f = 1$ Hz, $F = 10$ kHz, and $A = 10$ μm (400 μin.), the transmitted vibration amplitude, a, can be shown to be equal to 10^{-4} nm for intermediate frequencies. Therefore, a rigid STM not only allows fast image acquisition, but more effective vibration isolation, as well.

Tip Preparation

The two types of tip materials that are widely used are tungsten and platinum alloys (for example, Pt-Ir and Pt-Rh). Tungsten is strong, and it can be fabricated into a sharp tip easily, although it tends to oxidize rapidly in air. On the other hand, Pt alloys are stable in air, but they may not survive occasional tip crashes on surfaces.

Several methods can be used to create sharp tips of these materials. These include electropolishing (Ref 13, 14), cutting and grinding, momentary application of a high-bias voltage (a few volts), or simply waiting for a few minutes after setting up in the tunneling configuration.

Recently, a simple technique was described by Akama and coworkers, in which a sharp, amorphous carbon needle was grown by aiming a focused 25 keV electron beam at the apex of a tungsten tip inside a scanning electron microscope (SEM) for a few minutes (Ref 15). Decomposition of ambient hydrocarbons results in the formation of a carbon needle at the apex. A carbon tip several microns long with an apex radius less than 25 nm can be produced readily. Tips with such an elongated geometry are useful to image rough surfaces with minimal artifacts.

Data Acquisition and Analysis

A typical setup is shown in Fig. 6 (Ref 11). A voltage bias is applied between the tip and the specimen. The tunneling current so obtained is then compared with a preset value between, typically, 1 and 10 nA. The error signal then drives an integral feedback circuit, the output of which is used to control a fast high-voltage operational amplifier, which feeds voltage to the *z* electrode of the tube scanner. At the same time, raster-scanning is accomplished by using two digital-to-analog converters to control the output of two high-voltage operational amplifiers feeding voltages to the *x* and *y* electrodes of the tube scanner.

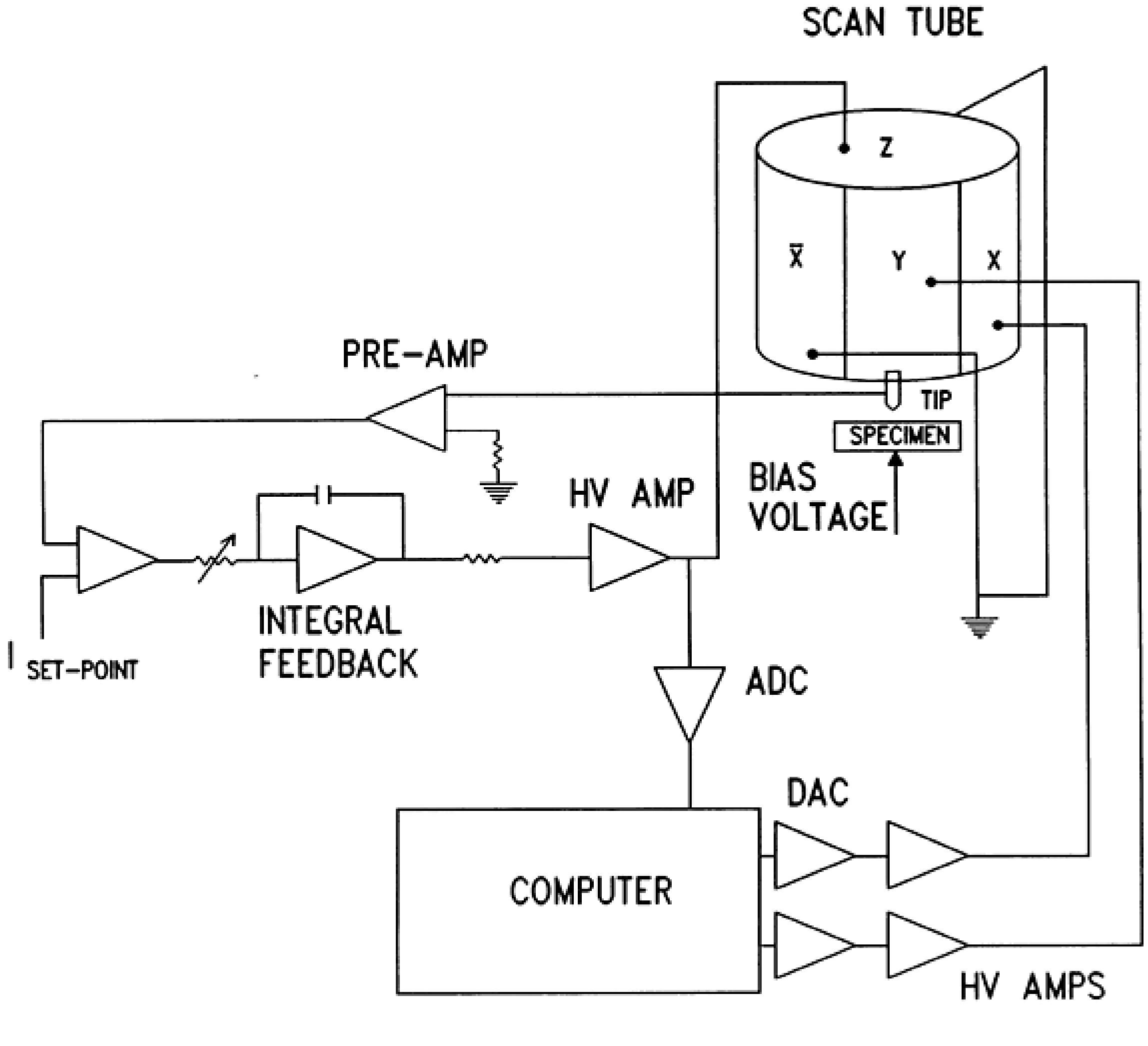

Fig. 6 Data acquisition and control electronics for STM

At each step, the *z* voltage required to maintain a constant tunneling current is read by the computer via a fast analog-to-digital converter (either through AC coupling or potential dividers). This *z* voltage, as discussed earlier, corresponds to the surface height at that *xy* location. This information can then be displayed in real time as gray-level images on an analog monitor. Most tube-based scanners allow image acquisition at the rate of several thousand pixels per second.

In the above setup, the feedback control is done by analog circuitry. Because of the availability of fast digital signal processors in recent years, microscopes can be designed to use signal processors to perform feedback via software.

Normally, the topographical data are stored a two-dimensional integer arrays. As a result, each image can be processed in a variety of ways, for example, to suppress noise, to enhance parts of the image, or to obtain certain surface roughness parameters.

Several commercial software packages are available for these types of image processing and analysis setups on personal computers and workstations. Hard-copy outputs can be obtained as either line plots or gray-level images. In the latter case, several methods are available. The most direct method is to photograph the monitor screen or use a film recorder to obtain an image. Another convenient method is to use a laser printer, color wax printer, or video printer.

Applications

A standard benchmark in testing STM performance is to obtain an atomic image from highly oriented pyrolytic graphite (HOPG) in air. Figure 7 shows an image obtained from HOPG in air, measuring about 1.4 nm × 1.4 nm. Bright protrusions are individual carbon atoms on the basal plane of graphite. The height of the protrusions is about 0.2 nm.

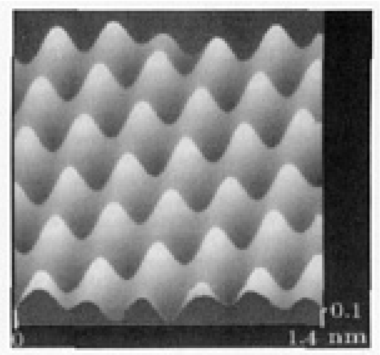

Fig. 7 Atomic image of HOPG graphite obtained in air

Figure 8 shows a 2.5 × 2.5 μm (100 × 100 μin.) region of a silver specimen that has been fatigued in oxygen (Ref 16). The stress axis is parallel to the *y* direction in the image. The image shows three parallel slip bands. Figure 9 shows a large-area scan from a silicon substrate with aluminum lines deposited on it.

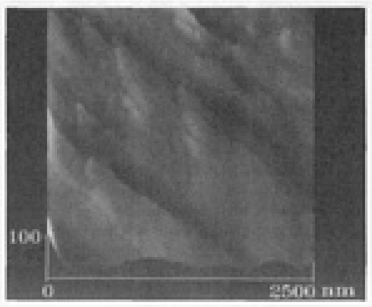

Fig. 8 Topography image from a fatigued silver single crystal showing parallel slip bands; faint vertical lines are due to polishing

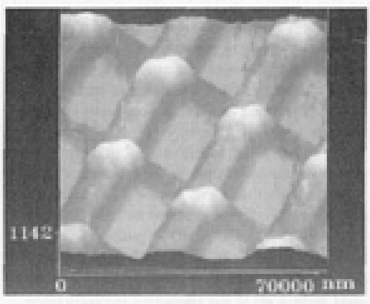

Fig. 9 Topography image of a large (70 × 70 μm, or 2.8 × 2.8 mil) region of a silicon wafer with aluminum lines. Specimen was coated with 50 A (2 × 10^{-7} in.) of gold to improve conductivity.

Scanning tunneling microscopy is normally applicable only to conducting surfaces because a conducting path is needed for the tunneling electrons. An interesting situation arises when a conducting surface is covered by some insulating species. For example, Koch and Hamers (Ref 17) found that when tunneling electrons of the proper energy are injected onto thin oxide patches on an otherwise clean silicon surface, the oxide traps the electrons and then releases them after some time. As a result, the tunneling current exhibits large amplitude fluctuations. On the other hand, no such large amplitude fluctuations are observed when the current is injected onto the clean surface.

Consider a map of tunneling current fluctuations as a current variance image. The image is obtained by measuring the fluctuation amplitude of the tunneling current at each point of the surface. The fluctuation amplitudes are then displayed as gray-level maps, with brighter regions indicating greater fluctuations.

One interesting application (Ref 18) is to image the distribution of thin layers of fluorocarbon lubricants applied on magnetic thin-film disk surfaces (fluorocarbon is an insulator). Figure 10 shows topography and variance images from scratched and unscratched portions of a magnetic thin-film disk. The topography images were obtained at a low bias (20 mV), whereas the variance images were obtained at a high bias (4 V). The variance image from the unscratched surface shows uniformly high variance, suggesting uniform distribution of the lubricant. The variance image from the scratched surface shows regions with low current fluctuations. This indicates that the scratched regions have bare spots.

Technique Comparison

Table 1 summarizes the characteristics of several other surface roughness measurement techniques, specifically, stylus profilometry, optical interferometry, and SEM stereomicroscopy (Ref 11). Although these techniques are easy to use, they have limitations.

Table 1 Comparison of several surface roughness measurement techniques

Type	Contact	Resolution, nm	
		Lateral	**Vertical**
Stylus profilometry	Yes	1000	5
Optical interferometry	No	500	1
SEM stereo-microscopy	No	10	60

For example, the lateral resolution in stylus profilometry is limited by the radius of the diamond tip, typically a few microns. Surface features with dimensions less than the tip radius are not resolved. There is also the possibility of specimen damage induced by the stylus during measurements. In principle, these problems can be overcome by using a sharp stylus and an ultralight load. Optical interferometry overcomes most of these problems, but is diffraction-limited in lateral resolution to a fraction of a micron (unless near-field imaging techniques are used). Stereomicroscopy in which an SEM is used gives relatively poor vertical resolution and requires placing the specimen in vacuum. In contrast, the STM achieves superb horizontal and vertical resolution and can be applied in virtually any environment.

Limitations and Solutions

The STM has two major limitations. First, the specimen surface must be reasonably conducting. Under typical operating conditions, the resistance of the gap separating the tip and the specimen is on the order of 10 MΩ (for example, tunneling

at 1 nA under a bias of 10 mV). "Reasonably conducting" means that the resistance of the electrical path from the specimen to the return circuit should be small, compared to 10 MΩ. This rules out the consideration of many ceramic and polymer materials. One solution is to put a conduction coating (such as gold or Pt-C) on such surfaces, assuming that the coating faithfully reproduces the surface topography of the substrate. Another solution is to use AC tunneling, that is, the bias is allowed to change sign rapidly (Ref 19).

The basic idea is that in the forward cycle, electrons are injected from the tip onto the surface. The behavior of the tunneling current with respect to tip-surface spacing is as predicted by Eq 1 in this portion of the cycle. Therefore, feedback control can be "locked" to the tunneling current in the forward cycle. In the next half cycle, the polarity is reversed, thereby clearing electrons from the surface of the insulating specimen. In this way, insulating surfaces can be imaged by the STM. The major difficulty is that high-frequency AC bias may be required for highly insulating surfaces. Stray capacitance between the tip and the sample may result in a large displacement current that can overwhelm the tunneling current.

Second, the STM suffers from limited scanning range. Using reasonable geometry (for example, a scan head on the order of a few centimeters long and a scan tube thickness of 1 to 2 mm, or 0.04 to 0.08 in.) and applied voltage (not exceeding 300 V), one finds that the maximum scan range is on the order of from 50 to 100 μm (2 to 4 mils). In general, because longer scanners have lower resonance frequencies, scanning rates must be reduced to obtain images over large areas. The important point is that the STM cannot replace the conventional SEM in terms of dynamic range.

Future Trends

In spite of its short history, the STM has developed into a mature tool for a wide range of applications in many science and engineering disciplines. For tribologists who are interested in surface roughness measurements, the new technique offers high resolution in both horizontal and vertical directions with few environmental constraints (in terms of vibration isolation and measurements under normal ambient conditions). Of course, tips with large aspect ratios are still required to image rough surfaces with minimal artifacts.

There are two important variants of the STM: the scanning capacitance microscope (SCaM) and the atomic force microscope (AFM). These new microscopy techniques allow the imaging of surface topography, and obtain other important surface properties, as well.

In a SCaM, the capacitance between the tip and the specimen surface is used as a sensor of the tip-surface spacing (Ref 20). Despite the very small capacitance involved in these measurements, spatial resolution of about 25 nm has been demonstrated. In addition, by exploiting the fact that the capacitance of a semiconductor surface depends on the carrier concentration, this technique can be used to image dopant distribution on semiconductor surfaces at high spatial resolution (Ref 21).

In an AFM, the tip is normally part of a small wire (Ref 22, 23) or a microfabricated cantilever (Ref 24). The force of interaction between the tip and the surface results in a deflection of the cantilever. In most modern designs, the cantilever deflection is sensed either by detecting the reflection of a light beam from the back of the cantilever (Ref 25) or by optical interferometry (Ref 23, 24). Under appropriate operating conditions, atomic resolution can be achieved (Ref 24). One important strength of the AFM is its ability to obtain images from insulator surfaces. By using a magnetized tip with the AFM, magnetic domains have been imaged (Ref 26).

Extensions of STM, such as the AFM, will continue to evolve. For example, by adapting the AFM to measure forces in the vertical and horizontal direction, one can turn it into a tribometer measuring frictional forces on the atomic scale (Ref 27).

In parallel with developments in research laboratories around the world, commercial versions of STM have been developed for applications in air and ultrahigh vacuum (Ref 28). Associated turnkey image processing software packages are widely available for different types of computers, thus making data analysis and presentation extremely convenient. With these developments, the STM should eventually become standard equipment in most analytical laboratories.

Measurement of Surface Forces and Adhesion

Roger G. Horn, Ceramics Division, National Institute of Standards and Technology

Introduction

BECAUSE ADHESION between two contacting surfaces is an important factor in terms of friction and wear, the ability to make controlled, reproducible measurements of this quantity is desirable. The methods to accomplish this and some of the significant difficulties involved in doing so are described in this article.

The common sense of the word "adhesion," that is, the joining of two materials with a thin film of a third material, is not of concern here. The engineering and chemical aspects of adhesives and adhesive joints are described in Ref 1 and 2. Rather, the concern is the innate adhesion between two materials that arises from interatomic and intermolecular forces. Such forces are always present, and act between all of the atoms and molecules in the system--not only within each material, but also those in different materials and those in any other media present. For example, two solid surfaces in close proximity are attracted as a result of all the van der Waals forces acting between the atoms of each solid. Furthermore, the interaction is affected by the molecules of whatever liquid or gas separates the solids.

Intermolecular forces that act between two separate bodies can generally be considered as acting between the surfaces of those bodies, and are therefore called surface forces (Ref 3, 4). Adhesion is one manifestation of the existence of surface forces. This article first describes surface forces and methods of measuring them before adhesion is discussed. Surface force measurements help one to understand the importance of various contributions to surface forces and adhesion, and therefore, ultimately, to design materials and environmental conditions to minimize or maximize adhesion, as required.

Basic Concepts

Surface forces have their origins in well-understood interatomic and intermolecular forces (Ref 3), but several indirect effects can occur to enrich the variety of surface forces that is possible in a given situation (Ref 4). It is convenient to classify surface forces according to their range of action. Short-range forces are those that act between atoms and molecules that are essentially in contact, say within 0.1 or 0.2 nm of each other. Examples are covalent and hydrogen bonding, as well as Born repulsions. Long-range forces act between surfaces that are further apart; long range in this context might mean a few nanometers. Examples are van der Waals and electrostatic forces.

To complicate this classification, forces that are effective at long range, but that are really the result of short-range forces, also exist. An example is steric repulsion, in which surfactant molecules adsorbed on a solid surface (via short-range bonding that can be van der Waals, ionic, covalent or hydrogen bonding) prevent a second surface from a approaching the first (via Born repulsions, either between the adsorbed molecules and the second surface of between one layer of adsorbed molecules and another layer). Boundary lubricants operate in this way to keep solid surfaces separated.

The study of forces between molecules and surfaces does not fall within the compass of "surfaces forces" in the sense used here, but they can be very important for the reason described above. Measurement of forces between one surface and another can often give indirect information on molecule-surface forces. For example, the presence or absence of an adsorbed layer can easily be detected using the methods described in this article.

In general, short-range forces are stronger than long-range forces, and make the most important contributions to adhesion. Unfortunately, long-range forces are easier to both measure and model. Therefore, knowledge of surface forces, both theoretical and experimental, is much sounder for long-range effects, and adhesion remains an area of difficulty.

Surface energy is the work required to create a unit area of new surface from bulk material. A though experiment is commonly employed to define surface energy, γ_s, as half of the reversible work, W_c, required to first divide a monolithic solid so as to create two new surfaces of unit area, and then to pull the two surfaces infinitely far apart in vacuum. Here, infinitely far apart means beyond the range of any surface force; usually, a few μm is ample. The term W_c is called the work of cohesion. In general, the separation process involves breaking interatomic bonds, the number (and possibly strength) of which depends on crystallographic orientation, so that surface energy varies from one crystal face to another (Ref 5).

Surface Energy and Surface Forces. In conducting the thought experiment described above, the act of separating two surfaces would require work to be done against the attractive surface forces present. Integration of this surface force, as a function of separation from 0 to ∞, gives a quantity

$$W_{SF} = -\int_0^\infty F_f(D)\, dD \qquad \textbf{(Eq 1)}$$

where $F_f(D)$ is the surface force between flat solids at a separation, D, using the convention that $F < 0$ for an attractive force. The subscript SF indicates that this is the contribution to W_c from the surface forces.

Sometimes W_{SF} is equated to twice the surface energy, but this is not generally correct because other energetic processes are likely to occur during the creation of new surfaces. In particular, the new surfaces are likely to reconstruct. Atoms near the new surface rearrange their positions to a configuration that is more favorable near a surface than was their original configuration in the bulk of the solid. Furthermore, there is the delicate issue of assigning the energy associated with breaking strong, short-ranged atomic bonds when the original solid is "magically" cleaved. This is certainly a contribution (probably the major one) to W_c, but it is unclear whether or not it should be included in the definition of W_{SF}.

Interfacial Energy. When a solid is not in vacuum but is in contact with a liquid or vapor, it is considered in terms of interfacial energy, γ_{SL} or γ_{SV}, respectively, rather than surface energy. If the above process were carried out in either a liquid or vapor environment, the work of cohesion would equal twice the interfacial (solid-liquid or solid-vapor) energy. The same remarks about reversibility and reconstruction still apply. Furthermore, in this situation there is also the likelihood that molecules of the liquid or vapor will adsorb to the new solid surface (which could be thought of as "reconstruction" of the fluid at the interface). Adsorption reduces the interfacial energy.

Note that the reconstruction of both solid and fluid depends on which materials are involved. For example, a given solid material may reconstruct differently in water than in a hydrocarbon liquid. The details of the interfacial structure are also likely to depend on the distance between one interface and the other. Again, careful consideration must be given in the thought experiment to the question of reversibility. If the adsorption is irreversible, then bringing the two solids back together after they have been separated will not remove the adsorbate, and the surfaces will never return to their original intimate contact and will not reform the original atomic bonding that existed in the monolithic solid.

The interfacial energy, γ_{LV}, between a liquid and its own vapor is also called the surface energy, or, more commonly, the surface tension of that liquid. The term "tension" comes from a real force that resists any attempt to increase the surface area of a given volume of liquid. Surface tension of a liquid can be measured directly. Determining either the surface or interfacial energy of a solid is much more problematic. Solid-liquid and solid-vapor surface energies are related to the liquid surface tension and the contact angle, θ, made by the liquid on the solid through Young's equation:

$$\gamma_{SV} = \gamma_{SL} + \gamma_{LV} \cos\theta \qquad \textbf{(Eq 2)}$$

Work of Adhesion. A thought experiment has been used to define the work of cohesion of a solid as twice the surface energy (because *two* surfaces are created) or interfacial energy, as appropriate. If a similar experiment were done in which

two *different* materials were separated from contact to a large distance, the work required would be the work of adhesion, W_A.

The work of adhesion can be equated with the energetic cost of creating new interfaces of each solid material in contact with the environment, γ_{1E} and γ_{2E}, say, where the subscript $_E$ could be liquid or vapor, as appropriate, less the energetic gain from removing the original solid-solid interface. The energy associated with the solid-solid interface is also termed an interfacial energy, γ_{12}, which is defined by the Dupré equation:

$$W_A = \gamma_{1E} + \gamma_{2E} - \gamma_{12} \quad \textbf{(Eq 3)}$$

In the discussion below, adhesion will sometimes be loosely used to mean work of adhesion.

In a similar way, one could define the work of adhesion between two pieces of the *same* solid material. This would differ from the work of cohesion if the two pieces were brought together in an environment so that adsorbate remained at the interface or if they were formed with their crystal orientations misaligned, giving a grain boundary at the interface. In that case, the quantity γ_{12} would be nonzero, and would correspond to a grain boundary energy, with or without extrinsic molecules present. Because grain boundary energy depends on grain boundary angle, the adhesion between two crystals of the same material depends on their relative orientation.

Note that there is another effect that can make the above definition of work of adhesion problematic. When two solids are pulled apart, it is quite possible, and often observed in practice, that separation does not occur precisely between the two materials. Many solids interdiffuse when in contact, particularly at high temperature, which makes it almost impossible to separate them in the ideal way that the simple thought experiment would imply. Even without interdiffusion, it is frequently found that joints break parallel to, but not precisely at, the interface. Many experimentalists have detected at least one of the materials on *both* sides of the division following separation (Ref 5).

When the environment includes a condensable vapor, an additional contribution to the adhesion between two solids occurs from an effect known as capillary condensation. Liquid condenses (as long as the contact angle is less than 90°) to form a bridge wherever the gap between the solids is small. Curvature of the liquid-vapor meniscus results in a negative Laplace pressure in the liquid, which acts as a cohesive force that holds the solids together. The magnitude of this force depends on the relative vapor pressure of the liquid, and on the geometry of the solids (Ref 3, 6). In some situations, this is the predominant factor in adhesion.

Measuring Surface Forces

Instrumental Requirements. This section discusses measurement of the surface forces previously described as "long range." However, the forces are weak and very short-ranged when considered on a laboratory scale. Typical forces range from 10^{-7} to 10^{-4} N, acting at surface separations from 1 to 100 nm. Therefore, measuring them is not a trivial matter. The magnitude of the forces increases with surface area (or, as shown below, with the radius of curved surfaces). Thus, in order to have measurable forces, it is desirable to have extended areas of surface. At the same time, to make sensible measurements of surface separation on a nanometer scale, it is necessary for the surfaces to be extremely smooth. A method of detecting small forces is required, as are methods of controlling and measuring very small surface separations.

Techniques. Although surface force measurements have been made for several decades, the inherent difficulties of surface preparation and cleanliness limited the number of materials studied and the amount of data to a small level, until about 1970. A review of the field up until 1982 is provided in Ref 7. Currently, the most popular technique is the crossed-cylinder apparatus devised by Tabor (Ref 8) and further developed by Israelachvili (Ref 9). This technique uses a surface force apparatus (SFA), which is commercially available.

The SFA consists of a closed stainless steel chamber designed to enclose a variety of liquid or vapor media, and is usually operated ambient temperature and pressure. Force is measured between two cylindrical surfaces, with the axes of the cylinders at right angles to each other (Fig. 1). The reason for choosing this geometry is one of experimental practically. If two planar surfaces were to be used (as one might have supposed), then there would be extreme difficulties in forming surfaces of sufficient flatness, mounting them exactly parallel, maintaining parallelism while moving the surfaces together or apart, and avoiding edge effects, all while working on a nanometer scale. As shown in the next section, "The Derjaguin Approximation," it turns out that there is no difficulty in interpreting the forces measured in this odd geometry, because

there is a simple relationship between the force measured between crossed cylinders and the energy of interaction between flat surfaces.

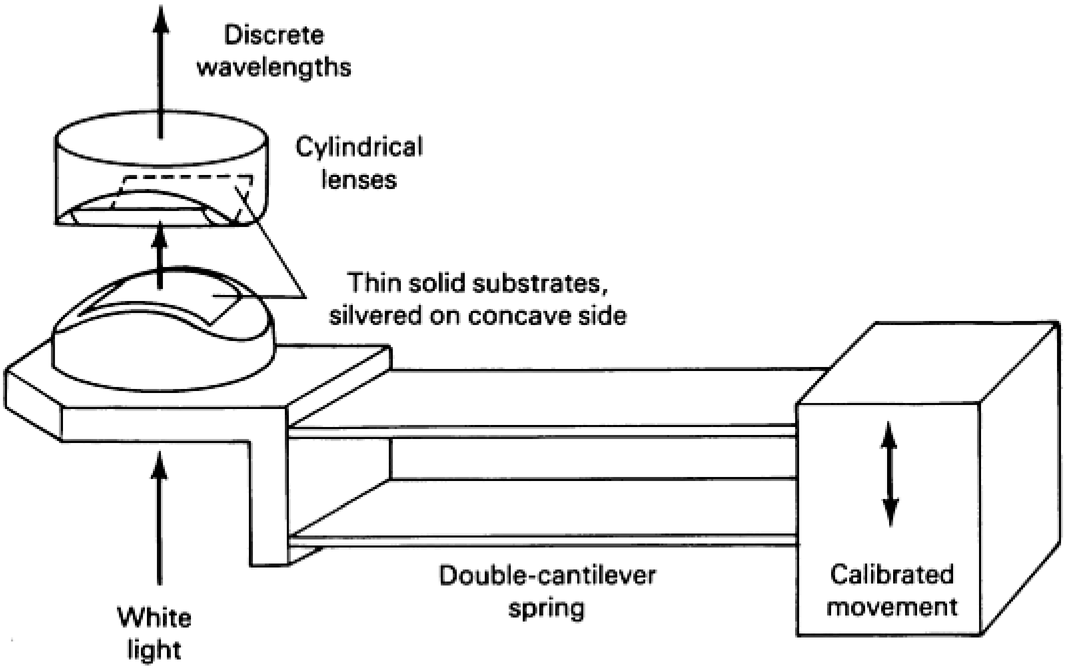

Fig. 1 Surface force apparatus, in which two thin solid substrates are mounted as crossed cylinders, with one of them supported by a cantilever spring whose deflection measures the force. An optical interferometric technique is used to measure the distance between the surfaces.

In order to measure surface separation, the SFA employs an optical interference technique (Ref 9, 10, 11). Under optimal conditions, this gives a resolution of 0.1 nm or better. Of course, one drawback is that it places a limitation on the solid materials that can be investigated, namely, that at least one of the pair whose surfaces approach contact must be transparent and rather thin (ideally, a few μm). As discussed further in the section "The Pull-Off Force," most of the measurements made with this apparatus have been made with thin foils of mica bent around and glued to cylindrical glass lenses.

To implement the optical method, a 95% reflecting silver layer is coated on the outer (that is, remote) surface of each solid substrate. Collimated white light is shone through the two substrates and whatever medium separates them (Fig. 1). Multiple-beam interference between the two silver layers selects only certain wavelengths of light, which are passed by the interferometer. All other wavelengths interfere destructively and are not transmitted. The transmitted light is collected and directed to a grating spectrometer, which spreads it according to wavelength, so that discrete wavelengths appear at the exit port of the spectrometer as spatially separated fringes of equal chromatic order.

The wavelengths depend on the thicknesses and refractive indices of the materials that are included in the interferometer: usually, the two transparent substrates and whatever fluid medium is between them. Measurement and analysis of the wavelengths allow computation of these thicknesses (Ref 10, 11). Because the two solids are of fixed thickness, those values can be subtracted from the total to give the thickness of the intervening medium, that is, the separation, D between the inner (adjacent) surfaces of the solids at their closest point of approach.

The zero value of separation is defined in practice as the position that the two solids come to, under the influence of an adhesive force (and without external load). This is a sound operational definition of $D = 0$, but it begs the question of precisely where the solid surfaces are with respect to each other. In many situations (for example, surfaces brought into contact in air), it is probable that one or more layers of adsorbate molecules remain trapped between the surfaces.

The interferometer must have a minimum thickness in order to give transmitted wavelengths in the visible region of the spectrum, but should also be rather thin to give a high resolution in measuring thickness changes. In practice, optimal

resolution is obtained when the total thickness (between the silver layers) ranges from about 3 to 10 μm (120 to 400 μ in.).

The surface force that one solid substrate exerts on the others is measured by a simple spring-deflection method. One solid is mounted on a cantilever spring, the remote end of which is moved up or down using a three-stage drive mechanism. The first stage is a micrometer that allows coarse positioning of the surfaces from a separation of a few mm to a few μm. The second stage is a micrometer that acts through a differential spring mechanism, which reduces the motion a thousand-fold, allowing positioning to approximately 1 nm. Finally, voltage applied to a piezoelectric tube expander gives positioning to a fraction of 1 nm.

After calibrating the drive mechanisms, it is straightforward to monitor any differences between a movement of the remote end of the spring and the distance moved by the end that bears one of the solids. This difference corresponds to a deflection of the spring. Multiplying it by the spring stiffness (typically 100 N/m, or 7 lbf/ft) gives the increment in force resulting from the movement. Because both the calibration and the movement of the solid are measured with a resolution of ~0.1 nm, it is possible to measure very small force changes (10^{-7} to 10^{-8} N) using this technique.

The Derjaguin Approximation. The force, F_c, between two gently curved surfaces is proportional to the interaction energy per unit area, E_f, between two flat ones at the same separation. This relationship, known as the Derjaguin approximation, allows straightforward interpretations to be made of surface force measurements between crossed cylinders (or between one sphere and another or between a sphere and a flat plate). It is also helpful in certain adhesion measurements, as described below.

The Derjaguin approximation is derived (see Ref 3, for example) by considering the force between each element of one curved surface and each element of the other, and then integrating over the two surfaces to obtain the total force. As long as the radius of curvature is much larger than the range of the surface force, this is approximately equivalent to integrating the force per unit area, F_f, between flat surfaces, from the minimum separation of the curved surfaces, D, to an effectively infinite upper limit, with some geometrical factors to account for the shape of the surfaces. The integral simply gives the interaction energy between flats, $E_f(D)$, which is the work done against the surface forces in moving the flat surfaces from infinity to D. For two spheres of radius R_1 and R_2, the geometrical factor is a constant, giving

$$F_c(D) = 2\pi R E_f(D) \quad \textbf{(Eq 4)}$$

where $1/R = 1/R_1 + 1/R_2$. It can be shown that the geometry of crossed cylinders of equal radii, R_c, is equivalent to a sphere of radius R_c approaching a flat plate, or to two spheres of radius $2R_c$ approaching each other.

The Pull-Off Force. A special case of the Derjaguin approximation occurs when two rigid curved bodies are in contact at a point, that is, $D = 0$. In this situation, the force between them is $2\pi R E_f(0) = -2\pi R W_{SF}$, because (from Eq 1), $E_f(0)$ is just $-W_{SF}$. This is also the magnitude of the minimum force required to separate the sphere from the plate, which is called pull-off force, F_p. (The pull-off force has the opposite sign as that of the surface force: $F_p > 0$ when there is attraction.)

Substrate Materials. As indicated above, the original and still most common solid material used in surface force measurements is mica, chosen because it satisfies the requirements (thin and transparent) of the optical interference technique used in the SFA and because it is easy to prepare large areas of molecularly smooth surface by cleavage. Experiments have been conducted on mica surfaces immersed in many different liquid and vapor environments (Ref 4).

Recently, there has been some success in extending these measurements to a wider range of surfaces. One approach is to coat mica surfaces by various techniques, including Langmuir-Blodgett deposition, surfactant or polymer adsorption from solution, plasma modification, and evaporative coating of thin metal, carbon, and metal-oxide films. An alternative approach is to find a means of preparing other transparent materials as micron-thick foils with very smooth surfaces. This has now been done for sapphire, silica, pyrex glass, and certain polymers. It is reasonable to expect that the range of materials studied will continue to increase in the near future.

Currently, the best way to prepare metal surfaces for the SFA appears to be thin-film evaporation onto mica or another smooth substrate. Because the optical technique requires some light to pass through the two films, their thicknesses cannot be more than a few tens of nm. It is possible to use the metal films themselves as one or both optical interferometer mirrors, but the fringes of equal chromatic order would disappear from the visible spectrum if the two

metal surfaces were brought closer together than about 1 μm (40 μin.). In that case, an alternative method of measuring separation, such as capacitance, would be required.

Environments. Experiments in the SFA can be conducted in many different liquids or vapors, as long as they are compatible with the materials of which the SFA is constructed, namely, stainless steel, silica, Kel-F, and Teflon. There is a provision to heat the chamber to around 100 °C (212 °F). Use of an appropriate heating jacket could extend the temperature range from, perhaps, -50 to 150 °C (-60 to 300 °F). At about 150 °C (300 °F), the silver layers used for interferometer mirrors degrade. This limit might be raised by using other optical coatings. The next limitation of the current design would be the maximum operating temperature of the Teflon seals, which is 250 °C (480 °F). In principle, the same or comparable techniques could be extended to operate at several hundred degrees, but, in practice, this would require a major redesign of the apparatus.

At present, the SFA is intended only to operate at or near ambient pressure. With some modifications to the seals it could be made to hold moderate vacuum, say 10^{-4} Pa (10^{-6} torr). A total redesign would be required to build a device for making comparable measurements in ultrahigh vacuum (UHV) conditions.

Preparation of Surfaces and Fluids. The first characteristic required of any solid to be investigated in the SFA is surface smoothness. This means that the solid should be smooth, compared to the range of forces of interest, if one wishes to interpret the results in a meaningful way. For van der Waals forces, this may be a few nm. For forces mediated by adsorbed polymer layers, this may be few tens of nm. For electrical double-layer forces inn water, this may be hundreds of nm. Electrostatic forces between charged surfaces in nonpolar liquids or vapors may extend for several μm.

Because the adhesion between surfaces is often dominated by very short-range forces, atomically smooth surfaces would be required to make fundamental and reproducible measurements of these. However, rough surfaces still adhere, and so measurements can be made without insisting on atomic smoothness. The drawback, in that case, is that it would be more difficult to obtain a straightforward interpretation of the results.

It is not difficult to understand that if one wants to measure surface forces between ultra-smooth, extended surfaces separated by a small number of nanometers, there are stringent requirements for cleanliness, both of the surfaces and of the environment. One speck of dust in the wrong place can spoil it all. The importance of surface cleanliness is again related to the range of force under investigation. For very short-range forces, even a monolayer of adsorbed vapor will dramatically influence results.

Considerable care must also be taken in preparing any liquid or vapor environment. Vapors must be free of dust, and liquids must be free of both particulate and molecular (for example, polymer or surfactant) contamination that can easily adsorb to solid surfaces and affect the results.

Other Measurements with the SFA. The techniques embodied in the surface force apparatus can be used to measure other properties of thin liquid or vapor films and solids at or near contact. These properties are described below.

Adsorption. The thickness of an adsorbed layer of surfactant or polymer can readily be determined by the change in surface separation before and after adsorption occurs. Compressibility of an adsorbed layer can also be measured.

Refractive Index. The optical interferometry technique can be used to measure the refractive index of very thin liquid films or adsorbed layers (Ref 10).

Viscosity. Measurement of the force when the surfaces are in relative motion allows a determination of the viscosity of ultrathin liquid films in a squeeze-film geometry (Ref 12) or simple shear (Ref 13).

Friction. A straightforward extension to lateral force measurements allows the friction between two molecularly smooth solids to be measured under controlled loads and well-determined surface separations and contact areas (Ref 14).

Atomic Force Microscopy

Following the invention of the scanning tunneling microscope (STM), which is described in a separate article by that name in this Section of the Volume, Binnig, Quate, and Gerber (Ref 15) devised an instrument which they dubbed an atomic force microscope (AFM). This instrument barrows elements from both the SFA and STM, in order to measure very small forces between a sharp tip and a flat surface (Fig. 2). Resolution in force is currently 10^{-11} N or better. Surface-

tip distances are resolved with a resolution as fine as 0.01 nm, and lateral distances along the surface are measured, typically, to 0.1 nm (see Ref 16 and the references therein). AFMs are now commercially available from a number of sources.

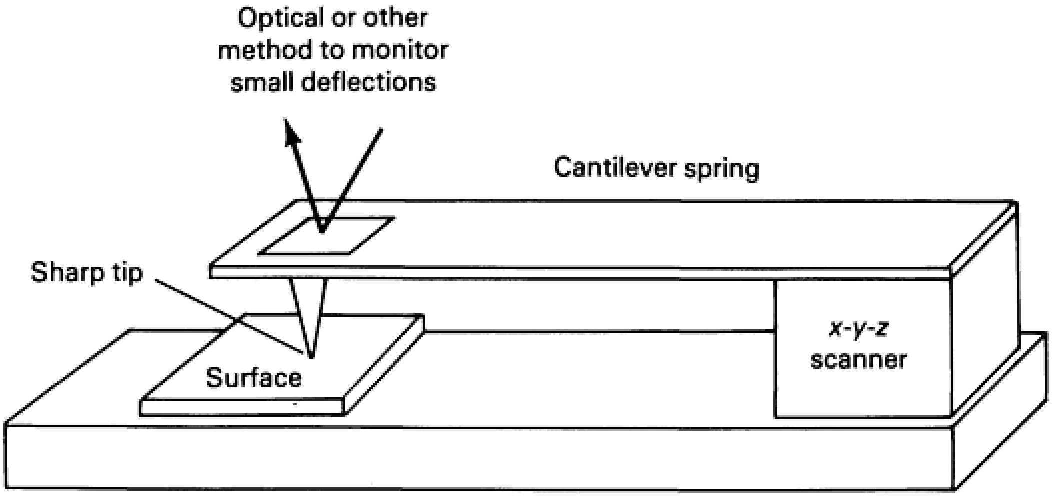

Fig. 2 Atomic force microscope, which measures the force between a sharp tip and a flat surface

Like the SFA, the AFM determines force by measuring the deflection of a cantilever spring, to which the tip is mounted. Several ingenious methods of measuring or monitoring extremely small spring deflections have been devised. The original AFM (Ref 15) used an STM tip at the back of the cantilever spring to monitor tiny movements of the spring. More recent versions have used optical interferometers or optical levers to amplify very small deflections.

The major use of the AFM to date has been as a method of obtaining atomic- or near-atomic-resolution images of surfaces that do not need to be conducting (in contrast to STM experiments). Much less work has been done on obtaining quantitative force measurements, although progress in this area is accelerating (Ref 17). In terms of measuring surface forces, the AFM has some advantages and some disadvantages, compared to the SFA technique described above.

The main advantage is the ability to measure forces between a tip and a very small region of the surface, so that surface inhomogeneities (including roughness) can be explored. A second advantage is that local surface imperfections or contamination (for example, a dust particle) can be avoided by moving to another region. In addition to forces measured out of contact, surface mechanical properties can be explored by using the AFM as a tiny indentation machine. Finally, the restrictions on materials are much less severe. Experiments could be conducted using any solid surface and any material from which a very sharp tip can be fashioned.

The major disadvantage of the AFM is that interpretation of the force is much more difficult between a tip and a surface than it is between two extended surfaces. Theories of surface forces in the tip-surface configuration are difficult at best, because the tip may be too small for continuum models to be appropriate, and too large for complete atomic calculations to be feasible. Furthermore, a proper theory would require a detailed knowledge of the tip shape and/or atomic structure, and this is rarely available. However, the field is progressing rapidly, and significant advances can be expected in the near future. There is already one impressive example of an atomic-scale computation that reproduces the features of an AFM experiment (Ref 18).

Measuring Adhesion

In light of the previous discussion, two views can be taken of adhesion measurements. One view is that to properly understand the forces and bonding that determine adhesion, an extremely careful experiment is required. This could be designated as a fundamental adhesion measurement, and the idea would be to match as closely as possible the thought experiment described in the section "Basic Concepts." For the reasons elaborated below, an exact match would be very difficult to achieve in practice.

On the other hand, adhesion is known to occur quite commonly in the real world between rough and comparatively dirty surfaces. Therefore, another view is that a practical adhesion measurement can be made if one simply wants to quantify the work of adhesion in a given engineering situation. If that is the case, then the measurement is somewhat easier than the surface force and atomic force experiments described above, because a single, comparatively large force is measured, and because surface separation does not need to be ascertained with any precision. However, even practical adhesion measurements present difficulties, because the results are very sensitive to the manner in which the two bodies are separated. These difficulties have precluded the establishment of standardized adhesion tests applicable to a wide variety of situations.

Indeed, there are so many variations on adhesion measurements (see, for example, Ref 19 and 20) that it would be impossible to describe them all fully here. Instead some general considerations are discussed, with the aim of helping readers establish sensible tests for their own particular purposes.

Fundamental Adhesion Measurements. From the earlier discussion, it is already apparent that the concept of work of adhesion includes considerable subtlety and difficulties, even in the thought experiment outlined there. Although one can blithely talk of "reversibility" in a thought experiment, that notion is particularly problematic in practice. In real adhesion measurements, processes such as surface reconstruction, interdiffusion, adsorption, chemical bonding, and either viscous or plastic flow (Ref 5) are all likely to be irreversible. This makes it very difficult to establish an unequivocal correspondence with the theoretical work of adhesion.

An ideal adhesion measurement would require a well-defined interface between two perfectly clean and atomically flat surfaces, with no adsorbate, and no interdiffusion of the two materials. The two surfaces would then need to be separated infinitely slowly in a controlled environment. These tasks would be difficult to accomplish. With these cautions in mind, the ways to conduct idealized experiments that are currently most practicable are discussed next.

Adhesion Between Curved Surfaces. To avoid problems associated with the mode of separation of two bodies (discussed further below), "fundamental" adhesion measurements can be conducted by separating two solids having curved surfaces. Examples include two spheres, a sphere and a flat, or crossed cylinders. As noted in the section "The Pull-Off Force," it is possible to make a simple association between work of adhesion (or at least, that part of it due to surface forces, W_{SF}) and the pull-off force, F_p that is the minimum tensile force required to completely separate the bodies:

$$F_p = 2\pi R W_{SF} \quad \textbf{(Eq 5)}$$

This relationship, sometimes called the DMT expression (Ref 21), is appropriate for rigid bodies that do not deform significantly upon contact. When the bodies are not completely rigid, adhesion between two curved bodies deforms them (elastically and/or plastically), and the contact point expands to a finite contact area. It was shown by Johnson, Kendall, and Roberts (JKR) (Ref 22) that if one or both of the bodies is deformable elastically, stored elastic energy is recovered in the pull-off process, and the force required for pull-off is reduced to

$$F_P = \frac{3}{2}\pi R W_{SF} \quad \textbf{(Eq 6)}$$

For example, determinations of W_{SF} have been made by measuring the pull-off force between rubber spheres (Ref 22), polyurethane, and glass (Ref 23), and crossed cylinders of mica (Ref 24), as well as measurements of the dependence of pull-off force on the relative orientation of two mica sheets (Ref 25).

If one (or both) of the solids is plastic, energy is lost during the deformation that occurs upon contact, and it is not recovered during separation. In fact, when clean metal surfaces come into contact, the surface forces alone are sufficiently strong to cause plastic deformation (Ref 26), and the simple elastic theory no longer applies. In that case, the pull-off force required to separate the bodies is greater than the JKR value (Eq 2); no upper limit can be specified.

Fracture Experiments. The well-known Griffith criterion for fracture of a monolithic brittle material equates the fracture threshold (measured as the "strain-energy release rate," or the stored elastic energy recovered as new crack is propagated through unit area) to the work of cohesion. In fact, a carefully conducted fracture experiment is as close as one can get to the ideal thought experiment described in the section "Surface Energy." If an experiment can be arranged so

that a brittle crack is propagated along the interface between two different materials, then the fracture threshold is the work of adhesion. This can be done for various material combinations, including adhesive joints and coatings (Ref 1, 19).

There is, in fact, a close analogy between brittle fracture experiments and the pull-off experiments using curved elastic bodies discussed in the preceding section. The JKR theory of pull-off (Ref 22) was derived from a fracture mechanics argument very similar to the original Griffith argument, balancing mechanical work and stored elastic energy against the interfacial energies involved in creating new surfaces. If sufficient care is taken in conducting either experiment, and attention is given to the considerations discussed below, then there is little, in principle, to choose between the two methods. The best grounds for choice would have to do with sample preparation and geometry. In particular, is it easier to prepare the requisite specimens in a curved shape or as flat, mated surfaces suitable for a fracture experiment?

History Dependence and Sample Preparation. As discussed previously, the quantity called the work of adhesion, that is, the work required to separate two bodies from contact to infinity, is a sensitive function of just where the "contact" is and the structure of the interface. Questions that need to be addressed include: Have the two solids really come into interatomic contact? Are the surfaces clean? Have they reconstructed? Have the solids annealed, cold-welded, or interdiffused? Is there still adsorbate trapped between them? What are their crystal orientations?

The answers to these questions partly depend on the properties of the two materials and their environment, and partly on the manner in which they have been prepared and brought into contact. Careful consideration must be given to these factors before meaningful and reproducible results can be obtained.

If the aim is to conduct an ideal adhesion measurement, then the two materials and any liquid or vapor environment in which the test is carried out must, at the very least, be scrupulously clean. If the aim is to design a test to measure adhesion in order to predict failure in a real engineering situation, the test conditions should be carefully chosen to match those that pertain to the real world. The adhesion measured between a given pair of metals under UHV conditions at room temperature, for example would have little to do with the adhesion that may occur between the same metals in a lubricated bearing operating at high temperature.

Rate-Dependent Effects. In many real situations, it is found that the force required to effect pull-off or crack propagation in separating two bodies depends on the rate at which the separation occurs. Rate-dependent effects can arise from viscoelasticity of one or both of the solids, viscosity of the environment, or diffusion-limited adsorption of environmental species to the newly created surfaces and possible chemical reaction with those surfaces. Generally, rate-dependent effects are always associated with dissipation of energy. Therefore, the work required to separate the bodies at anything other than infinitesimal speed is greater than the true work of adhesion.

The question of viscoelasticity in one or both of the solid bodies has been carefully examined by Greenwood and Johnson (Ref 27) and by Maugis and Barquins (Ref 23). The pull-off force becomes dependent on the rate at which it is applied, with the true pull-off force only being determined when the load is increased extremely slowly and when a very long time is allowed for the pull-off to occur. Because more rapid separation requires more force, measurements are likely to give an overestimate of the equilibrium value.

Rate effects can occurs for other reasons. For example, in some cases it takes a long time for molecules from the environment to equilibrate with the freshly exposed surfaces as a crack propagates or as the contact area between curved bodies decreases before pull-off occurs. This is well-known in the fracture mechanics field as environmentally assisted, or "slow," crack growth. Once again, unless the load is increased extremely slowly to the fracture threshold or to pull-off, the work of adhesion would be overestimated. To indicate the meaning of extremely slow, the load required to propagate a crack in glass in a humid atmosphere has been shown to be rate-dependent at crack speeds as low as 10^{-13} m/s (4×10^{-12} in./s). Ideal adhesion measurements could require some patience.

Practical Adhesion Measurements. There are many existing tests of adhesion that operate in a variety of geometries and modes of separation (Ref 1, 19, 20). A number of them are either empirical or semiempirical. Others give only a comparative test of adhesion, such as whether the adhesion between a thin film and a substrate is greater or less than the adhesion between Scotch tape and the film. There is a need for better-controlled and better-understood adhesion measurements, even at the practical level.

Practical adhesion tests involve applying a known stress to a joint or interface to determine when it fails. Failure is not always undesirable, as in the case where adhesion contributes to unwanted friction and wear. Stress can be derived from mechanical (including ultracentrifugal and ultrasonic), thermal, optical, and electromagnetic sources (Ref 20).

Apart from the difficulties outlined above, there is another complicating factor in the quest to measure the strength of an adhesive bond between two bodies. It is a common experience that the force required to separate two bodies with mating surfaces depends very much on the manner in which they are separated. For example, two microscope slides held together by a thin film of moisture are extremely difficult to separate in simple tension or even by wedging them apart, whereas they separate easily in shear. The reason for this lies partly in the fact that the work of adhesion can be done by applying a large force over a small distance (uniform tension) or a small force over a large distance (as in peeling or sliding), and partly because the fracture threshold actually depends on the mode of separation, such as tension versus shear. An adhesion test carried out in one mode might reveal little about failure in another.

Modes of Separation. Various arrangements that can be employed in adhesion tests are illustrated in Fig. 3. Detailed discussions of these can be found in texts such as Anderson *et al.* (Ref 19).

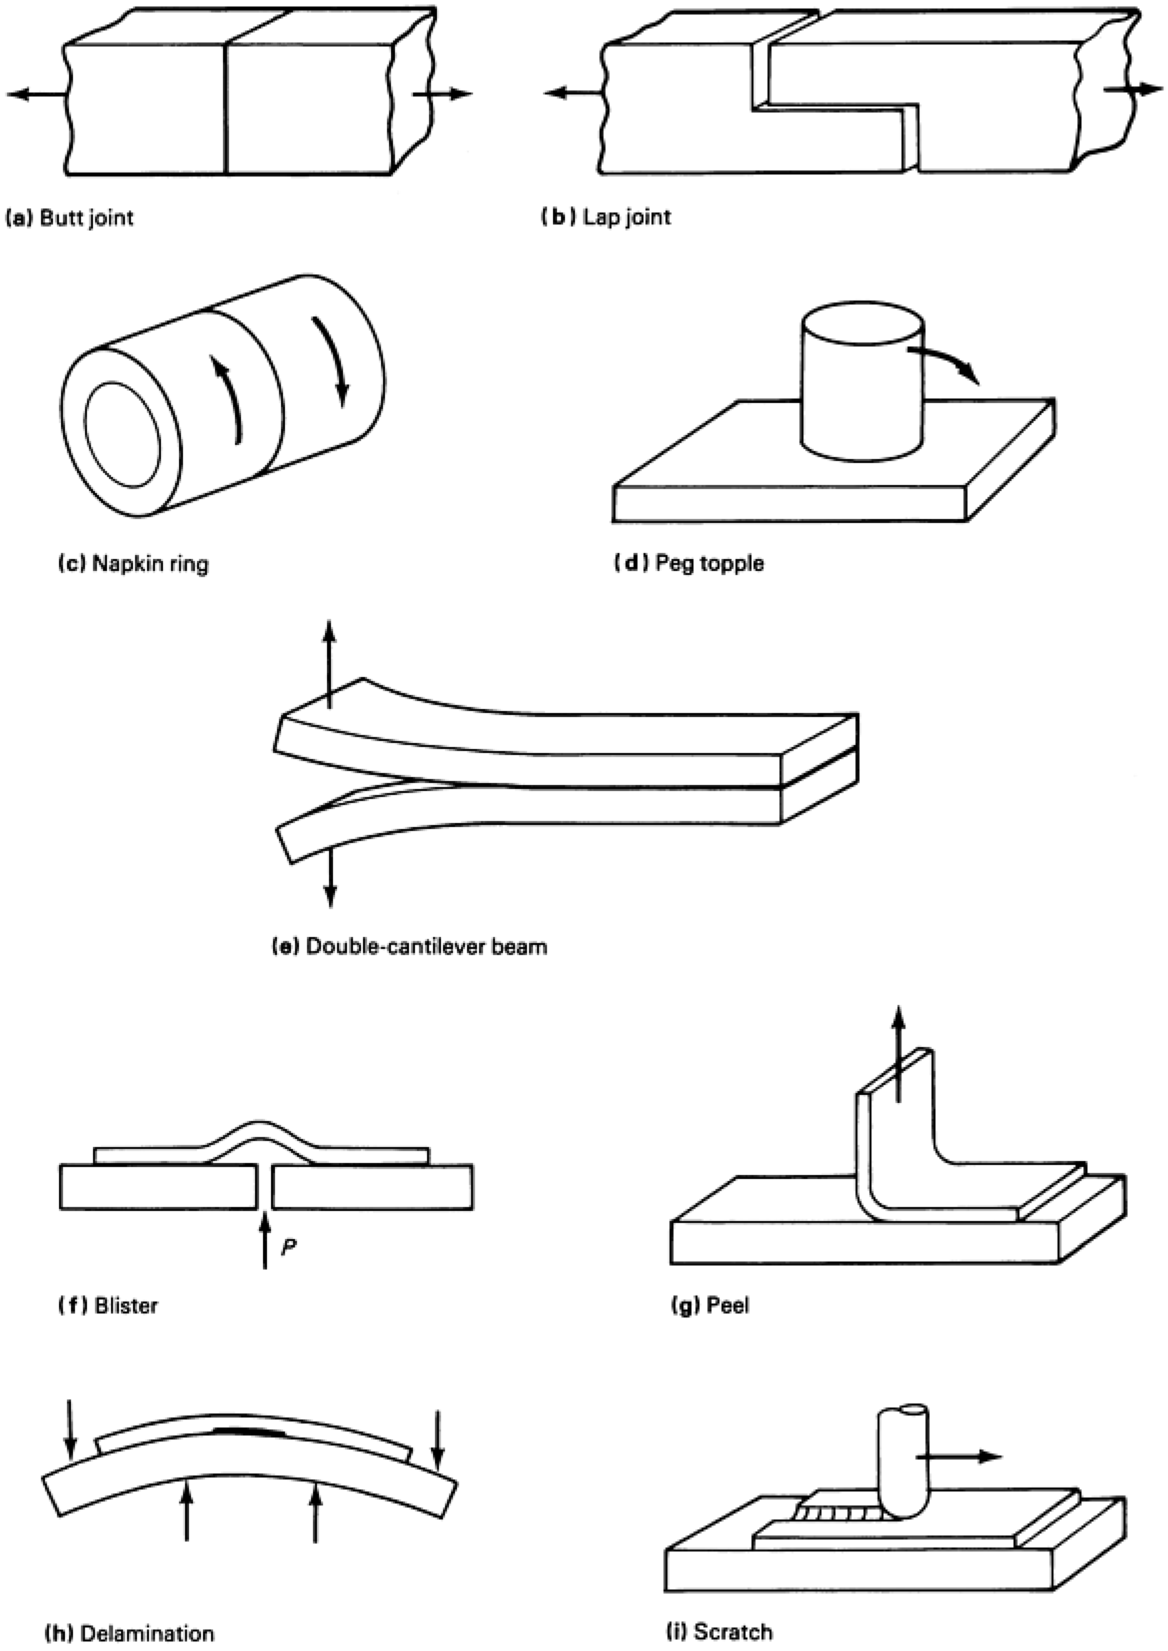

Fig. 3 Various arrangements for adhesion tests

For voluminous bodies (as opposed to films or coatings), the most obvious arrangement is the butt joint (Fig. 3a). Although it may look simple, the ease of fracture or failure can depend strongly on the presence of flaws in the joint, and on how and whether a crack/separation is initiated at the edges of the sample. A lap joint (Fig. 3b) is appropriate to test

shear strength, for example, in laminates. Care must be taken to avoid excessive bending of the beams during the test, because that introduces some tensile component. The ring shear, or "napkin ring," test (Fig. 3c) applies a more uniform shear stress to the joint, whereas the peg topple test (Fig. 3d) is closer to ideal tension, but not straightforward to analyze.

The double-cantilever beam geometry (Fig. 3e) provides an excellent fracture mechanics type of test if suitable samples can be prepared. A clever variation on this is to profile the beams in such a way that the fracture threshold is independent of the length of the crack (Ref 28), making the analysis very simple.

The tests described above are most commonly applied to testing of adhesive joints (bodies glued together with an adhesive), although they can also be used for "pure" solid-solid adhesion tests if samples can be prepared with their surfaces accurately mated together. This raises questions of surface roughness. Unless the surfaces are atomically smooth and their shapes conform precisely, the true area of contact will be less than the geometrical area of contact, and the interface will include unbonded flaws, which will serve to initiate failure. Indeed, most "flat" contacts actually involve only 8 to 50 areas of true atomic contact.

When thin films, thick films, or coatings are involved, there is another set of test geometries that can be utilized. The peel test is very common, with the force applied at various angles, not just the 90° angle shown in Fig. 3(g). Blister and delamination tests (Fig. 3f and h) can be very well controlled, and properly analyzed in terms of fracture mechanics (Ref 19, 29). The scratch test (Fig. 3i) is much more difficult to analyze, but it at least has the merit of being the only one of these configurations that tests adhesion under dynamic sliding conditions.

State of the Art

It is now possible to make accurate and well-characterized measurements of surface forces at long range, that is, surface separations from 0.5 to 100 nm, in a range of environments, and between an increasing number of materials, including mica, sapphire, glasses, metal films, and certain polymers. Information on forces between molecules and surfaces can often be gleaned by detecting adsorbed layers using the same techniques. The experiments are by no means trivial or routine, because they require a specialized, unautomated apparatus, and they are fraught with difficult problems of surface preparation and cleanliness.

Most of the measurements to date have been made at ambient temperature and pressure. They could conceivably be extended to higher temperatures and lower (or higher) pressures, but this would require some design modifications, which would add to the experimental difficulty.

Adhesion measurements present a different set of problems, because the work of adhesion is so sensitive to the precise state of the surfaces in contact and to the manner in which those surfaces are separated. The experimentalist must think carefully about exactly what he or she wishes to measure. On the one hand, fundamental measurements of adhesion under ideal conditions are inherently difficult because of the problems of obtaining perfectly clean surfaces in anything other than UHV conditions. On the other hand, more practical measurements of adhesion as it pertains to real-life applications depend very much on the mode of separation of two surfaces, making it difficult or impossible to design a single test that is appropriate for a variety of different situations.

Nevertheless, it is perfectly feasible to design adhesion tests for particular aims and applications. It simply must be accepted that the results of one test cannot easily be transferred to another situation, and this, for the time being, remains the state of the art.

Characterization of Surfaces by Acoustic Imaging Techniques

W. Arnold, U. Netzelmann, and S. Pangraz, Fraunhofer Institute for Nondestructive Testing (Federal Republic of Germany)

Introduction

SCANNING ACOUSTIC MICROSCOPY (SAM), high-frequency acoustic imaging (HAIM), and scanning laser acoustic microscopy (SLAM) are based on the interaction of high-frequency acoustic waves with the sample material. The contrast of acoustic images is primarily determined by the elastic properties of the object under investigation. Because acoustic waves can also penetrate opaque materials, it is possible to image internal structures of the sample, to look for defects, to evaluate homogeneity, and to gain information on elastic parameters. These properties make acoustic microscopy and high-frequency acoustics important tools for nondestructive evaluation (NDE) and materials characterization. Acoustic imaging at low frequencies ($\leq$10 MHz) is generally used for defect detection--an application of great practical importance. Whereas theories underlying acoustical imaging comprise both regimes, imaging at higher frequencies reveals more details about the microstructure, because scattering, absorption, and dispersion caused by defect agglomerates, second phases, dislocations, inhomogeneities, and plastic deformation become more significant. This can be exploited in materials science and technology.

Various types of commercial and experimental equipment on the market are suitable for this task. The SAM microscope is the analog of the optical microscope, because it uses focused waves (Ref 1, 2) covering the frequency range from 100 MHz to 2 GHz. HAIM equipment operates in the frequency range from 10 to 100 MHz and is generally employed to characterize advanced materials where small defects are to be detected (Ref 3). In SLAM, plane ultrasonic waves traveling through the sample (with a frequency ranging from approximately 30 to 500 MHz) are used for imaging (Ref 4). By scattering and absorption, the internal structures of the sample modify the sound field according to their elastic and geometric properties and thus can be made visible. This article presents typical examples of applications for the three types of instruments, outlining the physics of the contrast mechanism and the applications for these instruments in materials science, NDE, and tribology.

Scanning Acoustic Microscopy

Principles of SAM

In SAM, a focused ultrasonic beam is used for imaging. Two types of SAMs are commonly used: transmission mode and reflection mode. In commercial models, the reflection mode is dominant. Its working principle is shown in Fig. 1. The ultrasonic beam is excited by a transducer such as a ZnO film sputtered on the plane surface of a sapphire delay rod. On the opposite side of the delay rod, a spherical curvature is carved into it with high precision. The ultrasonic beam is then refracted by the curvature and is focused onto the surface of the sample to be examined, provided a coupling medium is used whose sound velocity (v_{Lc}) is smaller than that of sapphire (v_{Ls}), a material often used as a delay rod (v_{Ls} = 11.2 mm/μs). Distilled water is usually used as coupling medium (v_{Lc} = 1.5 mm/μs). The sapphire delay rod is cut into the *c*-direction because the ultrasonic absorption is extremely small in this material, and in particular in this direction. It is possible to propagate ultrasonic waves in sapphire of $\leq$4 GHz frequency at room temperature with an acceptable signal/noise ratio.

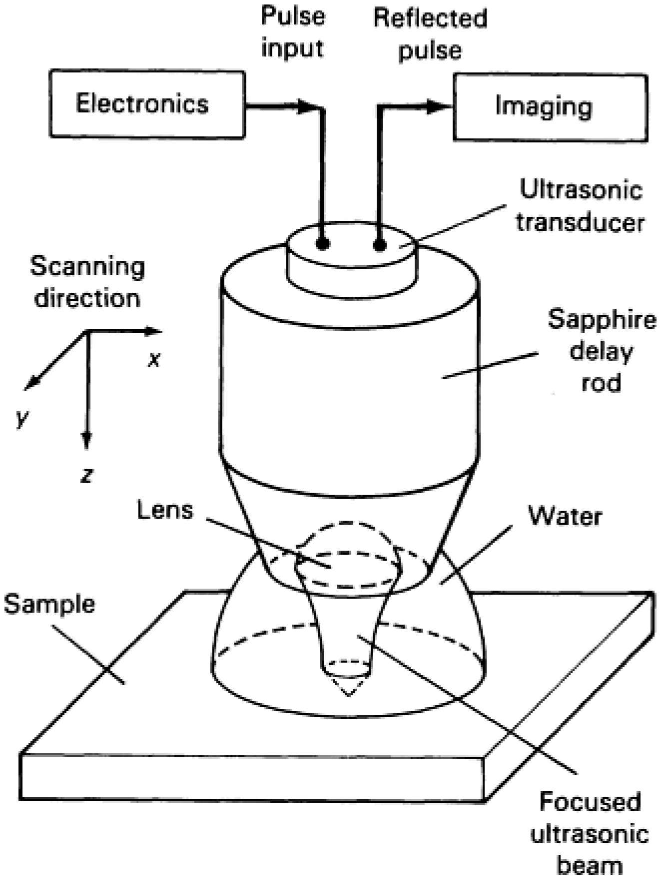

Fig. 1 Schematic showing key components of the SAM. The spherical interface between the sapphire rod and the coupling medium (usually water) acts as a lens with a large refractive index (~7.5) for ultrasonic waves traveling down the delay rod. The focused ultrasonic beam is reflected back into the lens, and an image is built up by scanning the lens in the *x*- and *y*-direction and displaying a signal on a screen proportional to the amplitude back-reflected.

The refractive index of such a one-lens system is n = 11.2/1.5 ≈7.5, much larger than that of objectives in optical microscopes. The large refractive index of the lens allows the SAM to be operated with only a one-lens objective, because spherical aberration is proportional to n^{-2} and hence is negligible in SAM. Chromatic aberration is not important, because the transducer is excited by a carrier signal with at least 10 cycles.

The focal length of an acoustic lens made of sapphire is f = 1.15r, where r is the radius of curvature of the lens. The resolution of such an instrument is approximately λ, the wavelength of sound in the coupling medium. For a frequency of 2 GHz, λ= 0.75 μm in water. Technical details such as electrical and mechanical impedance matching are important in the design and manufacture of a lens (Ref 1). The acoustic lens is scanned over the surface of the sample; acoustic energy is reflected back into the lens, is again detected by the transducer, and is converted into a radio frequency (rf) signal that is amplified, displayed on a screen, and stored in a computer after digitization. Because the signal carrying the information from the surface under inspection is time-delayed, it is gated out by a compatible electronic circuit. The reflection coefficient depends on the local elastic modulus, density, and, to a certain extent, ultrasonic absorption. Figures 2(a) and 2(b) show the images of a Vickers indentation in a metal and in a ceramic material, respectively. In the metal, the contrast change around the indentation caused by plastic deformation is visible. In the ceramic material, the cracks emanating from the corners of the indentation are clearly visible. This is because cracks disrupt the flow of acoustic energy because of the atomic disbond; that is, the crack opening displacement can be much smaller than the wavelength and the crack will still be visible.

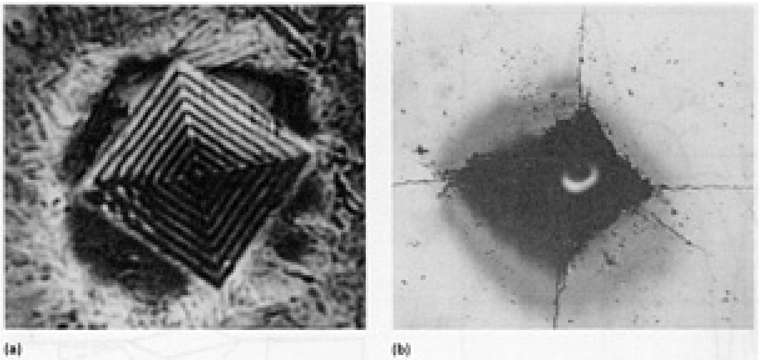

Fig. 2 (a) SAM images of Vickers indentations in two selected materials. Indentation in a steel taken at a frequency of 1.3 GHz. The change in signal surrounding the image of the indentation is caused by plastic deformation. The lines are caused by the change in contrast due to the slope of the pyramidal indentation. 913×. Courtesy of S. Ganz, Leica. (b) Indentation in SiC ceramic taken at a frequency of 1 GHz. Cracks are visible emanating from the corners of the indentation. Bulging of the material (and the possible presence of subsurface lateral cracks) changes the contrast close to the image of the indentation. 160×

There is a unique feature central to the understanding of the contrast mechanism of the SAM. The opening angle of the acoustic lenses includes the critical angle for surface-wave generation (Fig. 3). Because of the boundary condition (coupling medium instead of vacuum), the surface wave is not pure mode but rather a leaky surface wave that radiates back into the lens and interferes with all other rays. The resulting interference pattern is called a $V(z)$-curve because it becomes measurable only after defocusing the lens toward the surface by a distance z (Ref 5). The distance Δz between the maxima (or the minima) of the $V(z)$-curve is given by (Ref 2):

$$\Delta z = v_{Lc}/[2f(1 - \cos \theta_R)] \qquad \textbf{(Eq 1)}$$

with $\sin \theta_R = v_{Lc}/v_R$. Here, v_R is the Rayleigh velocity of the material under inspection, f is the operating frequency of the SAM, and θ_R is the critical angle.

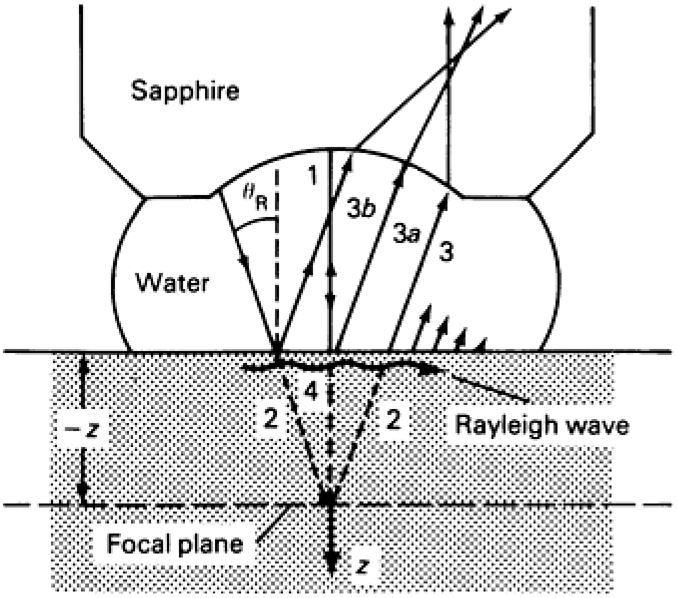

Fig. 3 Principle of Rayleigh wave generation by SAM in the framework of geometric acoustics. The ray incident under the critical angle, θ_R, generates surface waves (Rayleigh waves), because their wave fronts match one another. The central beam (ray 1) interferes with ray 3 because of their phase delay, which depends on the

actual defocus distance, *z,* thus causing the *V*(*z*)-curve. Ray 3 is caused by reradiation of the surface wave back into the water. Rays 3*a* and 3*b* do not contribute, because they are refracted such that they cannot reach the transducer. The "focal plane" is only meant for clarification of the defocus distance, *z.* In reality, the rays are refracted at the surface of the specimen under investigation.

The amount of defocusing set for the lens in a given SAM image determines the relative contrast of the features observed. Further defocusing may result in a total contrast reversal (Ref 2), considering that each given point in a SAM image exhibits a different $V(z)$-curve depending on the local elastic properties. In turn, measuring $V(z)$-curves allows determination of surface elastic modulus with a spatial resolution ranging from 5 to ~50 μm (given by the spot size of the acoustic beam at the surface), depending on the amount of defocusing and the material examined. Therefore, $V(z)$-curves are also called acoustic material signatures (AMS) (Ref 5) (see Fig. 4). In anisotropic materials, analysis of the $V(z)$-curve becomes more complicated (Ref 6). By using cylindrical lenses, it is possible to measure the Rayleigh velocity as a function of angular direction at the surface of a material (Ref 7). Finally, the scattering of the surface waves by inhomogeneities such as cracks, porosity, and inclusions is also an important contribution to the contrast in the images obtained, as can be see in Fig. 2.

Applications of SAM

Numerous applications of SAM have been reported in the technical literature that also illuminate the contrast mechanism. This discussion will be restricted to a few relevant examples regarding the use of SAM to measure the surface wave velocity, v_R.

Thin-Film Thickness Measurements. The excitation of surface waves by the acoustic lens may be exploited to measure the thickness of thin films coated on a base material (Ref 8) and to characterize their bond strength (Ref 9). The presence of a film whose elastic properties are different from those of the base material produces a composite in which the surface acoustic wave (SAW) travels and then becomes dispersive. It is possible to derive the film thickness from the measured dispersion curve, provided either a calibration curve is used or the propagation of the surface wave is modeled using the elastic data of the film and the base material (Ref 10). Continuous waves (cw) are also used to determine the velocity of SAWs via $V(z)$-curves in layered media (Ref 11). Here, a continuous change of the operating frequency allows the dispersion diagrams of several material combinations to be determined. The $V(z)$-curves obtained by cw excitation are similar to those of burst-generated $V(z)$-curves (Ref 11).

Evaluation of Surface Conditions Caused by Machining. Material topography is an important factor in the contrast of SAM images. This is caused by the phase difference of the various angular rays generated by the acoustic lens after reflection and by the phase-sensitive nature of the transducer. In fact, topography can be drastically enhanced by phase-sensitive electronic detection systems in SAM, allowing measurement of very tiny steps on a surface (less than 10 nm) (Ref 12) and the local stress distribution by exploiting the acoustoelastic effect (Ref 5, 13, 14), which describes the stress dependence of sound velocity in terms of higher-order elastic constants. Likewise, phase-sensitive detection enhances the capability of SAM for detecting small defects and cracks in machined surfaces; this process has been used for quality assurance of ceramic ball bearings (Ref 15).

Machining damage in metals alters the elastic properties of a surface layer to a depth of a few tens of micrometers. This may be caused by twinning of the crystallographic structure and by the introduction of dislocations. In turn, this lowers the surface wave velocity, which can be measured with high precision using the $V(z)$ technique. Such a measurement was undertaken in machined beryllium (Ref 5), and a 3% decrease in v_R relative to the undamaged material was observed (Fig. 4), similar to the decrease observed in wear studies of alumina surfaces (Ref 14).

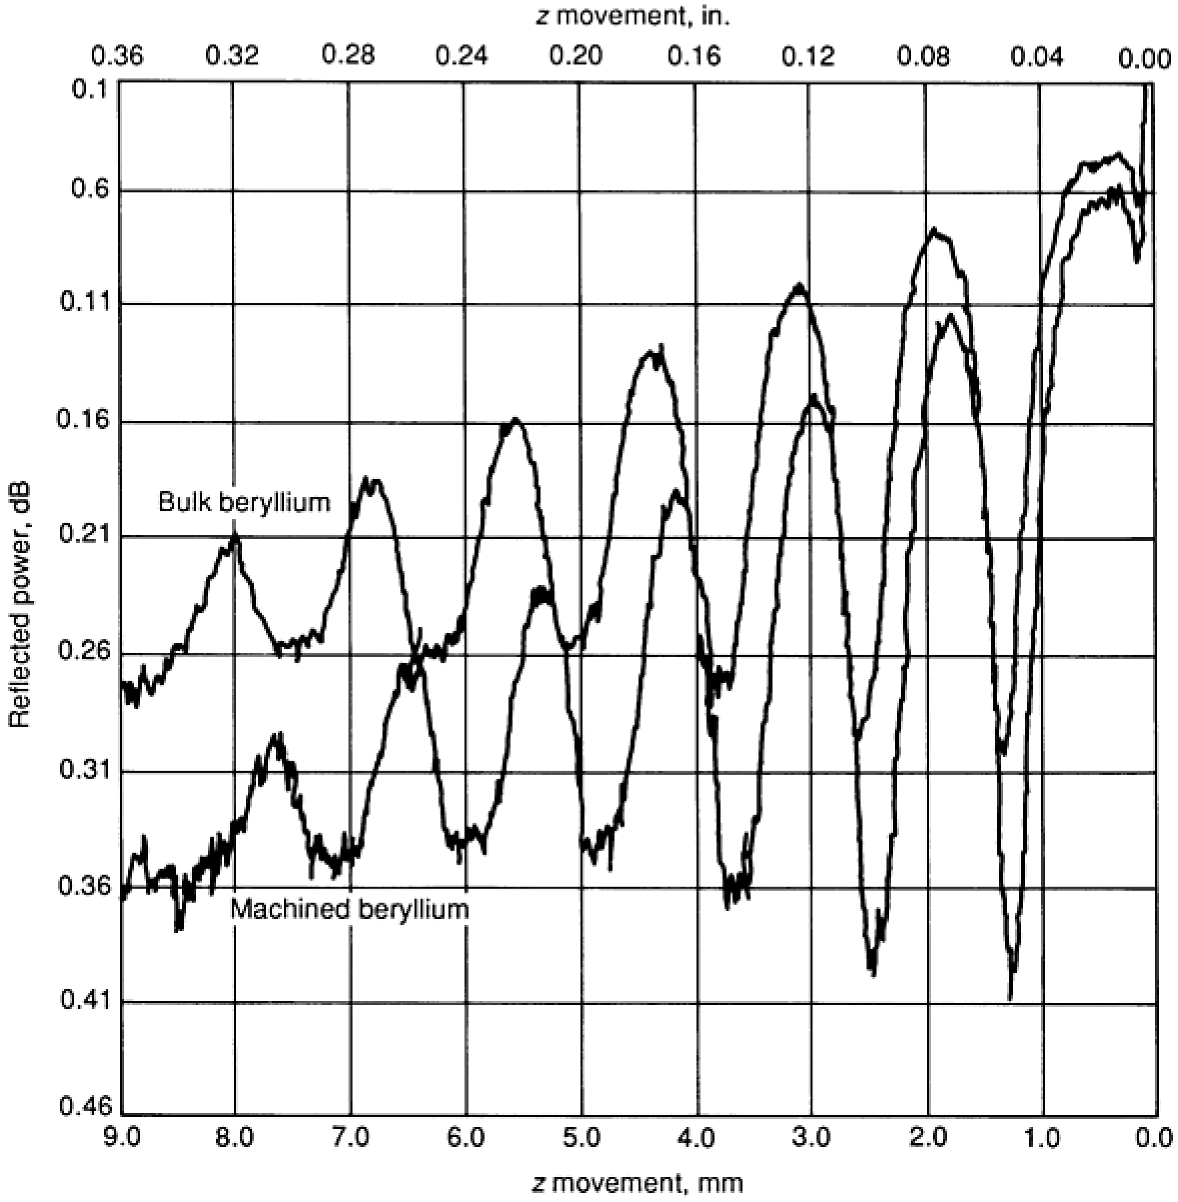

Fig. 4 *V*(*z*)-curves of machined beryllium surfaces taken at 35 MHz. The Rayleigh velocity, v_R, of the unmachined beryllium surface is 8.07 mm/μs; the v_R of the machined beryllium surface is 7.82 mm/μs. The number of maxima obtainable in a *V*(*z*)-curve depends on the ratio of the focal distance of the lens to the wavelength, λ_R, of the surface wave. Source: Ref 5

Extensive studies of damage and wear on ceramic surfaces have been carried out using SAM (Ref 16). First, the change of contrast observed in SAM images caused by the presence of subsurface lateral cracks in hot-pressed silicon nitride and steel ball bearings was examined (Ref 17) (Fig. 5(a) and 5(b)). Second, the fracture toughness, K_c, of the material was determined by measuring the lateral extent, C_1, of the contrast change close to the indentation using the expression:

$$C_1 = a\left[\frac{(E/H)^{3/4}}{(K_c H^{1/4})}\right]^{1/2} \cdot P^{5/8} \quad \text{(Eq 2)}$$

where a is a constant determined by the shape of the indenter, *E* is the Young's modulus, *H* is the hardness, and *P* is the indentation load. Furthermore, the sliding wear resistance of thin TiN films coated on a die steel was monitored by exploiting the scattering of the Rayleigh waves at surface and subsurface cracks. The onset of wearing of the TiN film as a function of the number of sliding cycles was clearly established in the SAM images (Fig. 6).

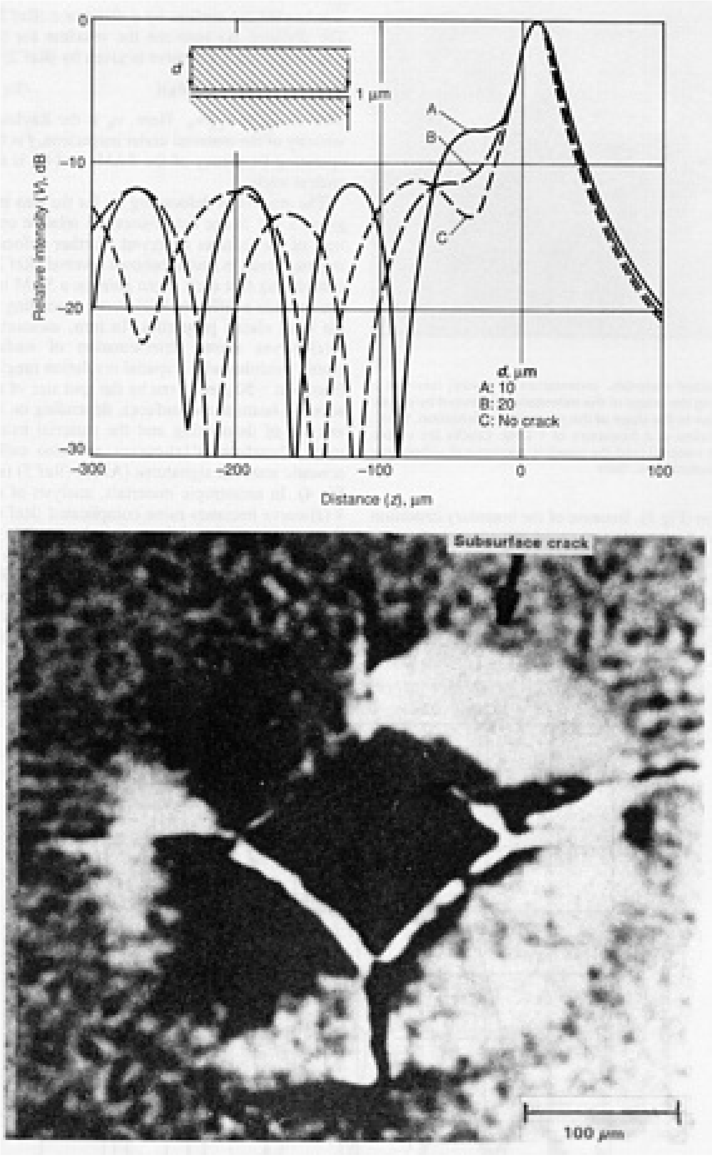

Fig. 5(a) SAM image contrast generated by surface defects in HPSN and steel materials. Top: Effect of a subsurface lateral crack present in the depth, *d,* in hot-pressed SiN on the *V*(*z*)-curve. Bottom: Change in *V*(*z*)-curve attributed to lateral cracks produces the change in contrast obtained close to the indentation. Measuring frequency was 200 MHz; half-opening angle of the lens was 60 °. See Fig. 5(b). Source: Ref 16

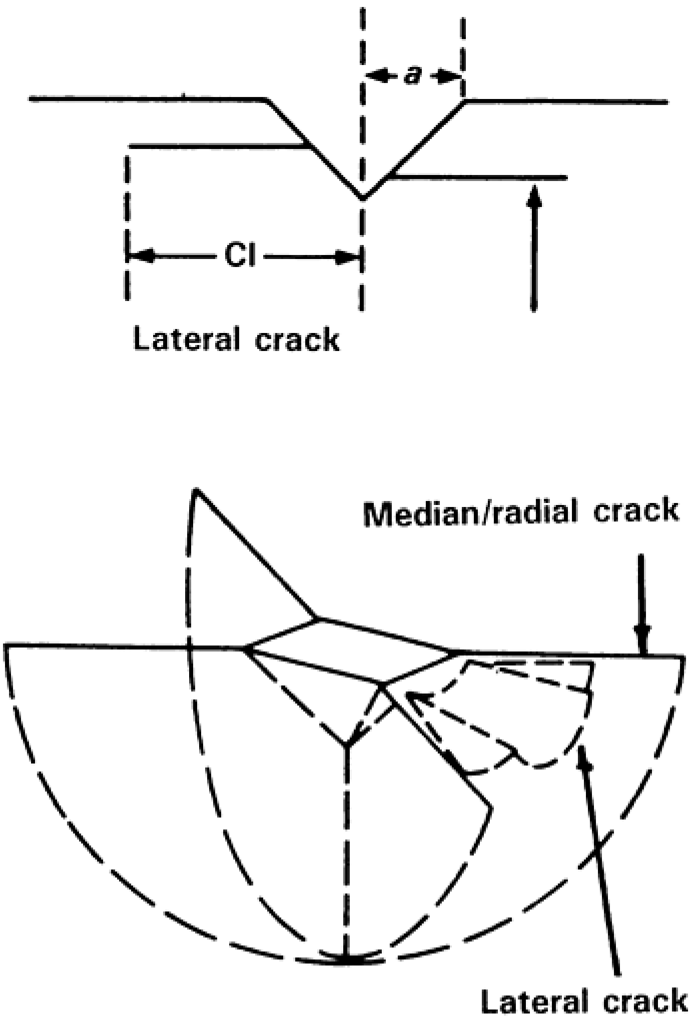

Fig. 5(b) Schematic showing detail of SAM image contrast generated by surface defects in HPSN and steel materials. Top: Lateral crack in HPSN. Bottom: Median/radial crack and a lateral crack in a steel ball bearing. See Fig. 5(a). Source: Ref 16

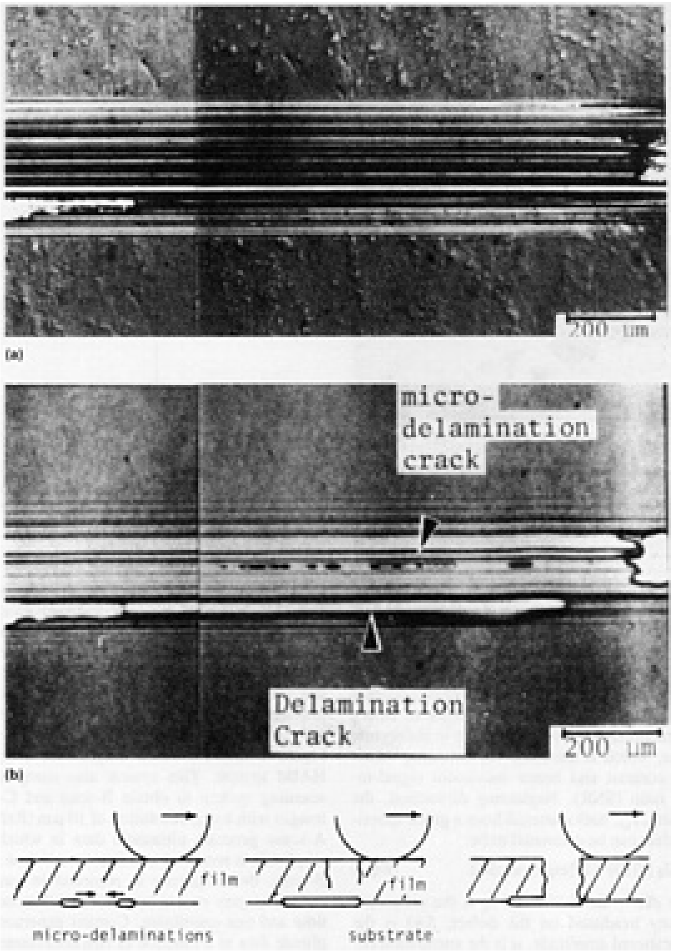

Fig. 6 Sliding damage incurred by a TiN film on a steel sample. (a) Optical image. (b) SAM image. A steel ball of 2.4 mm (0.094 in.) was slid over the film with a load of 4.9 N (1.1 lbf) (typically, 1000 repetitions are completed) and the onset of wear was observed. Microdelaminations develop that eventually grow into larger delaminations. These microdelaminations become visible in SAM images. Source: Ref 16

Machining damage in ceramics can also be evaluated by a different procedure using SAM. Common techniques for machining structural ceramics use alternating grinding (AG) and creep-feed grinding (CFG) to remove surface material. Parameters that can be varied in these processes are in-feed, feed-speed, and cutting speed, resulting in a given material removal rate. Zirconia (ZrO_2) and silicon-infiltrated silicon carbide (Si/SiC) were examined by taking SAM images after machining. A typical image is shown in Fig. 7(a). The number of cracklike indications, *N*, perpendicular to the grinding grooves per area were counted as a function of machining parameters (Table 1), exploiting the sensitivity of SAM to cracks present in a surface layer. *N* was clearly minimal in case of CFG (Fig. 7b).

Table 1 Recommended machining parameters to ensure the production of ceramic components with the least possible surface damage

Machining process	Sample groove location	In-feed		Feed speed		Cutting speed		Material removal rate (MRR) per unit wheel width	
		mm	**in.**	**mm/s**	**in./s**	**m/s**	**ft/s**	**mm^2/s**	**$(in.^2/s) \times 10^{-3}$**
Alternating grinding	N_1	0.03	0.0012	167	6.6	25	82	5	8
	N_2	0.03	0.0012	84	3.3	25	82	2.5	3.9

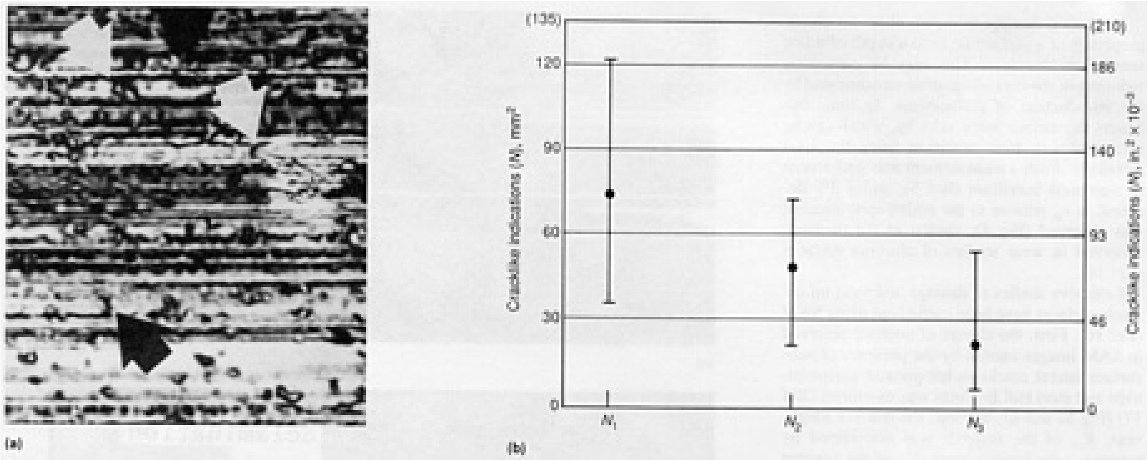

Fig. 7 Surface damage (in terms of cracklike indications) in ceramics relative to machining parameters and processes. (a) SAM image of an AG ZrO_2 sample with cracklike indications perpendicular to the grinding grooves was taken at a frequency of 200 MHz. The image size area is 780 × 740 μm^2. (b) Numbers of detected cracklike indications of ZrO_2 samples machined by AG (N_1 and N_2) and CFG (N_3) methods. The bars indicate over which margin the number of cracklike indications vary from sample to sample. The average value is marked by a dot.

Such cracks may cause failure after mechanical loading of the component. This was corroborated by measuring the bending strength of samples made of the same material and subjected to the same machining procedure. The bending strength was higher in the case of CFG (Ref 18). This evaluation technique is similar to one used to evaluate wear in a sliding experiment on hot-pressed SiN and partially stabilized ZrO_2 (Ref 16).

Furthermore, SAM has been used to evaluate corrosion attack on lacquered sheet. Again, this is based on the sensitivity of the contrast in SAM images on the elastic boundary conditions between the adhering film and the base material (Ref 14). Finally, plastic deformation occurring at grain boundaries has been observed by SAM after severely stressing polycrystalline steel containing 3% Si (Ref 19).

High-Frequency Acoustic Imaging

Principles of HAIM

The efficient detection of defects by ultrasound requires that the wavelength be comparable to the defect size. For example, because of fracture mechanics considerations, it is necessary to detect defects smaller than 100 μm in engineering ceramics and other high-strength materials. Because of the large sound velocities in these materials, use of high-frequency acoustics is required. However, the ultrasonic attenuation in the material examined may become quite large at frequencies beyond 100 MHz, limiting the penetration depth. Furthermore, the probes employed have an opening angle smaller than the critical angle θ_R, avoiding the generation of surface waves typical for SAM and hence yielding deeper penetration into the material. Otherwise, the mechanisms contributing to the contrast in SAM and HAIM are very similar.

Depending on the ratio of the defect size, *a,* to the employed ultrasonic wavelength, λ, three regimes can be distinguished that are important for defect detection: Rayleigh scattering ($a/\lambda \ll 1$), resonance scattering ($a/\lambda \sim 1$), and geometric scattering ($a/\lambda \gg 1$). As mentioned previously, the attenuation limits the propagation of ultrasonic waves in engineering materials at frequencies much above 50 MHz. Use of 50 MHz waves in ceramics and other materials with sound velocities above 6 mm/μs keeps detection in the Rayleigh regime for the order of defect sizes mentioned above, rather than in the regime $\lambda \sim a$, which is desirable for obtaining maximum contrast and hence maximum signal-to-noise ratio (SNR). Neglecting diffraction, the intensity, I_{sc}, backscattered from a given spherical defect can be estimated to be:

$$I_{sc} = I_0 \, [f(\pi)]^2 \pi a^2 [\exp(-\alpha r)] d\Omega \qquad \textbf{(Eq 3)}$$

where $d\Omega = \Delta F/4\pi r^2$, and I_0 is the ultrasonic intensity irradiated on the defect, $f(\pi)$ is the backscattered amplitude, α is the attenuation coefficient in the material, ΔF is the area of the transducer, r is the depth of the defect, and $d\Omega$ is the solid angle subtended by the probe as seen from the defect. Because $f(\pi) \propto a^2 f^2$ in the Rayleigh regime, $I_{sc}/I_0 \propto a^6 f^4$ (f is the ultrasonic frequency)! This means that very efficient transducers with a center frequency as high as possible must be employed in order to obtain a sufficiently high SNR for a given excitation voltage of the transducer. For other defect shapes, expressions similar to Eq 2 also hold true (Ref 20).

Therefore, the electronic systems and probes in a HAIM system must be designed such that the highest SNR is obtained and losses are absolutely minimized. In the setup currently used by the authors, the detection limit for defects is 30 μm for inclusions of a few millimeters depth, provided the ultrasonic attenuation in the material examined is less than 1 dB/cm at 50 MHz. Figure 8 shows a block diagram of a typical HAIM system. This system also comprises a scanning system to obtain B-scan and C-scan images with a step-resolution of 10 μm (Ref 21). A-scans generate ultrasonic data in which the amplitude is recorded as a function of time. In a B-scan, the amplitude is recorded in varying shades of gray or a color scale as a function of time and one coordinate. C-scans generate amplitude data as a function of two coordinates. In general, the maximum amplitude in C-scans is recorded for the image built up within a preset gate having a time delay that defines the time-of-flight of the signal and, hence, the depth of its origin within the sample. After rectification, the portion of interest of an A-scan is cut out by a gate and the signal strength within this gate is used to build up the image. The authors' system has been used to detect and evaluate defects, lack of adhesion between two different materials, homogeneity, and surface damage of components. Details about the design of the focusing probes can be found elsewhere (Ref 22). Various electronic systems are used for HAIM.

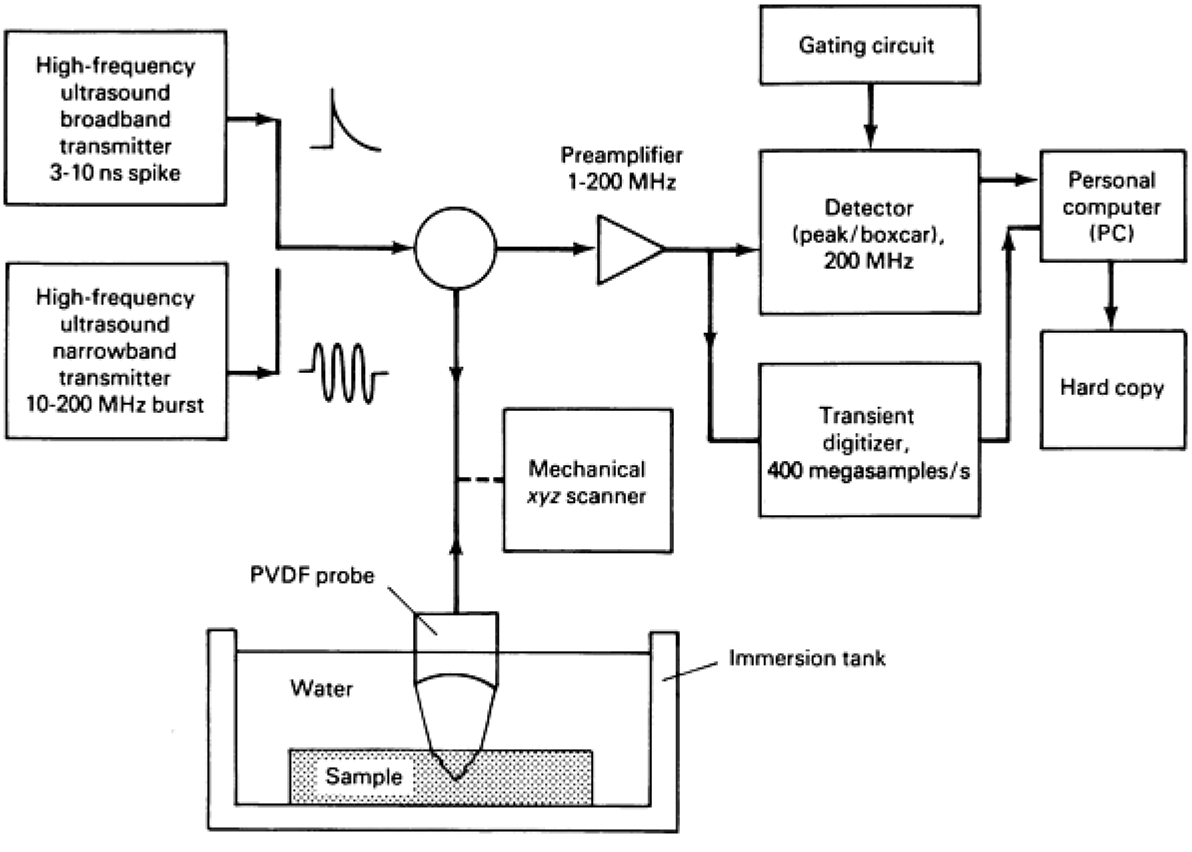

Fig. 8 Block diagram of a typical HAIM system. A transmitter excites the transducer, in this case a polyvinylidene-difluoride (PVDF) transducer. In order to obtain sufficient spatial resolution, pulses of less than 100 ns are needed. A large bandwidth for both the electronics and the transducer are then necessary. The transducer employed may be excited by either an exponentially decaying step-pulse (broadband excitation), typical in NDE electronics, or by an rf carrier pulse (narrowband excitation). The component is scanned by either an *xyz* scanning system or by a robotic system. Source: Ref 21

Applications of HAIM

High-frequency acoustic imaging is used to test bonding interfaces (Fig. 9). The typical sample used for adhesion tests for biomedical applications consists of a metal slab (15 × 10 × 2 mm, or 0.59 × 0.4 × 0.08 in.) bonded by a glue to a plastic slab of the same size. Using a 50 MHz focusing probe with broadband excitation by a spike pulse, ultrasound was sent through the surface of the plastic slab and the backscattered echo from the bonding interface was detected by a peak detector. The C-scan (16 × 16 mm, or $\frac{5}{8} \times \frac{5}{8}$ in.) shows typical distribution patterns of adhesive in the interface. Areas of large change of the acoustic impedance appear as bright colors (light in gray scale), low reflecting areas appear as dark colors (dark in gray scale). An enhanced sensitivity to surface damage can be obtained by radiating the acoustic energy under an oblique angle to generate surface waves. Surface wave scattering by defects is, therefore, the dominant source of contrast in a HAIM image, just as it is in SAM images.

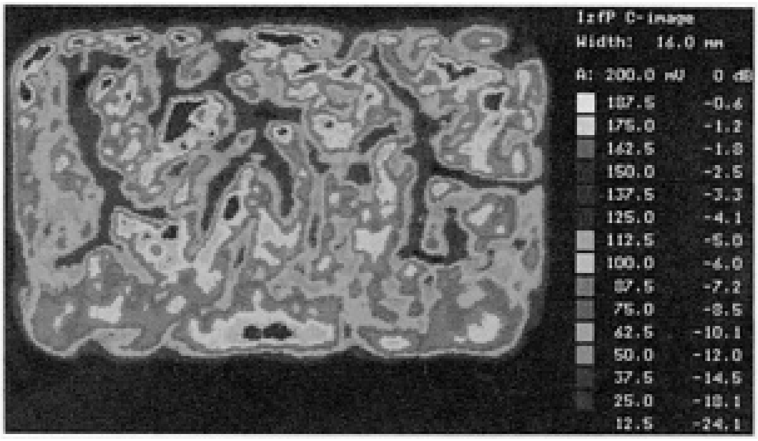

Fig. 9 C-scan image of a bonded structure obtained by high-frequency acoustic imaging. Center frequency of the probe was 50 MHz. The color scale (gray scale) is calibrated in relative intensity (dB). The width of the image is 16 mm. Original image is in color. Further details are explained in text.

Scanning Laser Acoustic Microscopy

Principles of SLAM

The operating principle of a SLAM is outlined in Fig. 10. A sample is insonified under a certain angle with respect to the surface of the sample. In a homogeneous sample, the ultrasound causes a ripple of the surface, off which a laser beam is reflected. The spatial and temporal periodic displacements of the surface cause the laser beam to be partially diffracted and frequency to be shifted by the Doppler effect. By a knife edge, one diffraction order is blocked. This then leads to an alternating current (ac) in the photodiode, because its output contains a mixing product between the undiffracted zero order and the still-present diffracted part. The frequency of the ac component is equal to the sound frequency, and its magnitude is proportional to the sound amplitude.

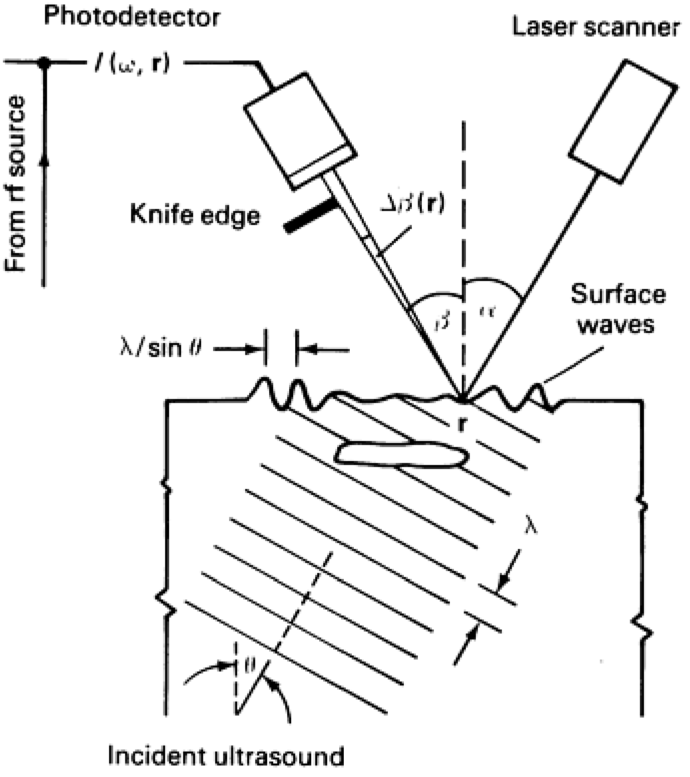

Fig. 10 Schematic showing key components and parameters of SLAM. The sound waves traveling through the sample under an angle, θ, generate a surface ripple with a wavelength of λ/sin θ. The soundwaves are detected by an optical knife-edge device in which the angle of reflection, β, is modulated by an amount, $\Delta\beta$, depending on the local amplitude of the surface ripple, according to the amount of scattering by defects present in the sample. The images obtained are acoustic holograms equivalent to Gabor holography in its original form. A quadrature receiver is used to detect the phase of the image required for holographic reconstruction. Here, the reference phase necessary for quadratic detection is obtained from the rf source driving the transducer. The images are obtained in real-time (that is, with 25 frames/second).

This technique makes possible the detection of coherent surface waves of extremely small amplitude ($\sim 10^{-6}$ nm/$\sqrt{Hz}$ bandwidth). When pores, inclusions, and cracks are present in the sample, the sound wave is scattered by these defects, which in turn become visible as a modulation of the otherwise homogeneous surface ripple. By rastering the laser beam over the surface of the sample, this modulation can be measured and displayed on a television screen (the rate of image buildup is the TV rate). The resolution in such images is given by the wavelength of the ultrasound and is typically 50 μm in most solid materials at 100 MHz.

It is obvious that the images obtained by SLAM are acoustic shadowgraphs, provided the size of the imaged structure is large compared with the wavelength. If the size becomes comparable to λ, diffraction patterns are obtained. If the surface of the sample is not optically reflective, the dynamic ripple caused by the sound field is then transmitted to a light-reflecting layer that is coupled acoustically to the sample surface by water.

Reconstruction of Images by Holography

In addition to the simple detection of defects in a given sample, SLAM techniques can be used to study their characterization and sizing. In general, this is a complex problem, because the SLAM provides two-dimensional images of a three-dimensional defect geometry deblurred by diffraction effects. Therefore, a defect appear much larger than it really is. It is possible, however, to detect both the amplitude and phases of the acoustic field in a SLAM image, allowing reconstruction of the defect by acoustic holography techniques (Ref 23).

Acoustic holography is a two-step process. First, the amplitude and phase of the acoustic field emanating from an insonified object are detected in a plane adjacent to its surface. Second, from these field data, the scattered field in the

defect plane, Φ, can then be reconstructed with a resolution of 1 wavelength. The relation between the fields $\Phi(x,y,0)$ and $\Phi(x,y,\Delta z)$ in two parallel planes in the sample under investigation, separated by a distance Δz, is given by a linear filtering process (Ref 24):

$$\tilde{\Phi}(k_x,k_y,k\Delta z) = \tilde{\Phi}_0\,(k_x,k_y,0)\cdot \exp\,(ik_z\cdot \Delta z) \qquad \textbf{(Eq 4)}$$

where $k_z = \sqrt{k^2-k_x^2-k_y^2}$ and $\tilde{\Phi}$ is the corresponding fields in k-space. k_x and k_y can be interpreted as the x- and y-component of the wave vector of a plane wave with amplitude Φ_0. Thus, the field distributions between the detection plane and the object can be obtained by calculating the two-dimensional Fourier transform of the field Φ, multiplying it with the filter function exp(- $k_z\cdot\Delta z$), and Fourier back-transforming it into spatial coordinates. This process is called back-propagation. Because outside $k_x^2+k_y^2=k^2$ the filter function is steeply increasing, the filtering is restricted to the innerface of the circle with radius k so that noise is reduced. The SNR in the back-propagated image can be further enhanced by deconvoluting the field data with the transfer function of the laser detection scheme employed in the SLAM, resulting in a total improvement of the SNR of approximately 10 dB compared with the original image.

Figure 11 shows the image of an iron inclusion in an Si/SiC bending bar obtained at an ultrasonic frequency of 100 MHz (Ref 24). The diffraction of the sound-field waves at the inclusion causes concentric ring patterns. Such images are typical for SLAM. However, by subsequently calculating the field distributions in planes of increasing depth, an image with an apparently optimal defect contrast is obtained that corresponds to the depth of the defect.

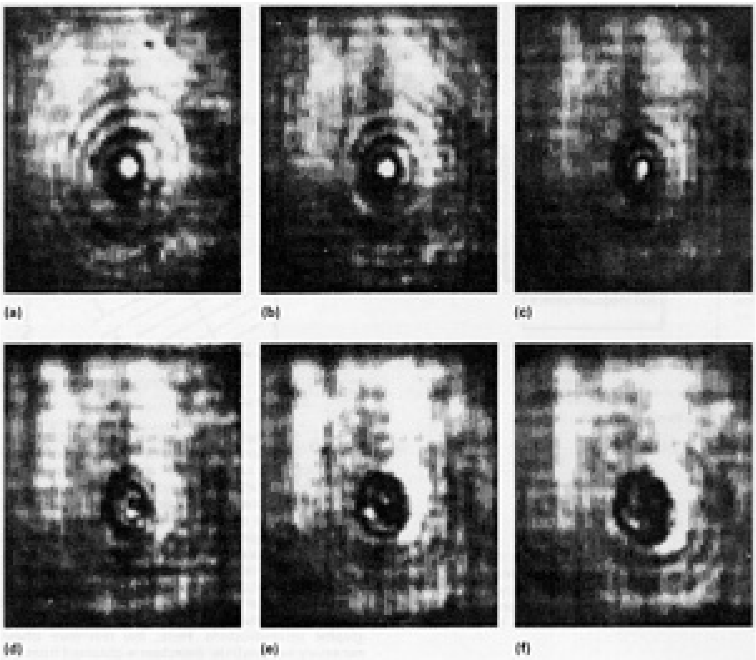

Fig. 11 SLAM image of an iron inclusion in an Si/SiC bending bar as obtained at the output detector. (a) z = 0 mm (the plane of detection at the surface of the sample). (b) to (f) Reconstructed images at various Δz (in increasing steps of 200 μm). As can be seen in (c) and (d), the defect appears focused, yielding a depth of approximately 500 μm. SLAM parameters: ultrasonic frequency, 100 MHz; field of view, 2.8 × 2.8 mm^2. Source: Ref 24

Summary

Acoustical imaging has gained tremendously from the comprehensive theoretical description of the contrast mechanisms involved and from the availability of high-speed computers. Such computers allow modeling and interpretation of the complex contrast underlying acoustic images and efficient handling of the large amount of data involved. Applications are primarily in NDE and materials characterization; some of these applications are related to problems in tribology. In the

future, high priority must be given to the integration of software that permits the reconstruction of defects by synthetic aperture techniques (Ref 2, 25, 26) and the use of robotic scanning systems in order to scan components of complex shape.

Microindentation Hardness Testing

Peter J. Blau, Oak Ridge National Laboratory

Introduction

MICROINDENTATION (MICROHARDNESS) HARDNESS TESTING is an important tool for characterizing the near-surface characteristics of materials, surface treatments, and coatings. It is extensively used in both applied and research aspects of tribology. It is a subgroup of the general field of penetration hardness testing, but the relatively low applied forces (typically, 0.01 to 10 N, or 1 to 1000 gf) make it particularly sensitive to the near-surface mechanical properties of materials. Some common uses of microhardness testing include:

- Investigating the variations in penetration hardness between various phases in a microstructure
- Initial characterization of the surfaces of materials for wear applications
- Quality control of surface treatments or coatings
- Profiling the depth of hardened surface layers and coatings
- Assessing the nature of subsurface damage on or below machined surfaces
- Assessing the nature of subsurface damage on or below wear surfaces

In addition to hardness number determination, there are other specialized uses of microindentation techniques in friction and wear technology. These include:

- Use of microindentations as wear markers (see the section "Wear Measurement Using Microindentations" in this article)
- Use of microindentations to generate cracks to determine fracture toughness of brittle materials (Ref 1)

The development of instrumented microindentation testing equipment in recent years permits direct monitoring and recording of the instantaneous force versus the displacement depth for hardness tests. Such equipment offers the advantage of not requiring optical measurement of the indentation. However, it demands very accurate penetration depth calibrations. This type of testing is described in the article "Nanoindentation" in this Section. In this article, the focus will be on more traditional tests involving optical microscopy measurement of the impressions.

Principles of Microindentation Testing

The purpose of microindentation hardness testing is to obtain a numerical value that distinguishes between the relative ability of materials to resist controlled penetration by a specified type of indenter which is generally much harder than the material being tested. (A notable exception is in the microindentation testing of very hard materials, like diamond, where the indenter and test specimen can be equal or nearly equal in hardness.)

After preparing the specimen via the application of good metallographic practice in order to avoid residual damage to the test surface, the testing procedure involves the following sequence of steps:

1. Mounting the prepared specimen so that its test surface is perpendicular to the direction of indentation
2. Causing the indenter to move downward and impinge on the surface of the specimen at a specified rate
3. Allowing the indenter to remain for a specified residence time after it stops moving
4. Retracting the indenter
5. Measuring a characteristic dimension of the residual indentation
6. Using the geometry of the indenter to calculate a hardness number

Nearly all commercially available microindentation hardness testers perform steps 2 through 4 automatically.

The accuracy and reliability of the numbers obtained in performing microindentation hardness tests are strongly dependent on three factors: the machine, the operator, and the material characteristics. The machine must be correctly calibrated for both the applied force and the optical measuring accuracy. It must also be isolated from vibrations during the test. The operator must be familiar with the correct mounting and specimen preparation methods (such as rigidly mounting the specimen, keeping the test surface level, and using sound metallographic polishing practice to avoid the introduction of factors detrimental to specimen preparation), capable of measuring indentations consistently and correctly, able to recognize invalid indentations, and aware of the need to avoid touching the machine during its operation. The material may not be homogeneous or the method of fabrication applied in its production may give it hardness numbers significantly different from those published in tables of "typical values."

One of the greatest sources of error in determining microindentation hardness numbers is in the reading of the indentation lengths. This problem becomes particularly important when hard materials are being tested or low forces are being used.

Hardness numbers should not be operator dependent. Therefore, all the individuals using the given hardness tester should be tested to see how closely the measurements of indentation length agree on the same set of reference impressions. Personal correction factors may need to be given to each person so that measurements on reference specimens agree. Well-polished austenitic stainless steel or nickel specimens are good for laboratory optical reading reference specimens because they tend to provide nicely shaped impressions and remain untarnished. Periodic rechecking, approximately once a year, is desirable because an individual's vision is subject to change. If a critical series of measurements are to be made more frequently, then recalibration must be performed before each series is started.

If the hardness testing apparatus does not read directly in micrometers, each reader should be familiar with the proper eyepiece ("filar") unit-to-micrometer conversion method. A "filar" unit is a unit of measure that relates to a scale that is visible in the measuring eyepiece of the testing machine. If the filar eyepiece is used with different objective lenses, the conversion between the filar units and micrometers must be obtained for each objective lens. This conversion factor is derived by measuring the number of filar units that correspond to the observed spacings on a precision, etched microscope slide that is graduated directly in micrometers ("stage micrometer"). As noted above, each individual using the system should have his or her own personal filar factors to maintain consistency within the laboratory.

The numerical values obtained by microindentation hardness testing techniques are dependent on a combination of material properties (for example, elastic modulus, compressive yield strength, mechanical properties, anisotropy, and so on) that interact under the stress state imposed by the indenter. Therefore, hardness numbers should not be considered basic properties of a material or a coating, but rather numbers that indicate the response of a given material to the imposed conditions of the penetration test.

The two most commonly used microindentation techniques are the Vickers and the Knoop microindentation tests. Other indenter geometries have been developed for special purposes. These will not be discussed here; the reader is instead referred to books, published standards, and review articles included in Ref 2, 3, 4, 5, 6, 7, 8, 9, and 10.

Most commercial microindentation hardness testers still in use today use gages calibrated in gram-force (gf). However, the correct International Organization for Standardization (ISO) unit for force (that is, "load") is the Newton (N). Aside from the hardness scales that report a relative index or number of dimensionless units (such as Rockwell hardness numbers), indentation hardness numbers are commonly expressed in units of pressure. Units of force and pressure are related to the traditional microindentation hardness units as follows:

To convert from	To	Multiply by
gf	N	0.00981
kgf	N	9.81
kg/mm^2	GPa	0.00981
GPa	kg/mm^2	102.0

Historically, Knoop microindentation hardness is calculated as force per unit of projected area of the indentation, whereas the Vickers hardness (sometimes known as diamond pyramid hardness, or DPH) is expressed as a force per unit facet area. This difference in the area is one factor that can lead to slightly different hardness numbers under the same applied indenter force, especially at relatively low indenter loads (that is, 0.01 to 1 N, or 1 to 100 gf); Knoop numbers are usually higher than Vickers numbers obtained at the same load.

Standard Reference Materials for Microindentation Hardness

The U.S. National Institute of Standards and Technology, or NIST (formerly the National Bureau of Standards, or NBS), in Gaithersburg, MD, has developed materials whose microhardnesses can be used for calibration purposes. Known as Standard Reference Materials (SRM), they can be purchased for either Knoop testing or Vickers testing over the range of 0.25 to 0.98 N (25 to 100 gf). Each specimen comes with a certificate and a set of microhardness numbers for that specimen. Both materials are electroformed deposits and have the designations listed in Table 1.

Table 1 Standard reference materials used to calibrate Knoop and Vickers microindentation hardness equipment

Catalog No.	Scale	Material	Microhardness, kg/mm^2
SRM 1893	Knoop	Copper	125
SRM 1894	Vickers	Copper	125
SRM 1895	Knoop	Nickel	550
SRM 1896	Vickers	Nickel	550

Vickers Microindentation Hardness Test

The Vickers indenter is more widely used throughout the world than the Knoop indenter. The face-to-face angle of the Vickers indenter was selected so that Vickers hardness numbers would be comparable to those obtained from the established Brinell hardness test that preceded it. It was recognized that the diameter of Brinell hardness indentations (d_B) varied between 0.25 and 0.5 times the ball diameter (D_B). Using the mean of $d_B = 0.375\ D_B$ gave a ratio of surface contact area to the projected area (circular area of the indentation viewed from above) for the Brinell case of 1.08:1. This ratio is approximately the same for a Vickers pyramid when the face-to-face apex angle is 136°; hence, this angle was chosen for the Vickers pyramid. Figure 1 shows the shape of the tip of a Vickers hardness (diamond pyramid hardness) indenter and defines the symbols used in subsequent equations.

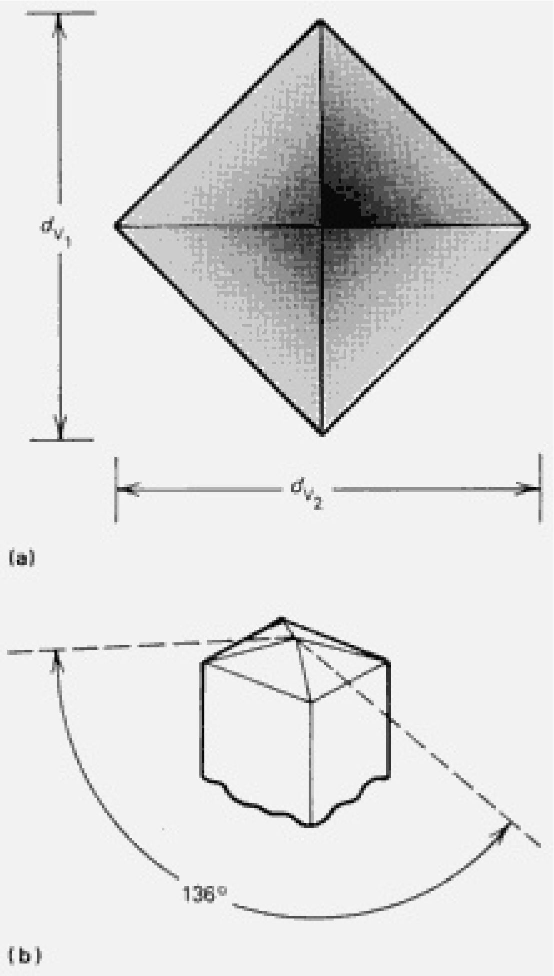

Fig. 1 Key dimensions and geometry for the tip of a Vickers indenter. (a) Diagonals d_{V_1} and d_{V_2}. (b) Face-to-face apex angle

There is some confusion in the literature as to the symbols used for microindentation hardness numbers using the Vickers indenter. Three commonly used symbols are DPH, VHN, and HV_P, where P represents the applied force. The later symbol is preferred by ASTM.

The general equation for Vickers hardness uses the average value of the two diagonals, *d**, where

$$d^* = \frac{(d_{V_1} + d_{V_2})}{2} \quad \text{(Eq 1)}$$

to calculate the hardness value

$$HV_P = C_v \left[\frac{P}{(d^*)^2} \right] \quad \text{(Eq 2)}$$

where P is the applied force, usually expressed in units of grams-force or kilograms-force, and C_V is a proportionality constant.

Vickers Indenter Versus Knoop Indenter. The Knoop indenter has both advantages and disadvantages over the Vickers indenter in microindentation testing. Because it is more blunt, the Knoop indenter tends to promote less cracking during the indentation of brittle materials (the penetration depth is 0.635 that of the Vickers indenter, assuming equal test

force and hardness number). Impressions are long and narrow, allowing the Knoop indenter to be used for hardness testing of thin layers or of narrow microstructural constituents. With the lower symmetry of the Knoop impression compared to the Vickers impressions, it tends to be somewhat more sensitive to crystallographic anisotropy than the Vickers indenter. The general shape of the ideal Knoop indenter tip and the symbols used in this section are shown in Fig. 2.

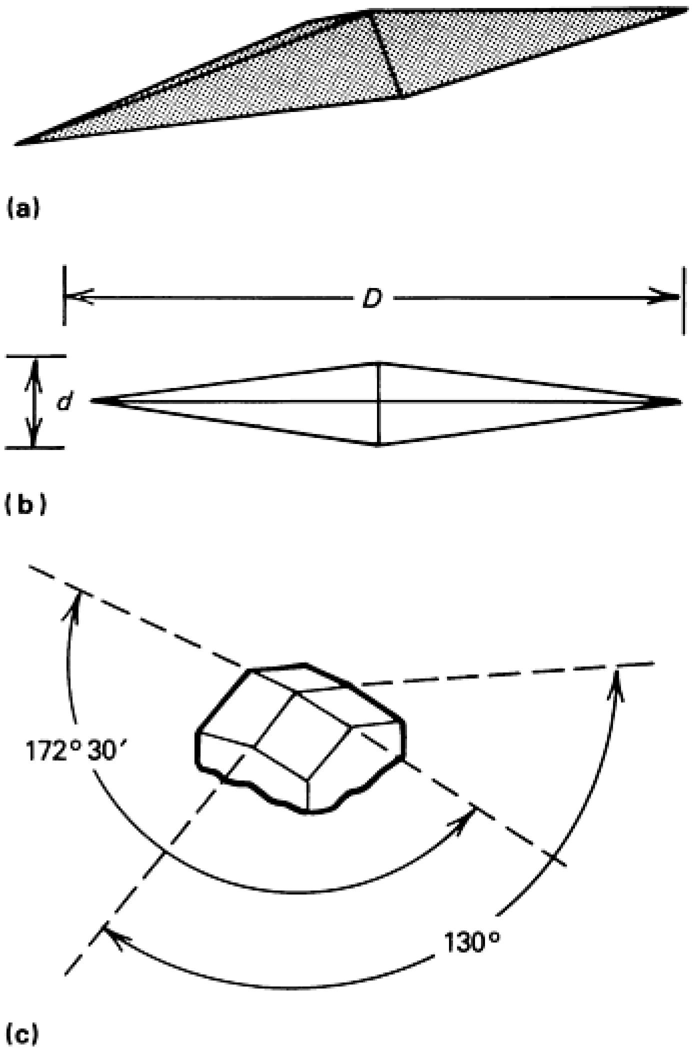

Fig. 2 Facets, dimensions, and geometry of a Knoop indenter tip. (a) Three-dimensional view of tip of Knoop indenter. (b) Diagonals *D* and *d,* where ratio of *D/d* is 7.1143. (c) Major (172.5°) and minor (130°) apex angles

Rather than requiring the averaging of two indentation diagonals, as in the case of the Vickers hardness calculation, the Knoop method requires only that the length of the longer diagonal, *D,* be measured. With the advantage of only one measurement per indentation comes the tendency for increased susceptibility to anisotropy in surface mechanical properties. The Knoop microindentation equation is

$$\mathrm{HK_P} = C_\mathrm{K}\left(\frac{P}{D^2}\right) \quad \textbf{(Eq 3)}$$

Table 2 gives the values for the proportionality constants C_V and C_K for various choices of units.

Table 2 Proportionality constants for Vickers and Knoop hardness scales as a function of hardness, force, and diagonal length

Constant		Applicable property value		
C_K	C_V	**Hardness**	**Force, *P***	**Diagonal length**

Microindentation Hardness Numbers of Materials

In the previous discussion, it was stated that microindentation hardness of materials depends not only on the composition of the material but also on the quality of the surface preparation, the method by which the material was produced, the indenter used, and the normal force (load) on the indenter. Therefore, the microindentation hardness numbers provided in this article are to be used only as a general guide to typical values for various materials. Owing to differences in surface preparation and microstructural condition, it is always better to obtain values on the specific specimen of interest than to use table values. Table 3 lists Vickers and Knoop microindentation hardness numbers that have been obtained on selected materials.

Table 3 Vickers and Knoop microindentation hardness numbers for selected materials

Material	Form[a]	Force, gf	Hardness numbers		Ref
			HV, GPa	**HK, GPa**

Microindentation Testing of Coatings

Film-covered surfaces and coated surfaces present special problems for micromechanical properties and hardness determination, especially if the properties of the thin layer(s) are to be separated from those of the substrate. Sometimes it is not necessary to separate the properties of the surface layer from those of the substrate if it is the materials system and not its constituent parts that is functionally important in the given application.

Single-Layer Coated Surfaces. Figure 3 indicates two of the four possible situations that can occur when indenting a surface covered by a film or a coating. In Fig. 3(a), the indenter moves directly through the coating layer without disturbing the coating of thickness *t*. In actual physical situations, it is unlikely that this situation will occur. The coating that originally occupied the volume now taken up by the indenter tip must go somewhere. If it behaves in a ductile manner, some of the coating material will be displaced to the side of the indenter and other portions may be drawn down into the indentation (Fig. 3b). Some materials that are normally considered to be brittle may behave in a ductile manner under the highly localized and confined compressive stresses beneath a sharp indenter tip.

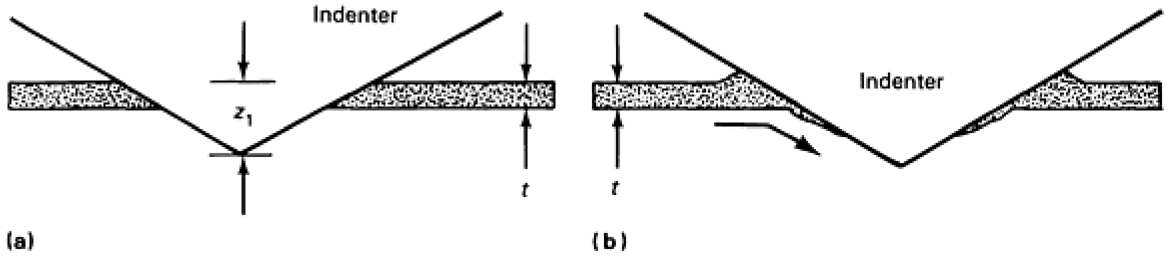

Fig. 3 Schematics showing two possible reactions of a coating layer to indentation. (a) In the ideal case, indenter moves directly through coating layer without disturbing coating thickness. (b) If coating reacts in a

ductile manner, the coating is drawn into the depression generated by the downward motion of the indenter tip.

The third possible reaction can occur if the coating contains significant levels of residual stress, if it adheres poorly to the substrate, if it is precracked, or if it is extremely brittle. That is, the coating will fracture or spall off in the neighborhood of the indentation. Trying to make sense of the hardness numbers obtained in this catastrophic coating failure is not worthwhile. In the fourth case, the coating may conform to the shape of the indenter and be pressed into the substrate without any change in thickness or the onset of fracture.

For the case where a portion of the coating material is drawn inward and another portion piles up to the side, the minimum facet contact area, *f,* occupied by the coating of thickness, *t,* when penetrated to a depth, z_1, can be determined by the equation:

$$f = 1 - \left[\frac{(z_1 - t)^2}{(z_1)^2}\right] \qquad \textbf{(Eq 4)}$$

From Eq 4, even when the penetration depth is twice the coating thickness, at least 75% of the indenter facet area is occupied by coating material. If the coating material is drawn into the indentation, this percentage may be higher, but the thin layer of coating material that coats the substrate at the bottom of the indentation is unlikely to have as important an effect on the load-bearing as the substrate itself.

Another issue involved with layered or coated surfaces is the strength of the bonding between the coating and the substrate. The action of indenting the surface may cause coating delamination to occur as the surrounding material buckles up and comes away from the substrate. Using this phenomenon, spherical indenters have been used in tests of polymer film bonding (Ref 16).

Several treatments for coating hardness have involved a rule of mixtures for the effective hardness number, H_{comp}. In one such treatment developed by P.J. Burnett and D.S. Rickerby (Ref 17), H_{comp} is determined to be:

$$H_{comp} = f_c H_c + f_s H_s X^3 \qquad \textbf{(Eq 5)}$$

where f_c and f_s are the respective volume fractions of coating and substrate materials being deformed; H_c and H_s are the respective coating and substrate hardnesses; and *X* is the interfacial parameter. The constraint parameters were found to be strongly dependent on the relative radii of the substrate and coating plastic zones. Also, for a weakly bonded film, the constraint parameter was closer to 1.0.

Jonsson and Hogmark (Ref 18) have developed an alternate formulation with the hardness of the film, H_f, given as:

$$H_f = H_s + \frac{H_c - H_s}{2Ct/D - C^2(t/D)^2} \qquad \textbf{(Eq 6)}$$

where H_s and H_c are the hardnesses of the substrate and the composite, respectively; *D* is the penetration depth (for Vickers, diagonal length/7); *t* is the film thickness; and *C* is the constant whose value depends on whether the film is brittle or whether it deforms to match the indenter shape. In the brittle case *C* is 0.0728, and in the ductile case *C* is 0.1403.

The use of two different treatments for the ductile and for the brittle films leads to the important issue of hard film on softer substrate versus soft film on harder substrate. The latter case is sometimes associated with the so-called "anvil effect." To obtain a "valid" hardness number for a material, ASTM standard E 384 requires that the penetration of the specimen material must be no more than one-tenth its thickness. This is a conservative position, because in some specific cases, the zone of affected material may extend to less than five times the thickness. In the absence of additional information about the material of interest, a factor of ten is generally reliable. If the penetration is not through the film or the coating, but represents say, one-half of its thickness, one would expect to see some effect on the hardness number by the substrate. Conversely, if the penetration depth is many times the film thickness, the effect of the film is expected to be

negligible. In one case where a submicron film of electrodeposited chromium on copper was Vickers hardness tested, it was found that the effect of the film was no longer significant when the penetration depth exceeded about twelve times the coating thickness.

When testing thin films or coatings, it is advisable to use a series of indentation loads. In doing so, a range of effects in the coating/substrate system can be examined. Empirical formulations can then be derived for comparing one coating system with another.

Multilayer coating systems (for example, electrical contacts) are even more complex to analyze mechanistically. The interaction of more than two constituents with different mechanical properties and the interfacial constraints between layers need to be considered. Scratch tests of various types are often used to assess the adhesion and durability properties of coatings. Scratch testing is a separate subject that is discussed in the article "Scratch Testing" in this Section.

References 19, 20, 21, 22, 23, 24, 25, and 26 may be helpful in regard to the microindentation testing of thin films and coatings. Some of these references use the nanoindentation techniques described elsewhere in this Volume.

Wear Measurement Using Microindentations

By utilizing the geometrical properties of microindentations, it is possible to estimate the amount of surface recession due to wear. For example, the ratio of the indentation depth to the length of the major diagonal of a Knoop indentation is 1:30.5, and the ratio of the depth of a Vickers indentation to the length of a diagonal is 1:7.00. These techniques can be applied only under the following two conditions:

- Wear surface material exhibits only a minor amount of elastic recovery after indentation, or the amount of elastic shape recovery is known
- Wear taking place is mild enough that the edges of the impressions are not unduly distorted or covered over

Microindentations can be used to measure mild wear in several ways:

- *Method 1:* periodical plastic replication of microindentations placed on the inside of a bushing or other normally inaccessible wear surface
- *Method 2:* calculation of incremental wear rate by measuring the changes in the dimensions of indentation diagonals
- *Method 3:* the smallest remaining indentation in a series that was originally produced at a succession of increasing loads

Method 1 (Ref 27). W.A. Glaeser used a Knoop indenter on the tip of a rigid rod tap a reference indentation inside a bronze bushing. By periodic replication of the indentation using plastic, Glaeser was able to watch the progression of wear in the bushing. In such cases, it would be advisable to place impressions at several locations because wear may vary from place to place on the contact surface of the bushing.

Method 2 makes use of the geometrical properties of indentations. When using this method, one assumes that the indentation geometry is similar to the indenter that produced the indentation. If substantial elastic shape recovery of the indentation occurs following the withdrawal of the indenter, then this method can only be considered to be approximate. By using the relationships between depth and diagonal length for Vickers and Knoop indenters, one can estimate a change in depth due to a change in the diagonal length due to wear:

$$z = \left(\frac{d_0 - d_f}{C}\right) \quad \textbf{(Eq 7)}$$

where z is the incremental wear depth, d_0 is the length of the diagonal of the hardness indentation before wear occurs, d_f is the length of the indentation diagonal after wear occurs, and C is a constant whose value is dependent on the type of

indenter used to generate the indentation. For a Vickers indentation with no significant elastic recovery in the surface, the value of C is 7.00; for a Knoop indentation with no significant elastic recovery in the surface, the value of C is 30.52.

This technique may be useful for measuring very small amounts of wear (for example, polishing). However, it is not effective when the wear process obscures the ends of the indentations. This method has been applied to determine wear patterns on magnetic recording heads (Ref 28).

Method 3 involves placing one or more rows of Knoop or Vickers indentations, produced at a series of loads, on the preworn surface of the specimen. After wear, the observer should note the smallest remaining indentation. Because a certain depth can be associated with each indentation, removal of a complete indentation indicates an increment of wear. If the hardness versus applied force behavior of the surface is known, indenter forces can be selected to give relatively equal depth increments. This wear measurement method has been suggested by L.K. Ives of the National Institute of Standards and Technology.

Correlation of Microindentation Hardness Numbers with Wear

There are many kinds of wear, as indicated in the Section titled "Wear" in this Volume. The types of localized stresses and directions of relative motion vary considerably between the various kinds of wear. Sometimes the stress conditions experienced by a wear surface are more similar to those imposed during a microindentation hardness test than in other cases. This means that the correlation between numerical values of microindentation hardness and wear rates may not necessarily correlate. Classic Russian studies of abrasive wear have established relationships of relative hardness to relative wear rates (Ref 29). However, this relationship does not always hold. There may not necessarily be a correlation between microindentation hardness numbers of the unworn surface and wear due to the following reasons:

Workhardening. In wear of metals and alloys, contact surfaces may change hardness greatly due to work hardening during wear. Therefore, using initial hardness numbers may be misleading.

Differences in Stress State. In a traditional hardness test, the indenter moves vertically down and up. In many forms of wear, material is deformed tangentially to the plane of the surface giving rise to shear stresses that do not occur in vertical penetration experiments.

Strain Rate Effects. In hardness testing, the rate of indentation (strain rate) may be small compared to that experienced by the same surface during wear. At high strain rates, materials are known to change their mechanical properties, often increasing in stiffness and yield strength.

Thermal and Chemical Contributions to Wear. Microindentation hardness numbers obtained under normal room environments may not accurately portray the mechanical behavior of a wear surface that is heated by friction. Furthermore, tribochemical effects such as oxidation or film formation may dominate wear behavior in ways that cannot be described by hardness numbers.

Third Bodies and Films. The microindentation hardnesses of the original surfaces may not bear any relationship to the properties of the material that accumulates on the wear surface during prolonged contact and that eventually governs wear behavior.

Effects of Brittleness. While many materials wear better if their surfaces are hardened, it is also true that very hard materials may be brittle and thus subject to fracture under the action of wear. The relationship of microindentation hardness to wear resistance may not be established for very brittle materials because the data simply cannot be obtained.

Nanoindentation

H. M. Pollock, School of Physics and Materials, Lancaster University (England)

Introduction

ONE REASON for the need to devote a separate article to nanoindentation, as distinct from microindentation, is that the type of instrumentation and data processing needed for nanoindentation has evolved in a different way. Additionally, some interesting phenomena that are especially important at the submicron scale occur, such as time-dependent behavior and the effect of ion irradiation. This article describes how nanoindentation data are obtained and interpreted, and provides examples of measurements involving polishing wear and other surface effects, surface treatments and coatings, fine particles, and other technologically important topics.

Nanoindentation Defined. Indentation testing becomes nanoindentation when the size of the indent is too small to be accurately resolved by optical microscopy. The concern is not solely with hardness and elasticity, because this definitely can be widened to include other types of tests, such as creep and even friction or film-stress measurement, which can conveniently be carried out with a nanoindentation instrument. In practice, the term nanoindentation usually implies the *continuous recording* of the distance moved by the indenter (penetration depth) and of the load, as well as other variables (such as time or frictional force), rather than single-valued measurements of contact area, as is usual with microindentation testing. This is simply because continuous depth recording (CDR) has proved to be the most direct solution to the problem of measuring very small indent sizes. However, as summarized in Table 1, not all nanoindentation testing involves CDR, which has its disadvantages. Conversely, CDR has proved to be a valuable addition to conventional microindentation instruments (Ref 1).

Table 1 Correlation (in practice) between CDR and micro/nanoindentation

Technique	Microindentation	Nanoindentation
Imaging of indents by microscopy	Usual	One type of commercial instrument only (Ref 2)
Continuous depth recording	Occasional examples in the scientific literature (see Ref 3)	Usual

The advantages of CDR include a high level of precision, ease of digitization, automation, and data processing. It is ideal for the measurement of creep, as well as of plastic and elastic work. Furthermore, each test normally gives a complete loading/unloading cycle, rather than just a single reading.

As a sole method of measuring indent size, its disadvantage is the need for simplifying assumptions in order to:

- Separate plastic from elastic effects
- Determine the true zero of the depth measurements
- Allow for piling-up or sinking-in of material around the incident
- Allow for geometric imperfection of the indenter when deriving absolute hardness values

Type of Information Obtained. Nanoindentation testing by CDR does not give values of absolute hardness directly. This is because hardness is usually defined as load divided by indent area projected onto the plane of the surface, and this area is not explicitly measured. However, the data can be processed on the basis of well-established assumptions (Ref 4) to yield relatively direct information that is of value in quality control.

This direct information on elastic recovery, relative hardness, work of indentation, and strain rate/stress relationship (Fig. 1) can provide a comprehensive "fingerprint" of a particular sample resulting, for example, from a change in either a production process or a wear test procedure. It is ideally suited to the comparison of one sample with a control or reference. The wider assumptions that are needed to derive indirect information on the material properties that are of particular scientific value are also defined in Fig. 1.

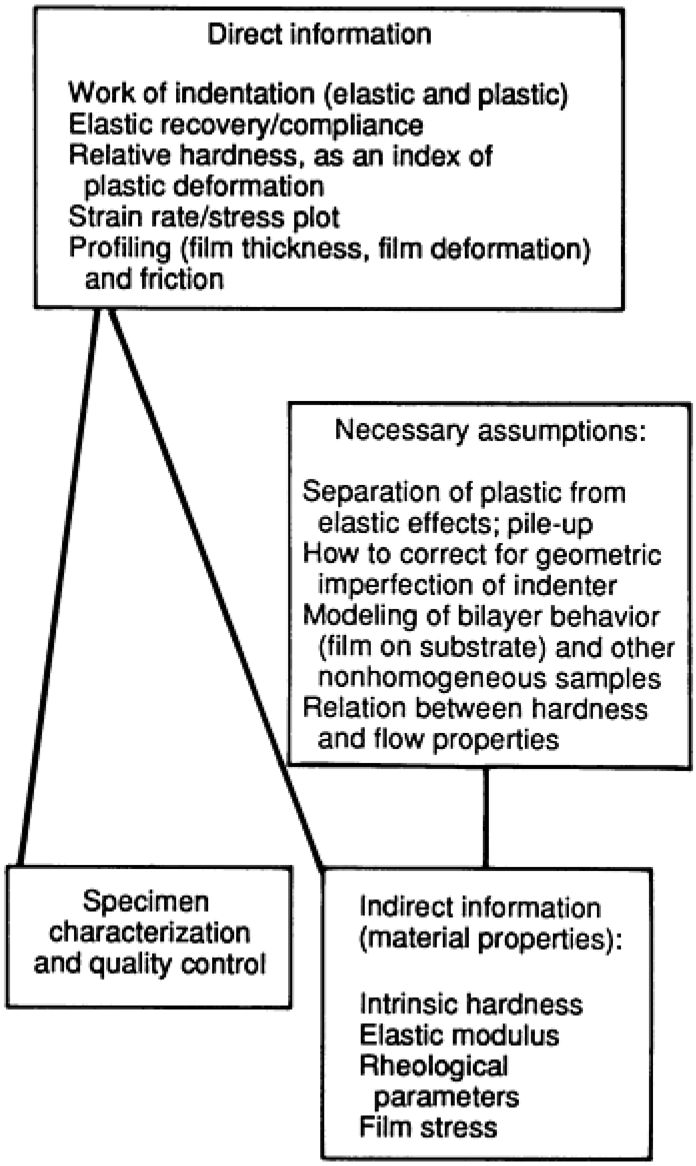

Fig. 1 Types of information obtained

The topic has produced some surprises, as mentioned in an earlier review (Ref 3) that discussed near-surface creep at low homologous temperatures, and some work in Japan that sometimes found a "critical load," below which no detectable plastic deformation remains. A number of years passed before independent confirmation was obtained, either experimentally (Ref 5, 6) or theoretically (Ref 7, 8).

The area under the depth-load curve is related to the work done by the indenter on the specimen. By subtracting the area under the unloading curve from the total area, W_T, the work, W_p, that is retained by the specimen (Fig. 5) is measured. For an elastic material, all the work is released upon unloading, that is, $W_p = 0$ and $\delta_p = 0$. For a plastic material, all the work is retained by the specimen, that is, $W_p = W_T$ and $\delta_p = \delta_T$. If the departure from linearity of the unloading curve is neglected, then:

$$\delta'_e = \frac{2W_e}{P_m} \qquad \textbf{(Eq 9a)}$$

and because R is defined as δ'_e/δ_p, with $\delta_p = \delta_T - \delta'_e$, Eq 2 in the preceding article follows directly. Alternatively, $P_m\, d\delta/dP$ can be substituted for δ'_e (Fig. 5), giving Eq 3.

To express R in terms of H and E, it is seen, from Eq 1, that $\delta'_e = (1 - \nu^2)P/(2Ea)$, and that from the definition of k_1, $\delta_p = a(\pi/k_1)^{1/2}$. Thus, $R = \delta'_e/\delta_p = P/(2Ea^2)(k_1/\pi)^{1/2}$. But, from the definition of hardness, $P/(\pi H)$ can be substituted for a^2, so that Eq 4 follows.

The quantity $H(1 - \nu^2)^2/E^2$, which is independent of k_1, can be calculated as follows: From Eq 4, $H(1 - \nu^2)^2/E^2 = 4R^2/(\pi k_1 H)$, and from the definition of k_1 and I_p, $k_1 H = I_p$, so that Eq 7 follows.

Acknowledgements

The way in which the nanoindentation test procedures are presented in this article reflects many discussions and much helpful criticism from Dr. R.H. Ion. I am grateful also to Dr. R.C. Rowe, Dr. J. Skinner, Dr. J.-C. Pivin, and Dr. M. Ghadiri for providing specimens for Fig. 3, 8, 10 and 12, and 15, respectively.

Nanoindentation Instruments

Where the prime requirement is to obtain absolute values of hardness in the sense of resistance to plastic deformation, a logical approach is to replace the optical microscope of a microindenter by an electron microscope. A nanoindentation attachment that can be used inside a scanning electron microscope (SEM), has formed the basis of patents and is commercially available (Ref 2). In principle, this approach makes it possible to establish a reliable comparison between nanoindentation hardness values and established scales of hardness numbers, such as those defined in national standards specifications. It is necessary to overcome the difficulties of imaging small indentations with sufficient contrast, and, at the smallest depths, to correct for the deformation of the required conductive layer of soft metal (Ref 9). In practice, many investigators have found the advantages of continuous depth recording to be overriding. Therefore, the discussion that follows deals primarily with nanoindentation testing using CDR.

The main features of existing instruments are listed in Table 2. Except when adhesion is being measured, the indenter is virtually always pyramidal, rather than hemispherical, given that the interest is in deformation at very small depths below the specimen surface. Vickers or Knoop indenters are sometimes used (Ref 1, 10), but a three-sided pyramid is more common, because this shape can achieve a better approximation to a perfectly pointed apex, either by polishing or by ion erosion. The apical angles can be chosen so that the nominal relation between indent area and depth is the same as for the Vickers shape.

Table 2 Potential design features of comprehensive nanoindentation instrument

Basic requirements
Vibration isolation and draft exclusion Indenter: normally a trigonal diamond pyramid
Soft testing designs
Loading device, such as coil in magnetic field
Depth-sensing transducer, such as capacitative, inductive, or fiber-optical
Analog or digital loading control (ramp mode; step mode)
Hard testing designs
Load cell (force-to-voltage transducer)
Displacement actuator
Analog or digital displacement control (ramp mode; step mode)
Data logging system
Data processing software
Options
Environmental enclosure
Optical microscope
Digital *x-y-z* sample displacement (from one indent position to the next; also, to microscopy location)
Additional ultrasmooth actuator for recalibration of depth transducer
Servocontrol of selected force or displacement
Modulation (ac component) of the load, for compliance measurements
Automatic detection of indenter-specimen contact
Additional programming: approach speed, loading/unloading cycle, series of indents
Vibration detector (data affected by vibration exceeding a set level to be discarded)
Temperature compensation
Hot stage

Friction measurement (smooth lateral displacement; transverse force transducer)
Scratch testing
Profilometry and depth sensing for measurement of film stress, Young's modulus, and other properties

Alternatively, a more acute angle (such as 90° between edges) can be chosen, on the grounds that thinner coatings can be tested without the data being significantly affected by the properties of the substrate. Also, sharp indenters give more consistent results when the specimen surface is rough (Ref 11). Like other mechanical instruments, nanoindentation devices can be either "soft" testing machines, where load is imposed and the displacement measured, or "hard" machines, where the displacement of the indenter into the specimen is imposed.

With soft machines (Ref 3, 12, 13, 14, 15), indenter and loading device must be mounted on a frictionless suspension. This often involves elastic design (spring hinges and leaf springs). In one instrument (Ref 13), an air bearing is used instead, and there is no need for the weight of the indenter to be counterbalanced. To minimize kinetic and impact effects, the moment of inertia of the moving assembly should be as small as possible. The relative movement of indenter and specimen (indentation depth) is measured by means of a displacement transducer, which can be a capacitance gage, a variable mutual inductance, or a fiber-optic device. The specifications of one commercial instrument (Fig. 2) are listed in Table 3.

Table 3 Commercial nanoindentation instrument specifications

Ultramicrohardness measurement	
Typical depth resolution	<1 nm
***X* resolution/travel**	0.02 μm/50 mm
***Y* resolution/travel**	0.02 μm/50 mm
***Z* resolution/travel**	0.02 μm/25 mm
Repositioning precision	0.1 μm
Typical force resolution	20 μN
Maximum load	0.5 N (0.11 lbf)
Software	Preprogrammed control and data analysis package with menu-driven facilities for custom program development
Dimensions	500 × 400 × 300 mm
Stress measurement	
Maximum sample size	200 mm diameter
Analysis field	50 × 50 mm square
Data obtained	Film thickness, film and substrate elastic modulus, substrate shape, and film stress
Curvature resolution	$(\Delta R)\infty, R$ corresponds to $R > 3 \times 10^4$ m
Friction measurement	
Maximum force	200 mN
Scan length	To 50 mm
Data obtained	Coefficient of static or dynamic friction

With hard machines (Ref 10, 16, 17), the indentation depth is controlled, for example, by means of a piezoelectric actuator. Force transducers used in existing designs include: a load cell with a range from a few tens of μN to 2 N (Ref 17, 18); a digital electrobalance with a resolution of 0.1 μN, and a maximum of 0.3 N (Ref 16); and a linear spring whose extension is measured by polarization interferometry (Ref 10).

As noted in Table 2, it should be possible to vary the load or, in hard machines, the displacement, either in ramp mode or with a discontinuous increment (step mode). The important effects of varying the ramp speed, that is, the loading rate, will be discussed in the section "Choosing to Measure Deformation or Flow" in this article. The ramp function needs to be smooth, as well as linear, and there is evidence (Ref 19) that if the ramp is digitally controlled, the data will vary for the same mean loading rate according to the size of the digitally produced load increments, unless these are very small.

The basic requirements include a system for data logging and processing. Scatter in nanoindentation data tends to be greater than with microindentation, partly as a result of unavoidable surface roughness, but principally because the specimen volume being sampled in a single indentation is often small, compared with inhomogeneities in the specimen (such as grain size or mean separation between inclusions). Thus, unless such indent is to be located at a particular site, it is usually necessary to make perhaps five, ten, or more tests, and to average the data.

The spacing between indents must be large enough for each set of data to be unaffected by deformation resulting from nearby indents, and the total span should be at least one or two orders of magnitude greater than the size of the specimen inhomogeneities whose effect is to be minimized by averaging. On the other hand, if the test results turn out to be grouped in such a way that reveals differences between phases or grains, then each group should be averaged separately. In either case, the number of data points to be processed is large.

A real-time display helps the operator to monitor the data for consistency between indents and for any systematic trend and arises, for example, from a change in the effective geometry of the indenter, if traces of material from the specimen become transferred to it. The most common reason for an inconsistent set of data is a vibration transient, the effect of which is visible at the time. A subjective decision can then be made to discard that particular data set. Rather than use a real-time display for this purpose, a more reliable approach is to use the output signal from a stylus vibration monitor (a simple modification of the detection system itself) to abort any individual test during which the vibration exceeds a certain level.

Options that can greatly increase the scope and convenience of a nanoindentation instrument are listed in Table 2, in addition to basic requirements. With many specimen types, it is essential to record the exact location of each indent. This is achieved with the help of a specimen stage driven by either stepping motors or dc motors fitted with encoders. However, such devices must not be allowed to increase the total elastic compliance of the instrument to a value comparable with the smallest specimen compliance likely to be measured (the measurement of compliance is discussed in the section "Slow-Loading Test" of this article).

It is useful to be able to displace the specimen, as smoothly as possible, toward and away from the indenter, as well as to minimize impact effects at contact. This also facilitates recalibration of the displacement transducer, which in some designs varies according to the location of the plane of the specimen surface. In at least one design (Ref 3), the specimen displacement stage allows the surface to be brought into the field of view of an optical microscope, by using computer control. Another system (Ref 18) uses a closed-loop TV camera to help reposition the indenter rapidly and safely.

Refinements to the electronic hardware and software have been introduced to give, for instance, servocontrol of the selected load, loading rate, or displacement. This allows automatic compensation for nonideal transducer parameters, such as finite load cell compliance. Furthermore, the choice of loading mode (constant ramp speed or discontinuous step) can be extended to include more elaborate modes, such as constant strain rate or constant stress. Useful refinements include automatic control of the speed with which the specimen approaches the indenter and detection of the instant of contact. Thus, the whole loading-unloading cycle, and any required series of cycles, can be automated. As described in the section "Averaging of Multiple Tests" of this article, one design (Ref 6) includes provision for ac modulation of the load, which allows the continuous measurement of the compliance of the contact.

Of course, drift can be a problem, and attention must be paid to temperature stability. On occasion, temperature compensation is necessary in connection with depth or load transducers. Thus far, the introduction of specimen heating stages has been delayed by the consequent major problems of thermal drift.

Other physical measurements that require the use of the transducers mentioned also can be carried out, in principle, by means of a modified indentation procedure. One example is the determination of Young's modulus for thin films and other small specimens in the form of simple or composite beams whose elastic compliance is measured (Ref 16). As with optical scanning techniques, values of film stress can be derived from measurements of deflection and curvature of the film/substrate composite. Likewise, biaxial tensile testing of free-standing films can be carried out by means of the bulge test: if the bulge shape is profiled at a number of locations by probing with the indenter, then the strains can be calculated without the need to assume that the bulge is spherical. In effect, this represents a specialized type of profilometry, of which other examples include the measurement of film thickness and scratch width, as discussed below.

Film adhesion can be characterized by various methods, two of which can be used, in principle, with the help of a nanoindentation instrument modified to act as a film failure mechanism simulator. The indentation fracture technique (Ref 20, 21) has the advantage that normal loading only is required, thus avoiding complications of interpretation that arise from groove formation. In addition, values of fundamental parameters, such as critical stress-intensity factor, can be derived, in principle. A variant of the CDR technique, which monitors the load-depth curve, together with acoustic emission, in order to detect debonding at fiber-matrix interfaces in composites is described in Ref 22.

The thin-film scratch test has successfully been carried out by Wu *et al.* (Ref 23), who used conical indenters with hemispherical tips of radii down to l μm, and a tangential load cell. These were fitted to a nanoindentation instrument, for which the servo system could be set to give either constant indentation speed or constant rate of normal loading while the specimen was being translated at constant speed. As with conventional scratch testing, the critical load at which film cracking or delamination begins is used as an empirical measurement of adhesion. It was found that a reliable indication of this load was the value at which a load drop first occurred during a scratch loading curve. Thus, in many cases, fractography by SEM was not required for the detection of delamination.

Other established methods of detection, such as acoustic (Ref 24) or use of friction signal (Ref 25), can readily be used in conjunction with this technique. Wu *et al.* (Ref 18, 23) discuss the prospects of thus deriving values of fracture toughness of film/substrate assemblies. They also describe how scratch hardness is derived from measurement of the width of the scratch track when this is contained solely within one material (either bulk specimen or film only). The instrument could be operated in a simple profilometer mode, and values of track width were obtained from the observed difference between transverse depth profiles measured before and after the scratch was made.

Likewise, microfriction tests can readily be performed (Ref 26) if the indenter is replaced by the required friction stylus mounted on a device for measuring transverse force, such as a piezoresistive transducer. Again, the flat specimen is translated at constant speed. Simultaneous measurement of the stylus motion normal to the specimen surface, using the existing depth transducer of the basic nanoindentation instrument, when correlated with the peaks and troughs of the friction trace, can help to either confirm or eliminate different alternative models of the friction process (Ref 27). Nanoindentation has been used to characterize individual submicron-sized powder grains (Fig. 3), and the deformation and brittle fracture of spray-dried agglomerates has been recently quantified (Ref 28) with the help of an instrument modified by the addition of a crushing device.

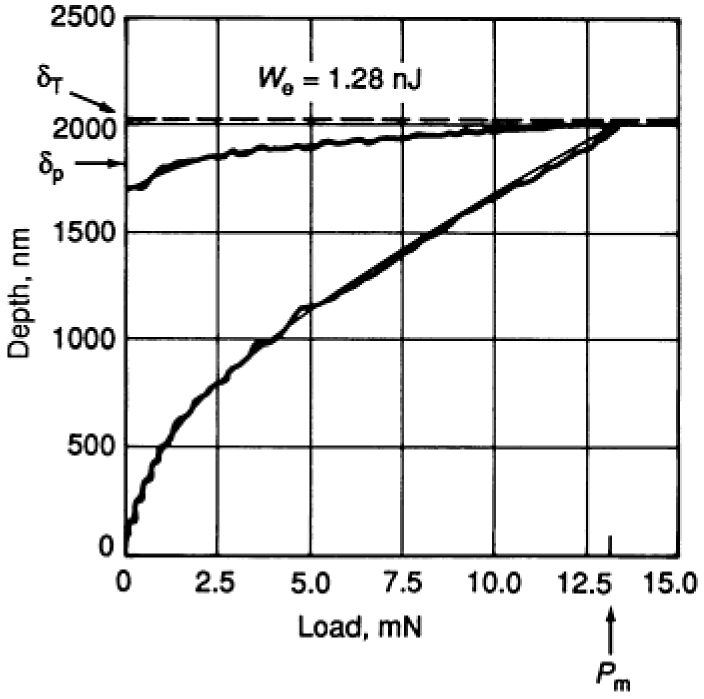

Fig. 3 Single test on individual 150 μm size grain of powder (lactose), with values of elastic recovery parameter, *R,* calculated by two methods: R_1 = δ'_e/δ_p = 0.095, and R_2 = $[(P_m\delta_T/2W_e) - 1]^{-1}$ = 0.107 (symbols defined in text and Fig. 5)

Test Procedures

Choosing to Measure Deformation or Flow. As yet, there is no universally accepted standard procedure or hardness scale that applies to nanoindentation with CDR. Consequently, the literature to date describes a variety of different data handling procedures, which generally have not yet been universally established. However, close examination shows that the differences are almost always a matter of presentation, rather than scientific content.

This review attempts to summarize all the principal techniques that have been published to date. Although the terminology used here has not necessarily been accepted in entirety, its usage is intended to emphasize the distinction made in Fig. 1 between the measurement of intrinsic material properties and the less ambitious task of characterizing particular specimens. Strictly speaking, terms such as loading rate will apply only when soft loading machines are used, but the equivalent hard loading procedure will be evident.

An assumption underlying the concept of hardness as a material property is that at or below some particular value of contact pressure, the plastic strain rate is zero. Unless the test is performed at the absolute zero of temperature, this is not strictly true. In many materials near the surface, indentation creep (including low-temperature plasticity) is often noticeable.

As discussed in an earlier review (Ref 3), if indentation depth varies significantly with timeas well as load, then even if the loading rate is held constant, and even if the material properties are independent of depth, there is no simple relation between load and depth. Furthermore, unless the indentation depth can be expressed in terms of separable functions of stress and time, the hardness, even if defined for a particular (constant) value of loading time or rate, will not be independent of load. Thus, as indicated in Fig. 4, a preliminary check is advisable.

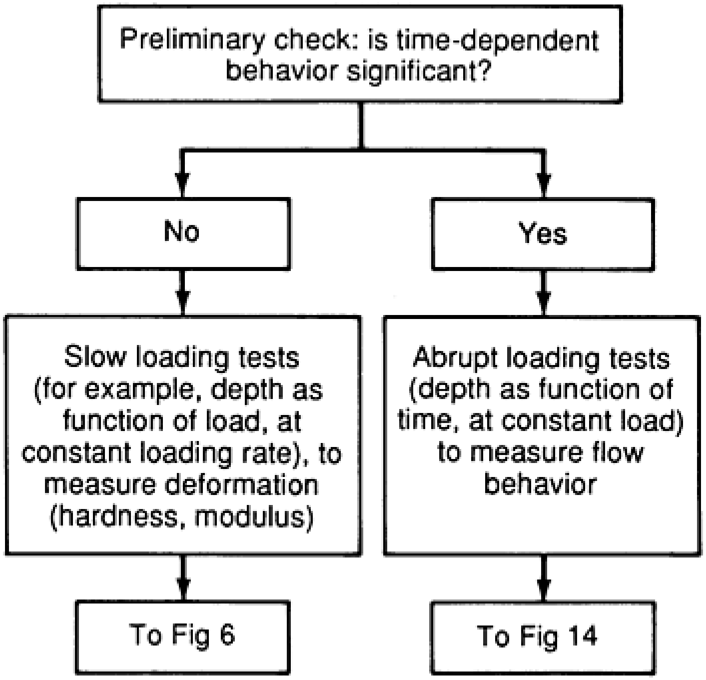

Fig. 4 Two principal types of test

The simplest way to measure deformation is by means of "slow-loading" tests, where the indentation depth is plotted as a function of slowly varying load, but it is wise to check the creep rate first by means of a load held constant for a time that is comparable to the duration of the proposed ramping load tests. Suppose that after that time, the creep rate is still *x* nm/s. Then, it would be reasonable to perform slow-loading tests in which the loading rate is always fast enough to produce a rate of indentation that is large, compared with *x*. If this is impractical, then rather than attempt a hardness test, it is logical to characterize the flow behavior, as discussed in the section "Flow Behavior" of this article.

Slow-Loading Test. Figure 5 shows a typical depth-load cycle, with load as the independent variable. Typically, a fresh location on the specimen surface is selected, and contact is made at a load of a few μN or less. The load is then raised at the required rate until the desired maximum is reached, and is then decreased, at the same rate, to zero. The "unloading curve," as shown, is not horizontal. The indenter is forced back as the specimen shows partial elastic recovery, and it is this phenomenon that allows the derivation of information on modulus. The amount of plastic deformation determines the residual, or "off-load" indentation depth, δ_p, and the plastic work, W_p (Fig. 5).

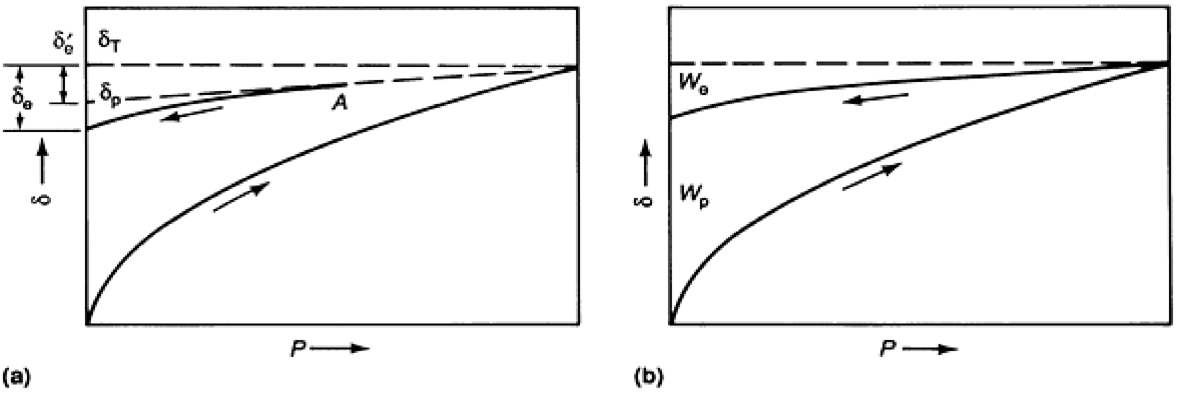

Fig. 5 Raw slow-loading data. (a) Depth, δ, as a function of load, *P*. (b) As (a), showing plastic and elastic work

A simple scheme for extracting information from such a test is shown in Fig. 6. Although there is no complete theory of elasto-plastic indentation, a useful approach is that of Loubet *et al.* (Ref 4). They used a simple approximation, namely that the total "on-load" elasto-plastic indentation depth, δ_T (Fig. 5), can be expressed as the sum of plastic and elastic components, δ_p and δ_e. It is further assumed that the area of contact between indenter ad specimen is determined by the plastic deformation only, and that δ_e represents the movement of this area as a result of elastic deformation (Fig. 7). If this were exact, δ_e would be given by Sneddon's relation (Ref 29) for a flat cylindrical punch normally loaded onto the plane surface of a smooth elastic body:

$$P = \frac{2Ea\delta_e}{1-\nu^2} \quad \textbf{(Eq 1)}$$

where P is the applied load, a is the radius of the contact region, E is Young's modulus, and v is Poisson's ratio. Thus, the unloading curve of δas a function of P would be linear.

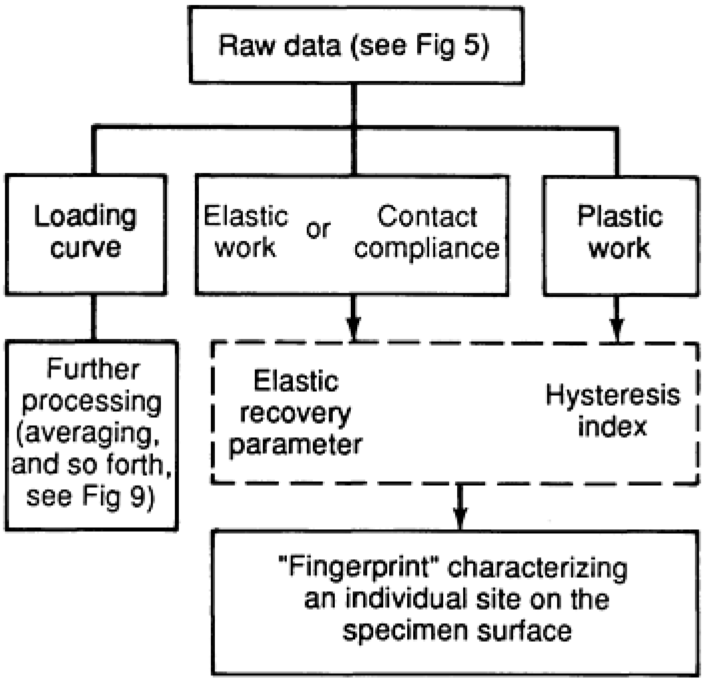

Fig. 6 Information from a single slow-loading test

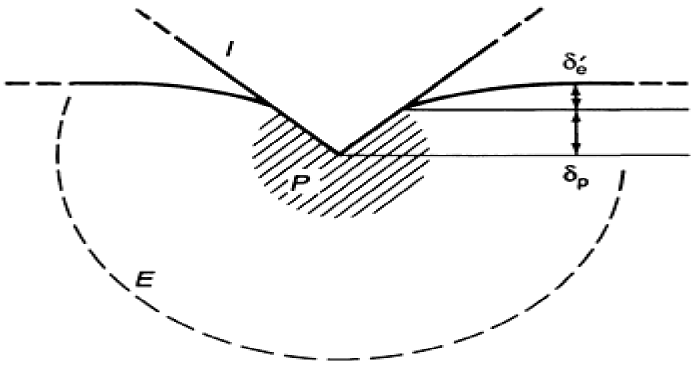

Fig. 7 Regions of elastic and plastic deformation (symbols as in Fig. 5); *I,* indenter; *P,* plastic zone; *E,* approximate limit of significant elastic deformation

In practice, there is some significant departure from linearity that occurs after a certain point (*A* in Fig. 5). This is attributed to a decrease in contact area arising from an opening of the apical angle of the indent, and a corrected value, δ'_e, is recommended instead of δ_e in Eq 1. Because δ'_e, as well as δ_T, can be determined experimentally, δ_p can be found. It is therefore possible to derive separate values of appropriate parameters describing the elastic and plastic behavior of the specimen.

Quite often, a typical specimen will show sizable variations in composition or structure, even within the small depth range sampled in these tests. Thus, before any attempt is made to derive values of material properties such as modulus, it is logical to define the most convenient indices that will provide a fingerprint characterizing an individual indent (Fig. 6). Ideally, these indices should relate directly to the raw test data, without the need for a sophisticated model or assumptions. In the simplest case of a homogeneous specimen whose material properties are constant, the values of these indices should also be constant, independent of depth. These conditions are satisfied by a fingerprint consisting of two numbers, an elastic recovery parameter, *R,* and a plastic hysteresis index, I_h.

The concept of an elastic recovery parameter was introduced by Lawn and Howes (Ref 30), who described its value in predicting how energy release provokes fracture in brittle materials. The definition was later modified (Ref 3, 31), so as to be consistent with the Loubet description above. It is defined as $R = \delta'_e/\delta_p$, and, as shown in Appendix , it is readily calculated from the area W_e (Fig. 5) that represents the mechanical work released during unloading:

$$R = \left(\frac{P_m \delta_T}{2W_e} - 1\right)^{-1} \quad \textbf{(Eq 2)}$$

where P_m is the maximum load. Alternatively, δ'_e can be found by fitting a tangent to the unloadingcurve at the maximum. In effect, this gives the contact compliance $d\delta/dP$, and thus (Appendix):

$$R = \left(\frac{\delta_T}{P_m \, d\delta/dP} - 1\right)^{-1} \quad \textbf{(Eq 3)}$$

Figure 3 shows an example. The physical significance of *R* is that for a homogeneous material, it is proportional to the ratio of hardness, *H,* to modulus $E/(1 - v^2)$, according to the formula (Appendix):

$$R = \frac{H(1 - \nu^2)(k_1 \pi)^{1/2}}{2E} \quad \textbf{(Eq 4)}$$

where k_1 is the geometrical factor that applies to the pyramidal geometry of the indenter used, namely the ratio of contact area (πa^2) to the square of the plastic depth (δ_P^2). The value *R* is a useful index, because it is a dimensionless quantity and because, in the case of an ideally homogeneous specimen, it will be independent of depth or load. Since *R* is derived from the contact compliance $d\delta/dP$ (according to Eq 3), any formula that includes *R* can of course be rewritten in terms of compliance.

The hardness will be proportional to P/δ_P^2, but a more direct measure of the resistance to plastic deformation is the hysteresis index, I_h, based on the plastic work, W_p. It is easy to show this in the simplest case of a specimen that shows fully plastic behavior with *H* independent of depth, $W_p \alpha \delta^3$ (Ref 3). Thus, I_h has the same dimensions as hardness if defined as:

$$I_h = P^3/W_P^2 \quad \textbf{(Eq 5)}$$

In the simple case mentioned, the value of *H* will be $I_h/(9\,k_1)$.

Figure 8 shows an example of indents located within individual grains in a two-phase material (cermet), illustrating the differences in *R* and I_h. It is important to realize that although I_h characterizes a plastically deformed zone whose

dimensions are not much greater than δ_p, the value of R is determined by the behavior of a much larger elastic hinterland (Fig. 7).

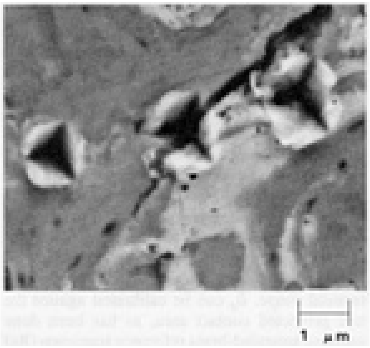

Fig. 8 SEM images of indents in a two-phase material (nichrome/chromium carbide cermet). Different maximum loads were used to give approximately the same indent depth in each case. Nanoindentation fingerprints, from left to right: Indent in dark region (carbide), R = 0.19, I_h = 754; mixed region, R = 0.19, I_h = 509; light region (nichrome), R = 0.12, I_h = 282

Averaging of Multiple Tests. In principle, a major advantage of CDR is the ability to obtain graphs of hardness as a function of depth from a single test. However, for the reasons outlined earlier, it is usually necessary to perform a number of tests on each specimen and to average the data (see Fig. 9). As it has been shown, each test yields only a single value of R, and it is advantageous to vary the maximum load between tests, so that R can be obtained as a function of depth. If the compliance of the instrument itself is significant, compared with the contact compliance $d\delta/dP$, it can be eliminated with the help of a plot of compliance against reciprocal of depth (Ref 32), extrapolated to infinite depth, before Eq 3 is used to calculate R. If $E/(1 - v^2)$ is known, the value of k_1 can be derived from a plot of this type (Ref 33).

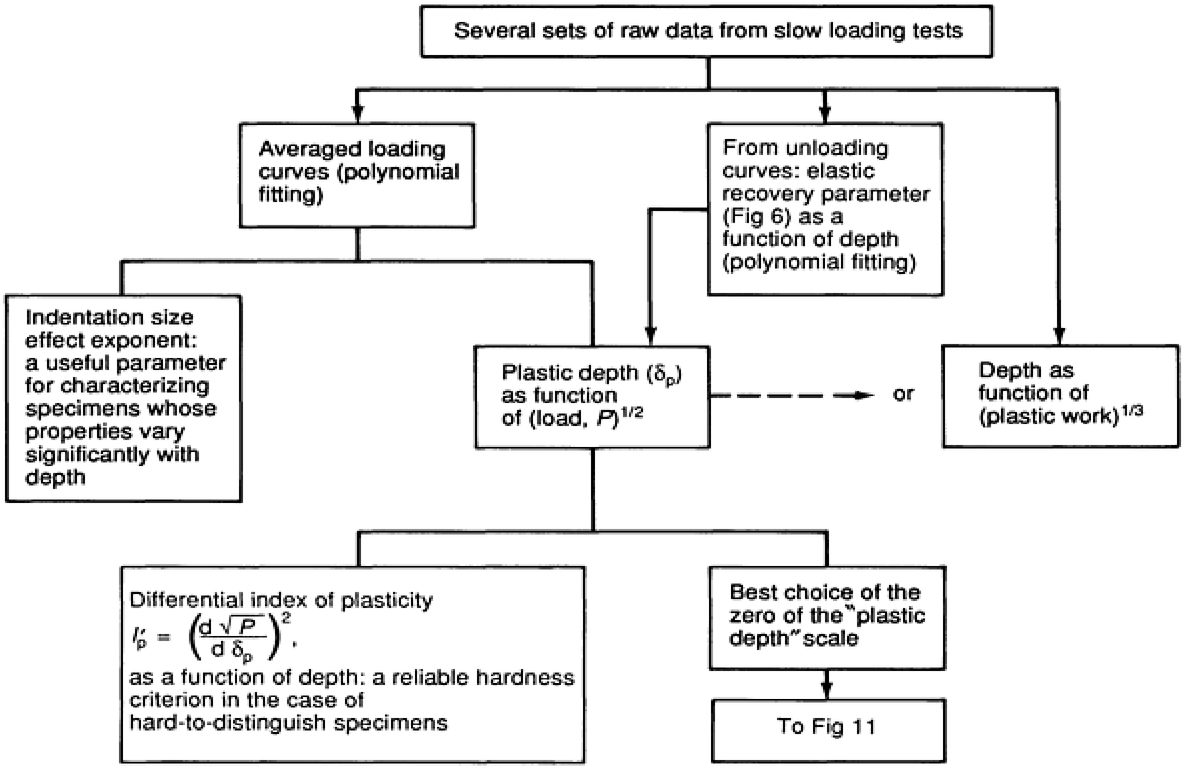

Fig. 9 Averaging of multiple tests

The need for discrete loading and unloading cycles to different values of maximum load is avoided if $d\delta/dP$ is continuously measured by means of a differential loading technique (Ref 6). An ac current source is used to add a small oscillatory modulation to the load, and the resulting oscillations in depth are detected with a lock-in amplifier. It is necessary to allow for the machine compliance and for damping inherent in the depth-sensing transducer.

No indenter pyramid is perfectly sharp, and with an indenter of finite tip curvature, plastic deformation is initiated at a finite depth below the surface. For this reason, and because of other complications (vibrational noise, pile-up around the indentation, and specimen roughness), the accuracy with which the instant of contact and the depth-zero can be identified is much poorer than the resolution of the depth measurement (typically, 1 nm or better). Methods that allow for the exact indent geometry are discussed in the section "Hardness and Modulus" of this article. In practice, the zero of plastic indentation depth can be determined with reasonable precision, for example, as shown in Fig. 9 and described below.

First, polynomials are fitted to the averaged loading curves and the graph of R against depth. From the relation $\delta_p = \delta_T - \delta'_e$, this allows δ_p to be plotted as a function of $P^{1/2}$. This function is chosen simply because, for an ideal material, it would be linear. In practice, after a certain depth has been exceeded, linearity is often seen over a considerable depth range, and the appropriate depth-zero can be found by extrapolation back to zero load (Fig. 10a). The result can be confirmed (Ref 3) by means of a (linear) plot of $W_p^{1/3}$ against depth, with extrapolation back to zero W_p.

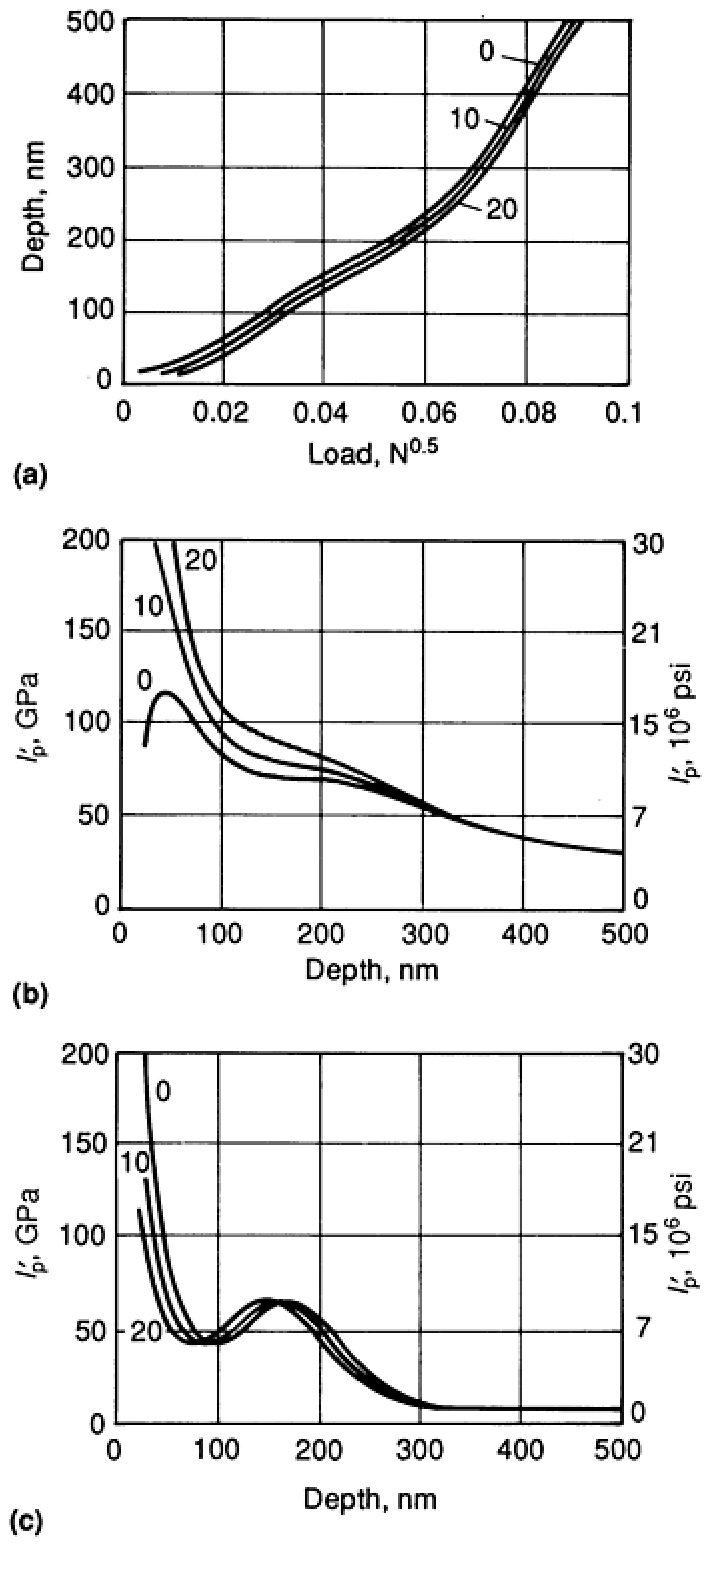

Fig. 10 Alternative data presentations, showing effect of changes in chosen depth-zero; numbers against curves indicate the depth offset in nm (specimen: multienergy boron implant into titanium). (a) Depth against square root of load. (b) I_p against depth. (c) I'_p against depth. Source: Ref 34

Subsequently derived profiles of relative hardness, in particular their shape at small depths, can show wild variations according to the choice of depth-zero (Fig. 10b), and should be interpreted with caution. For some materials (Ref 3), this near-surface difficulty is exaggerated by the interesting "critical load effect," whereby no permanent (plastic) indent size is made below a certain indent size. To study this, nanoindentation with depth recording was first used by Tazaki *et al.*

(Ref 35), whose work has been largely unacknowledged, although recently the effect has been confirmed for both sapphire and electropolished tungsten (Ref 6).

For hard ceramics, yielding can occur at intervals, with the observed increment in indent radius corresponding to the spacing (projected parallel to the surface) of discrete bands of deformation, separated by a characteristic distance (Ref 8); the relevant nanoindentation evidence is described in Ref 36. The critical load in, for example, sapphire or silicon carbide may correspond to the nucleation of the first plastic band. The formation of subsequent bands may be associated with the steps, or "serrated behavior" (Ref 17) often seen on loading curves.

Fortunately, when the aim is to characterize differences between samples, rather than absolute values of intrinsic hardness, the rather arbitrary effects of the choice of depth-zero may be minimized. Figure 10 illustrates one of the chief merits of nanoindentation with CDR, namely the fact that parameter values are derived for all depths up to the maximum reached in the series of tests. Because, in the case of an ideal material, hardness is directly related to the slope of the $\delta_p/\sqrt{P}$ curve, it is useful to convert this slope to give a parameter that has the dimensions of stress and to plot its value against depth, as shown. The definition of this differential index of plasticity (Ref 3) is:

$$\Gamma_p = (d\sqrt{P}/d\delta_p)^2 \quad \textbf{(Eq 6)}$$

As indicated in Fig. 9, this gives a reliable criterion for distinguishing between specimens of slightly different hardness, as well as for identifying small changes in penetration-resistance at certain depths. This is illustrated in Fig. 10(c), where the Γ_p curves show a feature at about 170 nm that is almost unnoticeable unless the data are presented in this way.

Hardness and Modulus. The idea of a differential hardness is physically obscure, and a measure of the hardness itself is often needed. As outlined in the second row of Fig. 11, this is possible subject to any uncertainties in the choice of depth-zero, and the comparative quantities listed are valid only when the same indenter is used for all tests. The bottom row of Fig. 11 lists quantities whose values can be used, in principle, when comparing specimens tested with different indenters. Here, the danger of systematic errors is, of course, greater.

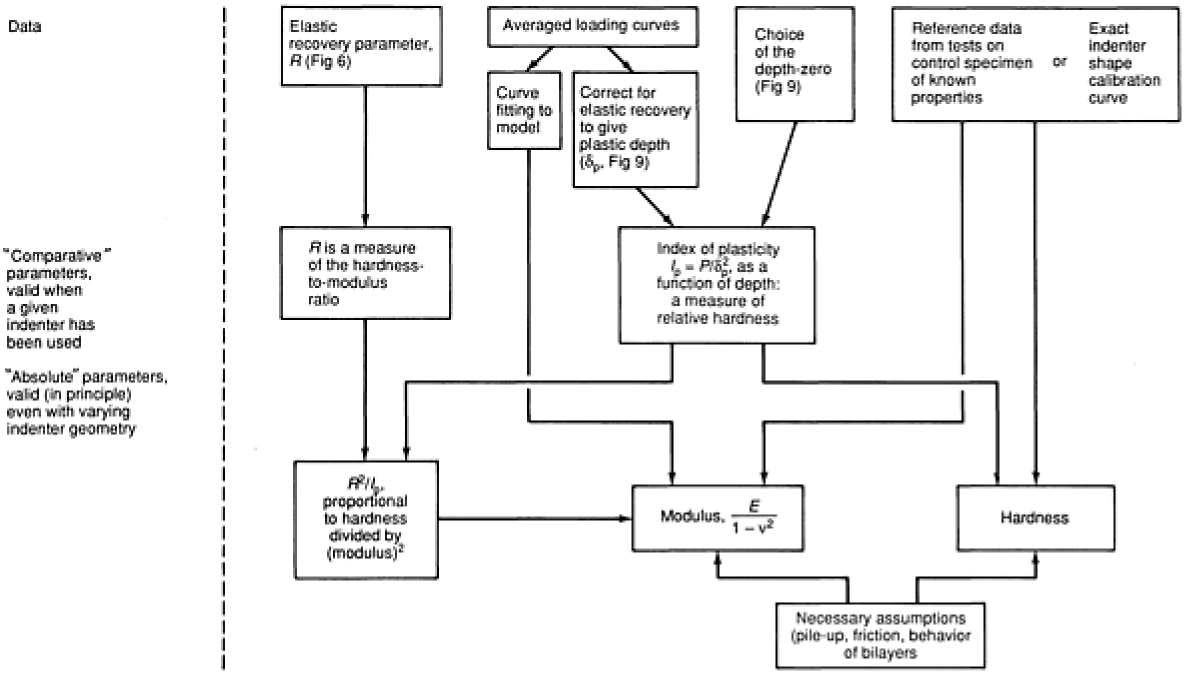

Fig. 11 Hardness and modulus

The comparative parameters include *R*, which is a measure of the ratio of hardness to modulus. As regards relative hardness, the appropriate index of plasticity, I_p, can be defined as P/δ_p^2 (Ref 3). Figure 12 shows examples of I_p as a

function of depth. For an "ideal" specimen and pyramidal indenter, the value of *H* will be I_p/k_1, but the danger of systematic error is reduced if values are normalized to data obtained from tests made on a control. These control data can themselves show a variation with depth. Accordingly, it can be useful to normalize each point on the graph to the individual value given by the control at that particular value of depth, rather than to a constant average value.

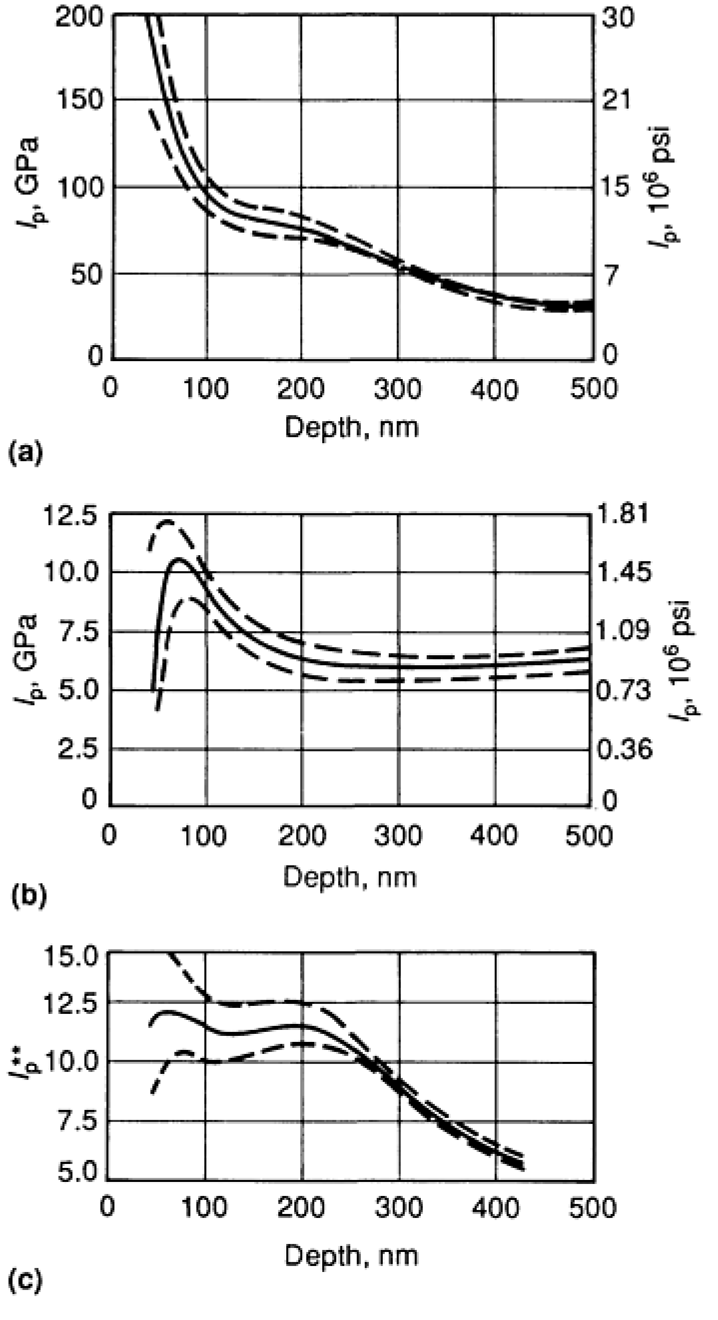

Fig. 12 Normalization at each value of depth. (a) Boron-implanted titanium, same as Fig. 10(b). (b) Nonimplanted titanium. (c) Curve a, normalized to curve b

In Fig. 12, the result is denoted by I^*_p. The parameter I_p or its equivalent has been used to quantify the relative hardness of a wide variety of surface layers, ranging from ion-implanted nickel (Ref 37, 38) and compositionally modulated multilayers (Ref 39) to titanium nitride layers produced by ion implantation (Ref 40) or reactive sputtering (Ref 41). C^+ implantation is known to increase the resistance of Ti_6Al_4V alloy to polishing wear, by a factor of nearly 100 (Ref 42). Unfortunately, the wear is not layer by layer, but is nonuniform over the surface, producing a rippled texture. Nanoindentation data were obtained and confirmed the reason for this behavior, namely that the polishing process produces its own strain-hardened gradient, with the more strained (hardened) regions wearing more slowly.

If the $\delta_p/\sqrt{P}$ curve is markedly nonlinear over the range of interest, it is clear that values of material parameters are varying significantly with depth. In this case, instead of plotting I_p, it may be simpler to derive the indentation size effect (ISE) exponent, *n*, which is related to the raw data more directly (see Fig. 9). The value *n* is defined by $P \propto d^n$, where *d* is the diameter or the depth of the pyramidal indent (Ref 43). (Sometimes *n* is termed the Meyer index, but it is important not to confuse it with the Meyer index that applies when a spherical indenter is used, and whose value depends on work-hardening behavior.) The *n* value is derived from log-log plots of δ_T versus *P* or, alternatively, from the formula (Ref 31):

$$n = P\delta_T/W_T - 1 \quad \textbf{(Eq 7)}$$

It has been used to detect the effect of traction (drawing) on the near-surface region of polymer films, as well as the point at which a substrate begins to influence the data obtained by testing a bilayer.

One precaution most needed when quantitative data are required is a regular check on the exact indenter geometry. As is evident from the above equations, any departure from the ideal pyramidal form, leading to an effective variation of k_1 with depth, or any change in its mean value, will alter the derived parameter values. This is particularly important if the aim is to derive absolute values, although as pointed out recently (Ref 44), the quantity $H(1 - \nu^2)^2/E^2$ is independent of k_1. As shown in Appendix , its value can be obtained from the formula:

$$\frac{H(1-\nu^2)^2}{E^2} = \frac{4R^2}{\pi I_p} \quad \textbf{(Eq 8)}$$

Clearly, the indenter geometry can be altered by accidental damage, but a more common cause is material that is transferred from specimens and adheres to the diamond. Clean, soft, work-hardening metals tend to be the worst culprits. Such contamination can often be removed by either ultrasonic cleaning or chemical attack.

A useful general cleaning procedure is to make a controlled indent into a polymer, such as polyethylene terephthalate (PET), in the hope that the contamination will adhere more strongly to the polymer than to the diamond. The regular checks on indenter geometry are typically performed before and after important data have been obtained, by simply making measurements on a control specimen of known properties. Suitable materials of reasonably uniform hardness include single-crystal silicon (001), for which no significant hardness anisotropy would be expected (Ref 45). With nanoindentation, experiment appears to confirm that the azimuthal orientation of the indenter is not important. Tungsten single crystals or thick, sputtered, pure metal films (Ref 17) have also been used.

Figure 11 emphasizes that in order to compare data obtained from tests made with different indenters, some type of indenter shape calibration is needed, because no indenter has a perfect pyramidal shape. δ_p can be calibrated against the true projected contact area, as has been done using an annealed-brass reference specimen (Ref 32). Two-stage carbon replicas of the indents were imaged in a transmission electron microscope. By means of this calibration, δ_p was converted into an "effective depth" that was exactly proportional to the square root of the area at all depths.

In effect, this procedure allows a constant value of k_1 to be used, so that *H* is given by I_p/k_1, and $E/(1 - \nu^2)$ is given by Eq 4. Time does not always permit the use of this delicate procedure, and a spherical cap model (a sphere of given radius capping a truncated pyramid) has been used (Ref 41) to given an approximation to the shape calibration function.

Whether an approach of this type is employed, or the less ambitious criteria discussed earlier (R^2/I_p; I^*_p) are used, certain factors that produce largely unpredictable variations in the resulting numerical data still remain. Several years ago (Ref 46), hardness values derived from nanoindentation at large depths were shown to agree to within 10 to 20% with values obtained from optical microscopy data, and agreement at this level should normally be expected, especially if k_1 is the same for the two indenters involved. However, the technique at present remains better suited to comparative testing than to the measurement of properties intrinsic to a given material, and no strictly valid correlation with Vickers microhardness values is possible (Ref 14).

Use of the above depth/area calibration procedures to derive so-called absolute hardness values neglects the fact that for most materials, even load divided by projected area will be different if a change from one indenter to another is made, because hardness varies with indenter shape. Moreover, the specimen under test and the reference specimen may have

significantly different characteristics with regard to indenter/specimen friction, as well as pile-up of material around the indentation, which is not detected in depth-sensing tests, but will affect the data (Ref 46).

Chaudhri and Winter (Ref 47) showed that for work-hardened mild steel and copper, the piled-up material supports a pressure equal to that supported by the rest of the indentation. As argued by Ion (Ref 34), the load-bearing area in such cases will correspond to a depth that exceeds δ_p, and may even be as large as δ_T. In other words, the on-load hardness can have more physical significance than the off-load hardness.

Apart from these factors, the main limitation on using the technique to measure material properties is the problem of interpreting data from specimens whose properties vary with depth, such as film/substrate bilayers. Of course, this is a problem at all levels of indentation testing, but is particularly important in nanoindentation because of the interest in indentation size effects, thin-film properties, and the often dominant effects of surface layers of oxide or contaminants.

For example, the presence of a very thin soft film can have surprisingly little effect on the raw loading curves (Ref 48). This is because at a given load, in the presence of the soft films (case A), δ_p will be greater than when no film is present (case B). In case A, however, the load is spread over a large area, so that δ'_e is less than in case B (see Eq 1, in which the elasticity of the substrate will be dominant). Thus, the difference between the totals $\delta_p + \delta'_e = \delta_T$ is quite small, and could be lost in experimental scatter.

When the elastic modulus of a film is calculated from elastic recovery or contact compliance data, the chief limitation is the fact that the effective value of *E* in Eq 4 is determined by the properties of a much larger volume of material (Fig. 7) than the plastically deformed region of hardness, *H*. An empirical model has been used (Ref 32) to describe the relative contributions of film and substrate to the measured compliance with appropriate weighting factors. Closed-form elasticity solutions have been used to model how the effective bilayer modulus varies with the projected area of the indent and agree well with experimental nanoindentation data (Ref 49, 50). The hardness of bilayers has been modeled by means of elastic-plastic finite-element analyses (Ref 51), and by an incremental kinematic method that takes account of frictional, as well as plastic, work (Ref 52).

In principle, it should be easier to measure film hardness if the film is softer than the substrate. This is because the value of mean pressure is affected more by the cumulative depth-integration of the work done by the indenter, than by whether or not the film has been penetrated. In the case of a film that is softer that than the substrate, even when the indenter (a 90° trigonal pyramid) has penetrated a distance of 1.4 times the film thickness, the measured hardness is still within 10% of the intrinsic hardness of the film (Ref 53). For films that are harder than the substrate, the critical depth, beyond which the influence of the substrate is significant, varies greatly with the indenter-specimen friction, and is less than the film thickness. Substrate, as well as film, deforms plastically at an early stage, and in cases of high friction, the film can be pushed down through a distance δ_p that exceeds the film thickness, without being pierced (Fig. 13). However, it still has proven to be possible to measure the intrinsic properties of a hard 300-nm thick Ni-25% B film on nickel, as shown by a plateau in the I_p versus δ_p graph (Ref 48).

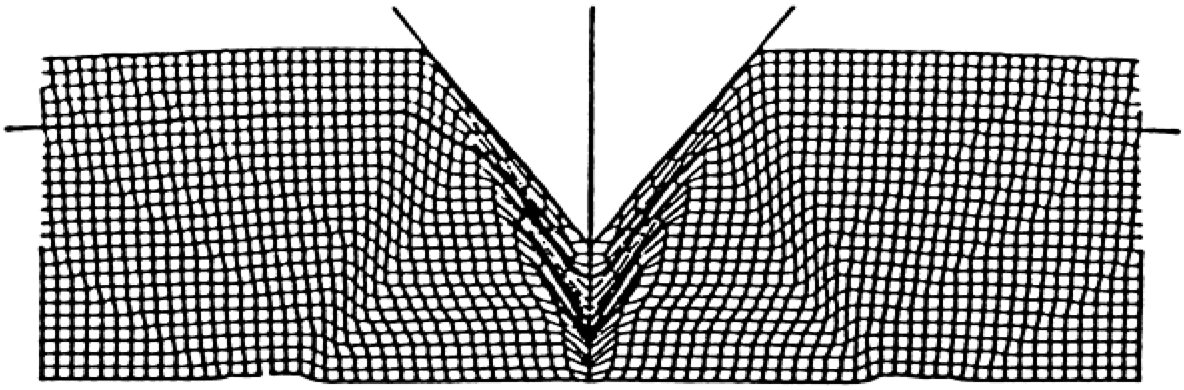

Fig. 13 Calculated field of deformation of hard film on substrate, with high friction. In this example, although the movement δ_p greatly exceeds the film thickness, the film has not yet been pierced (after Ref 53).

Flow Behavior. Exciting possibilities follow from the ability of the CDR technique to quantify the behavior of a specimen under load, even if the preliminary check (Fig. 4) suggests that slow-loading tests will be of little value. Recent calculations (Ref 7) show that most materials will exhibit indentation creep at temperatures as low as room temperature. The very high stresses involved induce dislocation glide as the principal mechanism, unless the grain size is less than a few hundred nm. The prediction has radical implications for the design and use of hard materials. Moreover, as argued in more detail elsewhere (Ref 3), the concept of a hardness that varies with time, with the theoretical complications involved, is not necessary. Instead, direct information on strain rate, as well as stress, and, hence, on the dislocation glide mechanism, is obtained without the need for a series of indentations with different loading times.

Consider an abrupt loading test, in which the load at the start is suddenly increased within less than a second to a chosen value, after which indentation depth is measured as a function of time. Subject to a number of simplifying approximations (Ref 3), the stress will decrease as P/δ_T^2, whereas the strain rate at any time is proportional to $\dot{\delta}/\delta$, that is, the speed of the indenter divided by the depth reached. (This last approximation follows from an earlier model, Ref 54, in which the strain rate is associated with the rate at which the plastic-elastic boundary of a spherical cavity moves on into the material.) Thus, this type of test corresponds to a vertical line on a Frost and Ashby temperature-stress deformation map (Ref 55), crossing successive strain-rate contours. The indenter never comes to rest (zero strain rate).

In principle, the flow mechanism can be identified, whether low-temperature plasticity (Ref 7), power-law creep as reported for stainless steel and aluminum (Ref 56), or various types of visco-plastic behavior, as shown by polymers (Ref 31), are involved. A major limitation is the difficulty of varying the specimen temperature without introducing thermal drift, the effect of which would dominate the observed value of $\dot{\delta}$.

The theory needed to interpret such data is at an early stage of development. If the main object is to characterize the difference in strain-rate sensitivity between specimens, then it is often wise to be satisfied with a graph of $\dot{\delta}/\delta$ against P/δ^2, on log-linear or log-log scales (see Fig. 14 and 15).

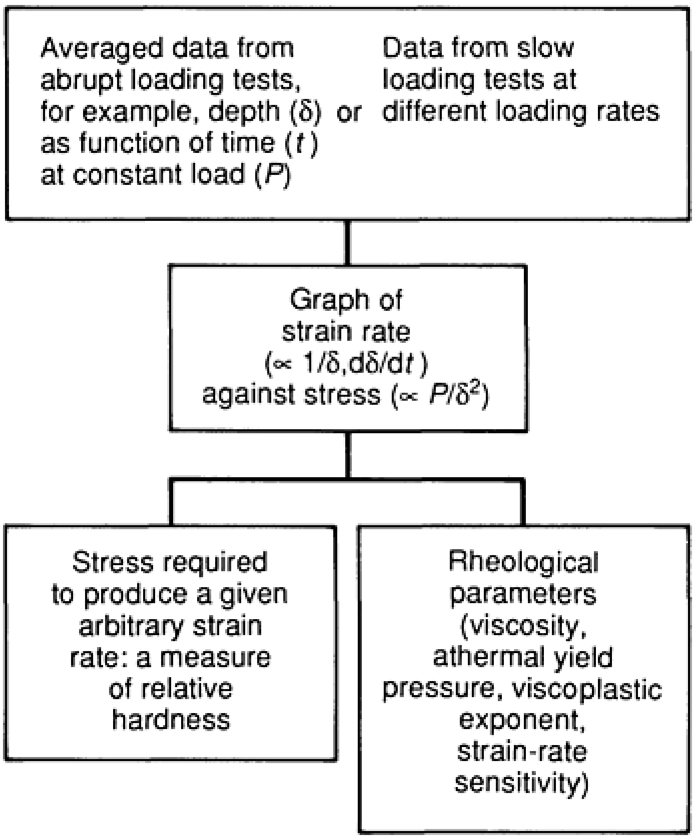

Fig. 14 Flow behavior

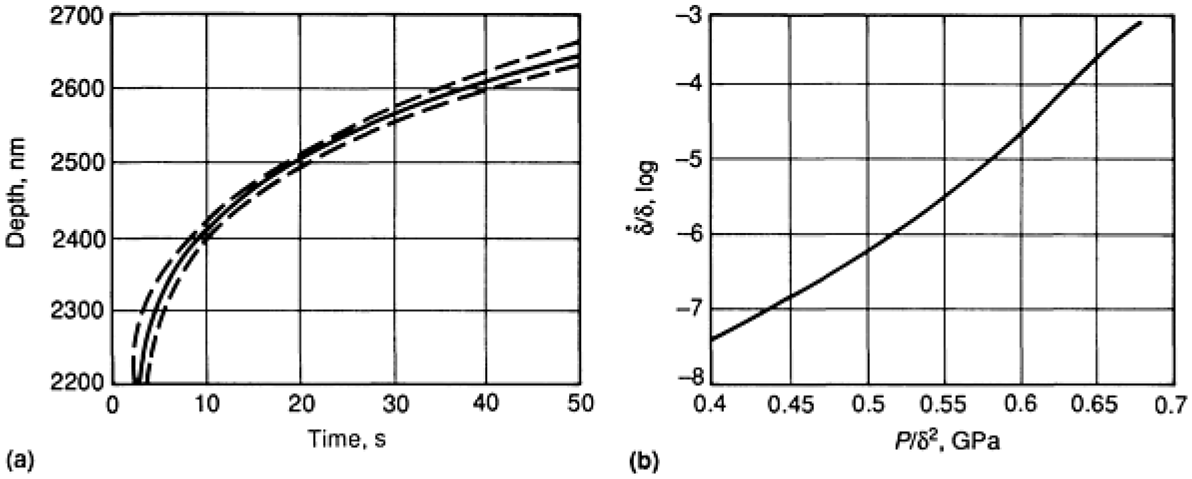

Fig. 15 Indentation creep of sodium chloride. Load, 3.3 mN. (a) Raw data. (b) $\dot{\delta}/\delta$ against P/δ^2

Variations from the above procedure have been described. With servocontrol, it should be possible to maintain $\dot{\delta}/\delta$ constant throughout a test or, alternatively, P/δ^2. Instead of these quantities being measured continuously (Ref 31), or over a small number of time intervals (Ref 57), conventional slow-loading (δ - P) tests at different loading rates have been performed (Ref 5) and analyzed to give information on strain-rate sensitivity.

Time-dependent, but recoverable (anelastic), deformation can be analyzed (Ref 31), following both the initial abrupt increase in load and a subsequent abrupt decrease in load to zero. After the initial plastic deformation appears to be complete, further changes in δ are dominated by recoverable behavior, with negligible further change in stress. Here, following the "flat punch" argument summarized earlier, the value of $\dot{\delta}$ can be taken as an indication of the anelastic strain rate.

Materials whose strain-rate behaviors have so far been studied include superplastic Sn-38% Pb, a nanophase ceramic (TiO_2) of a grain size from 5 to 12 nm, submicron films of Al on Si with both good and poor adhesion, and a polymer, PET. From log-log plots of stress $P/(k_1\delta^2)$ against strain rate $\dot{\delta}/\delta$, the strain-rate sensitivity, *m*, defined as d log(stress)/d log (strain rate), was measured for Sn-38% Pb, and the results supported a core-mantle model of superplastic deformation as an explanation of the observed enhancement of strain-rate sensitivity by grain boundaries (Ref 5).

Nanophase TiO_2 is more strain-rate sensitive than the single-crystal material (Ref 57), suggesting that the material in bulk form could show significant ductility. With a film-substrate system, the yield zone is confined by the interface (Ref 18), and for Al on Si, it was found that with good adhesion, the strain rate was lower at a given stress. Surface layers of PET show an anelastic compliance that fits well to a simple formula characterizing a lightly cross-linked polymer with a broad spectrum of relaxation times (Ref 31). The total recoverable deformation increases at high strain rates. Indentations to depths of less than 300 nm reveal that the near-surface layers are pseudoplastic, the behavior being further from ideal plasticity in the case of PET that has been uniaxially stretched or drawn.

Future Trends

Nanoindentation with continuous depth recording is being increasingly used in the characterization of submicron layers, surface treatments, and fine particles. Modified instruments are used also to measure film stress, thickness, adhesion, scratch hardness, and microfriction. Currently, the technique is best suited to providing a comprehensive quantitative fingerprint of the sample and to comparing it with a control, or reference. This direct information includes work of indentation, relative hardness, elastic compliance, and strain-rate/stress characteristics. There is no universally accepted absolute hardness scale that applies to nanoindentation. With the help of a number of assumptions, it is possible to derive values of intrinsic material properties, such as hardness or modulus, although it is not yet clear to what extent these values depend on test variables, such as the indenter geometry used. Furthermore, time-dependent behavior, for example, the effect of variations in loading rate, tends to be especially noticeable at the submicron scale.

A reading of the recent nanoindentation literature suggests that technical advances are likely to emphasize the following points:

- The processing of indentation creep data as an important aspect of material characterization
- The introduction of a new hardness scale (Ref 14) based on the method of continuous depth recording
- The development of multipurpose nanoindentation instruments that also perform scratch testing, profiling, and measurements of scratch hardness, film stress, friction, and other surface-mechanical properties
- Routine industrial testing, which requires improved automation so that the monitoring of changes in indenter shape, for example, is more reliably performed
- The introduction of specimen heating stages, together with a satisfactory method of compensating for thermal drift

In the longer term, picoindentation instruments are likely to be widely used to extend the technique to a still smaller scale, with the help of techniques developed for atomic force microscopy. Already, plastic deformation at depths of a few atomic layers, as well as the effect of surface forces, have been quantified by means of depth-load measurements, using a point force microscope, that is, an atomic force microscope operated in static (nonscanning) mode (Ref 58).

Appendix 1: Elastic Recovery Parameter

The area under the depth-load curve is related to the work done by the indenter on the specimen. By subtracting the area under the unloading curve from the total area, W_T, the work, W_p, that is retained by the specimen (Fig. 5) is measured. For an elastic material, all the work is released upon unloading, that is, $W_p = 0$ and $\delta_p = 0$. For a plastic material, all the work is retained by the specimen, that is, $W_p = W_T$ and $\delta_p = \delta_T$. If the departure from linearity of the unloading curve is neglected, then:

$$\delta'_e = \frac{2W_e}{P_m} \quad \textbf{(Eq 9a)}$$

and because R is defined as δ'_e/δ_p, with $\delta_p = \delta_T - \delta'_e$, Eq 2 in the preceding article follows directly. Alternatively, $P_m\, d\delta/dP$ can be substituted for δ'_e (Fig. 5), giving Eq 3.

To express R in terms of H and E, it is seen, from Eq 1, that $\delta'_e = (1 - v^2)P/(2Ea)$, and that from the definition of k_1, $\delta_p = a(\pi/k_1)^{1/2}$. Thus, $R = \delta'_e/\delta_p = P/(2Ea^2)(k_1/\pi)^{1/2}$. But, from the definition of hardness, $P/(\pi H)$ can be substituted for a^2, so that Eq 4 follows.

The quantity $H(1 - v^2)^2/E^2$, which is independent of k_1, can be calculated as follows: From Eq 4, $H(1 - v^2)^2/E^2 = 4R^2/(\pi k_1 H)$, and from the definition of k_1 and I_p, $k_1 H = I_p$, so that Eq 7 follows.

Scratch Testing

Staffan Jacobsson, Michael Olsson, Per Hedenqvist, and Olof Vingsbo, School of Engineering, Uppsala University (Sweden)

Introduction

SCRATCH TESTING is a method of mechanically testing a specimen surface. In this method, a hard scratching element (indenter and stylus) is used to generate a groove in the specimen surface. The scratching action may, or may not, be accompanied by the formation of a chip or particles. The general objectives of performing scratch tests in materials research and testing are to:

- Clarify the mechanisms of deformation and/or material removal
- Evaluate or rank materials relative to abrasion resistance
- Measure scratch hardness
- Evaluate the adhesion of a surface coating to a substrate

The results of a scratch test can vary widely depending on the specimen material analyzed. Scratch test effects range from plastic grooving in a ductile material, to chipping in a brittle material, to interfacial deadhesion of a coated specimen.

Types of Scratch Test Devices

Apparatus Classification. Scratch test devices can be organized into three main categories (see Fig. 1):

- *Type 1:* low-speed bench top scratching machines, normally equipped with a stylus to produce a scratch on a flat with a single pass (Fig. 1a), with a reciprocating movement (Fig lb), or with a multiple pass (Fig. 1c)

- *Type 2:* low-speed scratching devices that operate *in situ* in the beam path of a scanning electron microscope (SEM); intended for detailed mechanism studies
- *Type 3:* high-speed scratching machines, which include penduli (Fig. 1d) (Ref 1, 2) and grinding wheels (Fig. 1e) (Ref 3, 4, 5); essentially used for single pass grooving

The categories can be further subdivided into machines for fixed-depth or fixed-load conditions. Type 1 and type 2 machines are usually equipped with deadweight or spring-controlled normal force, and the penetration depth is determined by the load and the deformation resistance of the workpiece material (that is, they are run under fixed-load conditions). In type 3 machines, which generate arc-shaped grooves, the normal force cannot be preset but is instead determined by the selected feed, the position along the groove, and the deformation resistance of the workpiece.

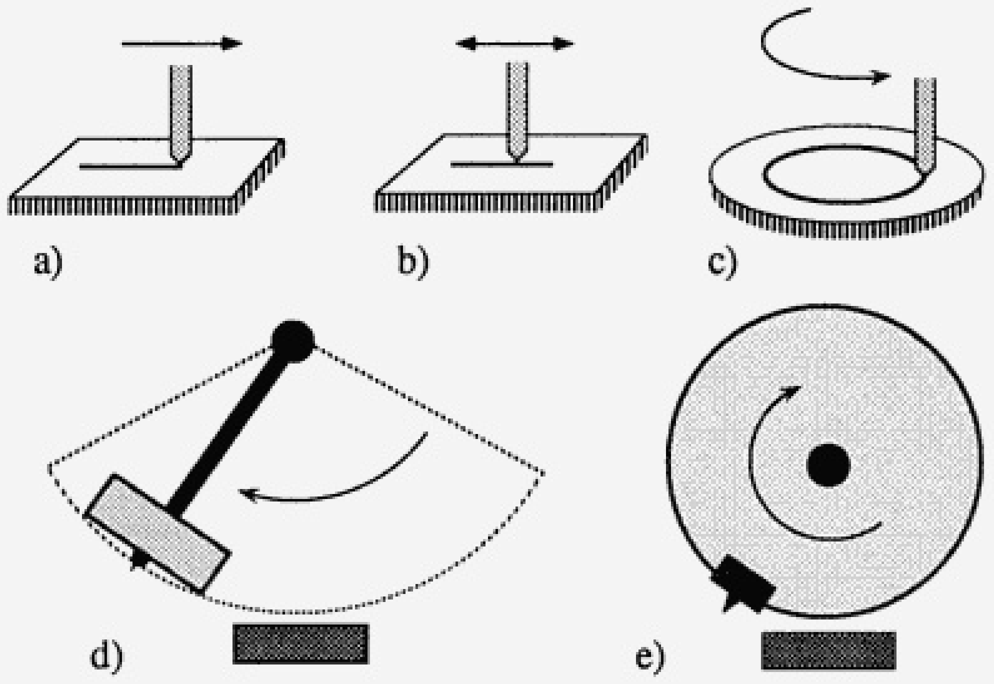

Fig. 1 Schematics showing setup and motion of components in selected scratch test devices. (a) Single pass. (b) Reciprocating. (c) Multiple pass. (d) Modified Charpy pendulum. (e) Modified grinding machine. Devices (a) to (c) are classified as low-speed machines. Devices (d) and (e) are classified as high-speed machines.

Measured Quantities. Many scratch testing devices are equipped with gages for continuous monitoring of the friction force. Furthermore, parameters such as the penetration depth and the acoustic emission are also sometimes monitored. Some methods involve posttest determination of groove shape, groove size, and specific grooving energy.

Scratching Elements. Scratch tip shapes can be classified as:

- Sharp conical
- Spherically rounded conical
- Sharp pyramidal
- Truncated pyramidal
- Irregular (abrasive particles)

Abrasive particles are employed in case studies of abrasive mechanisms, whereas the regular shapes are employed in investigations where maximum control and minimum geometric complexity are desired.

Because it is desirable that the scratching tip maintain its initial shape throughout a test series, it must be tough and substantially harder than the material to be scratched. The tip is ordinarily made of diamond, sapphire, tungsten, cemented carbide, or hardened steel. Rockwell and Vickers hardness test diamonds have well-defined shapes and are easily available. Thus, the Rockwell and Vickers hardness test diamonds have become the most commonly used scratching tools. Furthermore, it has been pointed out (Ref 6) that the width/depth ratio of a service groove typically varies between 5:1 and 50:1, a range that covers values for Vickers or Rockwell indenters.

***In Situ* Scratching Devices.** With the objective of producing detailed high-resolution studies of scratch formation mechanisms, a number of research groups have developed devices for *in situ* scratch testing applications in the beam path of a scanning electron microscope (Ref 7, 8, 9, 10, 11). The capabilities of such a device are shown in Fig. 2 (see the section "Scratch Adhesion Testing of Thin Hard Coatings" in this article). The limited volume of the specimen chamber sets limits on the size of the equipment, and the vacuum requirement of the SEM equipment restricts the use of any fluid lubricants or polymer specimens with a high degassing rate. Furthermore, the SEM technique requires electrically conductive specimens. Insulators can be studied if they are supplied with a conductive coating (for example, a sputtered gold film) prior to the investigation. However, this extra coating may affect the results of the analysis.

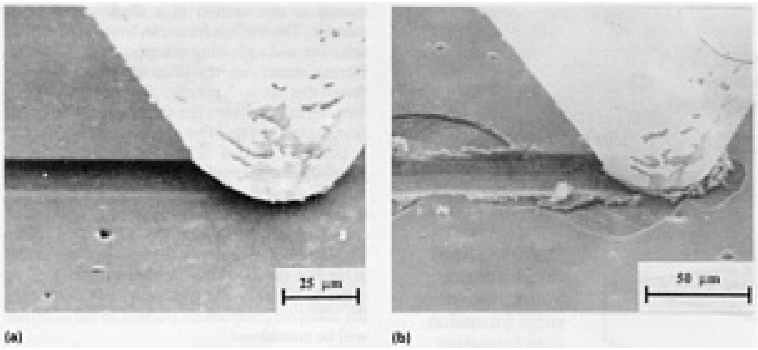

Fig. 2 Scratch channels from an *in situ* scratch testing experiment using an SEM apparatus. (a) $F_N < F_{N,C}$. (b) $F_N > F_{N,C}$. F_N, applied normal force; $F_{N,C}$, critical normal force

The observation of the deformation process with the SEM setup is facilitated if the scratching tip has a fixed position (typically centered on the monitor screen), while the specimen is slowly moved. Because the process is to be observed at high magnifications, the scratching speed has to be reduced to suitable values (for example, at 2000× magnification a speed of 5 $\mu m \cdot s^{-1}$ on the specimen table corresponds to a speed of 10 $mm \cdot s^{-1}$ on the screen).

Quick-Stop Devices. Quick-stop devices make it possible to abruptly stop the scratching action, thereby "freezing" the deformation process. The subsurface microstructure of the quick-stopped specimen is subsequently placed under a microscope to examine the polished and etched cross section of the groove. This technique facilitates highly detailed studies of the deformation mechanisms in front of and under the scratch tip (including the deformation of individual grains and phases, the formation of shear zones, cracks, and dead zones; see Fig. 3). Without the quick-stop technique, these studies would be impossible.

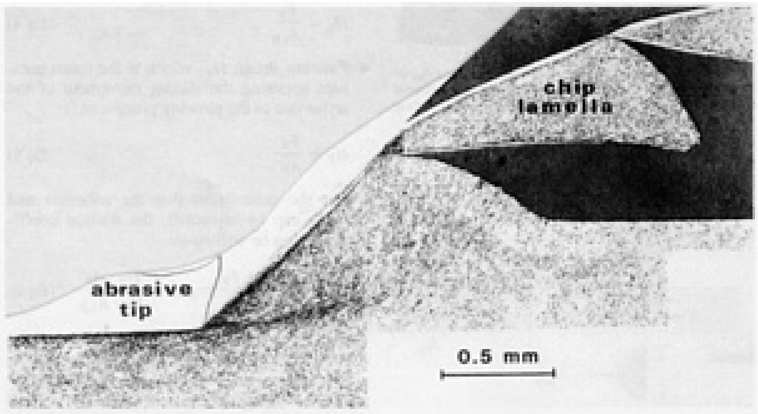

Fig. 3 Light optical micrograph of a cross section through a high-strength low-alloy (HSLA) steel specimen quick-stopped in the Uppsala pendulum. A truncated pyramid cemented carbide tip moving at a speed of 5.6 m/s (18 ft/s) was used as the scratching element.

The quick-stop event must be virtually instantaneous for the test to be relevant. Furthermore, the introduction of vibrations or extra movements must be avoided, or the microstructure of the cross section being examined will not be representative of the preset scratch speed, feed, and so on, but only typical of the braking process alone.

Fundamentals of Scratching Deformation

A large number of parameters interact in a general scratch test (Fig. 4).

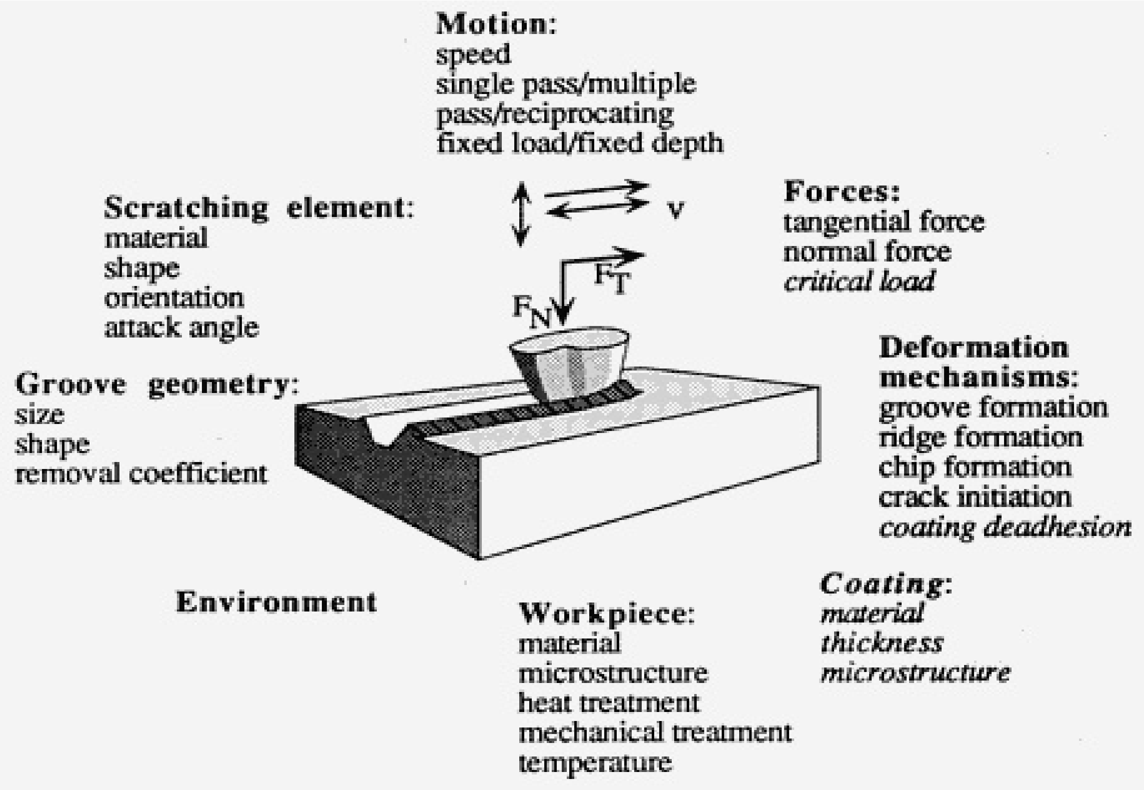

Fig. 4 Schematic showing parameters encountered in scratch testing. F_T, tangential friction force; F_N, normal load, *v*, scratching speed. Parameters in italics are directly associated with surface-coated materials.

The contact geometry at the tip of the grooving element is a function of the following area parameters (Fig. 5, 6):

Area parameter	
Symbol	**Component**
Cross-sectional area	
A_D	Displaced material
A_P	Resulting groove
A_R	Formed ridges
A_W	Removed material
Load-bearing area	
A_{LB}	Vertical projection of the contact area

The first four parameters above refer to cross sections that are perpendicular to the grooving direction (Fig. 5), whereas the fifth parameter is the vertical projection of the contact area (Fig. 6).

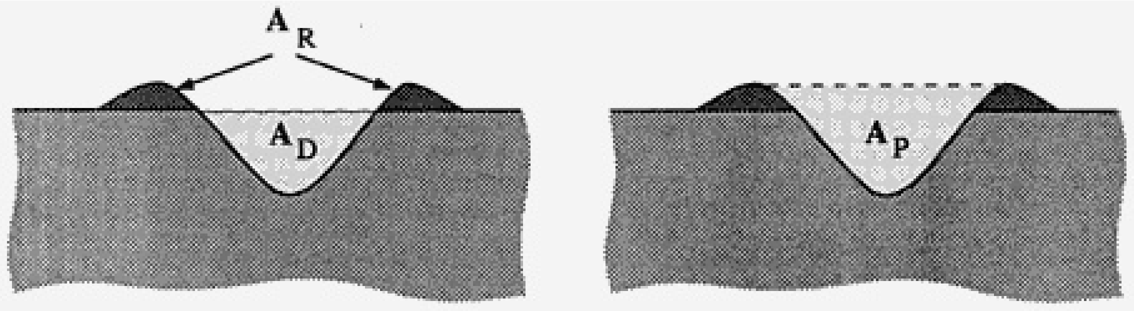

Fig. 5 Cross-sectional area perpendicular to a groove on an initially flat surface. The cross-sectional area A_W of the worn-off material equals A_D - A_R. A_W, cross-sectional area of removed material; A_D, cross-sectional area of displaced material; A_R, cross-sectional area of formed ridges; A_P, cross-sectional area of the resulting groove

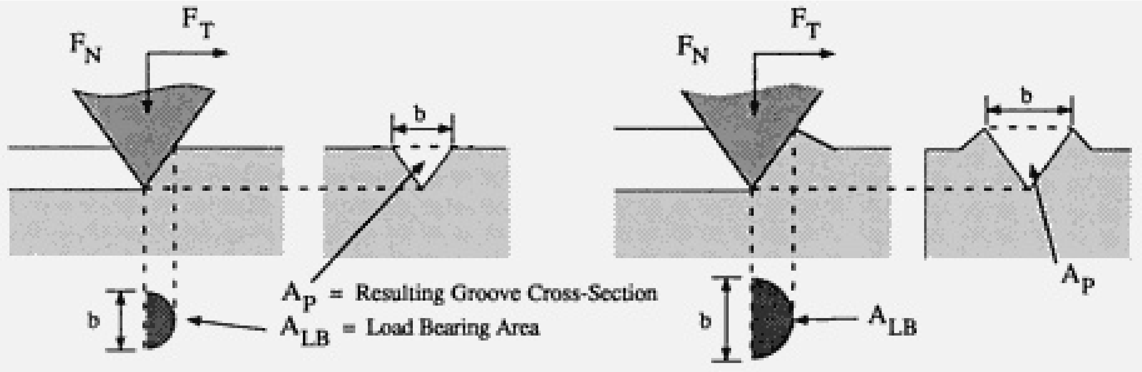

Fig. 6 Effect on load-bearing area, A_{LB}, of scratching with a conical tool. (a) Pure cutting (no ridge formation). (b) A more realistic situation of ridge formation (that is, mixed microplowing and microcutting). b, groove width

Removal Coefficient. The efficiency of material removal of the scratching process can be expressed in terms of the removal coefficient, η, defined as:

$$\eta = \frac{\text{Volume of removed material}}{\text{Volume of displaced material}} = \frac{A_W}{A_D} = \frac{A_D - A_R}{A_D} \quad \textbf{(Eq 1)}$$

Alternative designations for this property are ***degree of wear*** or *abrasive fraction.* The removal coefficient can be used to compare the efficiency of different scratch element shapes or the gage the response of different materials to scratch deformation by forming ridges rather than being worn by chip formation.

Specific Grooving Energy. Another aspect of the efficiency of the material removal process in scratching is the study of the energy required to remove the unit mass of material. This term is often denoted the specific grooving energy, ***e,*** and is defined as:

$$e = \frac{\text{Energy consumed to form the groove}}{\text{Mass of the removed material}} \quad \textbf{(Eq 2)}$$

(Alternatively, the specific grooving energy could be defined as the energy required to remove the unit volume of material.) The specific grooving energy varies with the material as well as with the groove size. Similar to the removal coefficient, the specific grooving energy can be used to relate the performance of different shapes of scratching elements, and to evaluate the response of different materials. Specific grooving energy can also be used to study the influence of groove size on abrasion resistance.

The specific grooving energy is, in fact, the inverse of grindability, a quantity that is often used in the science and practice of grinding. Furthermore, e essentially corresponds to the integral of the specific cutting force k_s, a notation mainly used by the metal cutting industry

Relation of Friction to Scratching Deformation. The process of plastic deformation of material during a scratch test is more complex than that during indentation and will be discussed in this section in a slightly simplified manner. The friction force can be divided into an adhesive and a plowing component (Ref 12, 13). During scratching, the presence of deformation forces that act both parallel and perpendicular to the interface between the stylus and the material being scratched must be determined (Fig. 6).

Under the action of parallel forces, adhesive junctions are sheared and material will flow relative to the stylus. These shear forces constitute the adhesive friction component, F_A, of the total tangential friction force, F_T. Generally, these forces do not necessarily act only in a tangential plane but can also have normal components. In order to simplify the treatment, however, only the adhesive components parallel to the interface will be considered.

The forces acting in a direction normal to the contact surface correspond to the flow pressure of the deformed material as it undergoes deformation. In the present simplified treatment, the vertical flow pressure component is considered to represent the normal load, F_N, and the tangential component constitutes the plowing component of friction, F_P. Provided that the two friction components do not interact, the friction force can be defined as:

$$F_T = F_A + F_P \quad \textbf{(Eq 3)}$$

The sliding contact area can be projected on planes perpendicular to the normal force and on planes perpendicular to the tangential force to give the load-bearing area, A_{LB}, and the scratch cross-sectional area, A_P, respectively (Fig. 6). Those elements of the stylus/workpiece contact area (that correspond to contact against the ridges and against the prow, respectively), are normally included in the projected areas, because they are supposed to contribute to the resistance to deformation. Two stresses may then be defined:

- Scratch hardness, H_S, which is the load per unit load-bearing area (that is, the mean pressure resisting deeper penetration):

$$H_S = \frac{F_N}{A_{LB}}$$ **(Eq 4)**

- Plowing stress, H_P, which is the mean pressure opposing the sliding movement of the stylus due to the plowing process only:

$$H_P = \frac{F_P}{A_P}$$ **(Eq 5)**

-

Under the assumption that the adhesion and plowing can be separated, the friction coefficient, μ, can be written as:

$$\mu = \frac{F_T}{F_N} = \frac{F_A + F_P}{F_N} = \mu_A + \frac{H_P \cdot A_P}{H_S \cdot A_{LB}}$$ **(Eq 6)**

where μ_A is the adhesional component of the friction coefficient. In friction experiments in which the plowing term of the friction is considered to be negligible, Amonton's law is obeyed (that is, the friction coefficient is independent of load). Therefore, it is reasonable to assume that μ_A is generally independent of load and groove size, and that any variation in μ will be due to variations in the plowing term.

In a non-working-hardening material, the plowing stress should be approximately equal to the scratch hardness. However, it has been found (Ref 7) that for annealed polished surfaces the H_P/H_S ratio is ~2 for both microscopic and macroscopic experiments. Furthermore, the H_P/H_S ratio is independent of the scratch width. (It appears that $H_P > H_S$ indicates a higher degree of work hardening in the zone immediately in front of the slider than in the zone underneath it. However, abraded or ground materials are known to be fully work hardened throughout the superficial layer, and thus the work hardening should be the same under and in front of the slider, which would correspond to an H_P/H_S ratio close to unity.)

Assuming that the H_P/H_S ratio has a constant value, *c*, independent of the scratch geometry, the expression for $\mu$is reduced to:

$$\mu = \mu_A + c\ \frac{A_P}{A_{LB}}$$ **(Eq 7)**

The complex load, material, and geometry dependence of this sum has been analyzed for a number of well-defined scratching element shapes of Goddard and Wilman (Ref 13). The friction coefficient was calculated as a function of scratching element shape, orientation, and penetration depth for spherical elements, cones, triangular pyramids, and square pyramids. In addition, Goddard and Wilman also discussed the coupling to actual abrasion.

Scratch Testing of Monolithic Solids

Although scratch testing of bulk material can be performed with numerous objectives, these objectives can be grouped into three categories:

- Scratch hardness evaluation
- Scratching mechanism studies
- Abrasion resistance measurements

Scratch Hardness. Mineralogists and lapidaries have used scratch tests for some time to assess the hardness of stones and minerals.

Mohs Hardness Scale. In 1824, Mohs proposed his famous scale of ten minerals, chosen so that each mineral will scratch all the minerals positioned below it on the scale, but none of the minerals above it on the scale (Ref 14):

Mineral	Hardness	
	Mohs	**HK**
Talc	1	. . .
Gypsum	2	32
Calcite	3	135
Fluorite	4	163
Apatite	5	360[(a)], 430[(b)]
Orthoclase	6	560
Quartz	7	710[(a)], 790[(b)]
Topaz	8	1250
Corundum	9	. . .

(a) Parallel to axis.

(b) Perpendicular to axis

The Mohs hardness of a workpiece or raw material is determined by attempting to scratch it with pieces of the different reference materials. The Mohs hardness number is determined to be the number of the hardest of the reference minerals that fails to produce a scratch on the specimen.

The scale might seem rather arbitrary, but it has been shown by Tabor (Ref 15) to have scientific relevance. It has been shown that in order for one piece of material (shaped as a sharp point) to scratch a flat of another material, it must have an indentation hardness of [ges]1.2 times that of the material of the flat. Thus, any comparative scratch hardness scale such as the Mohs scale must be logarithmic and expressed in indentation hardness numbers with the smallest possible factor between consecutive numbers being 1.2 (that is, every basic material has to be at least 1.2 times harder than the preceding one).

Tabor has shown that the Mohs scratch hardness scale, with the exception of the corundum-to-diamond interval, very closely follows the logarithmic relation to indentation hardness. However, the ratio of indentation hardness for each Mohs number interval is ~1.6. Thus, each increment in the Mohs scale corresponds to a 60% increase in indentation hardness (Knoop or Vickers) and the scale is less accurate than it could ideally be.

State-of-the-Art Scratch Hardness Technology. Scratch hardness was defined above as the load per unit load-bearing area during scratching, taking into account the formation of ridges and a prow (Fig. 6). Because it is generally difficult to measure the load-bearing area during the scratching experiment, it is calculated from the width of the scratch obtained after the test is completed. It is obvious that measurements of the prow that forms in front of the scratching tip poses a problem. As an approximation, it is normally assumed that the prow and the ridges have the same height.

Using this assumption, the scratch hardness can be expressed in terms of the groove width, *b*, for any well-defined scratching tip configuration. This expression varies with tip geometry. For tips of circular cross-sectional area (cones, spheres, and parabolas) the equation is:

$$H_S = \frac{8F_N}{\pi b^2} \quad \textbf{(Eq 8)}$$

For square-base pyramids of leading-edge or leading-face orientation, the equation is:

$$H_S = 4 \frac{F_N}{b^2} \quad \textbf{(Eq 9)}$$

Similar to ordinary quasistatic indentation hardness, scratch hardness is dependent on the shape of the scratching element. This dependence is primarily due to the effect of scratching element shape on prow formation (that is, the size and the extent of upward flow and flow surrounding the tip). Square-base pyramids of leading-face orientation constitute a specific problem because it is not known which faces carry the load: the front face alone, or the front face in combination with the two side faces. Experimental evidence has been presented for both contact situations (Ref 16, 17), and factors such as material selection and experimental design are of major importance. Therefore, this orientation is not recommended for scratch hardness measurements.

One major advantage of scratch hardness testing is that, for very shallow deformations, it is substantially easier to accurately measure the width of a long scratch than to measure the diagonal of an indentation. Long ridges are simply much easier to discern than the outermost corners of an indentation. Thus, scratch testing yields better conditions for testing small structures and very thin surface layers.

Another advantage of scratch hardness relative to indentation hardness measurements is the possibility of studying hardness variations along the scratch. The hardness of different phases (for example, the hardness depth profile caused by deformation hardening or case hardening, or even hardness differences between different crystallographic orientations) can be determined by making one single scratch (Ref 18). The relative hardness changes are easily monitored using a microscope or film records, that is, micrographs. The absolute values at specific positions can be calculated by measuring the groove width and by applying the appropriate hardness formula.

Furthermore, if the hardness value is used to predict abrasion resistance, scratch tests, because they are akin to the abrasion process in many respects, should correlate better than ordinary indentation measurements (Ref 19).

Scratching Mechanisms. Various kinds of scratch tests have proved to be successful in studies of detailed deformation and removal mechanisms. Because both grinding and abrasive wear are functions of the cumulative action of individual grits, scratch testing is a valuable tool to gain understanding of these processes.

The parameters studied include:

- Interrelations between grinding experiments and scratch testing using Rockwell and Vickers diamonds (Ref 6)
- Side wall stripping as a mechanism of material removal during abrasion (Ref 20)
- Mechanisms of carbide removal in white cast iron, including the influence of multiple passes over a preworn surface (Ref 11)
- Transitions between different chip shapes as the one angles of conical scratch tools are varied
- Formation and effect of a stagnant zone ahead of the scratch tool (Ref 5)

In general, it has been determined that material is more easily removed with repeated traversals as opposed to a single scratch across a polished surface (Ref 6).

Size Effects. In an investigation of scratch deformation *in situ* in a scanning electron microscope, Gane and Skinner (Ref 7) used a spherically rounded tungsten stylus with a tip radius of ~1 μm (~40 μin.) to carry out microfriction experiments on gold and copper materials. They determined that H_S rises steeply with decreasing groove sizes. For a groove width of ~0.3 μm (~12 μin.), hardness values were three to five times the bulk hardness. This size effect is also well known from static indentation investigations, but was found to be much more pronounced under scratch deformation testing.

The H_P/H_S ratio was ~2 and independent of the scratch width. At the smallest scratch sizes, the plowing stress H_P was even found to approach the theoretical strength of the perfect crystal. It would seem likely, therefore, that a limit has been reached, and that any further reduction in size would not lead to any appreciable increase in hardness.

The coefficient of friction was found only to exhibit the size dependence generated by the term A_P/A_{LB}, as predicted by Eq 7. This is a direct result of the proportional increase in H_P and H_S for small groove sizes.

Abrasion Resistance. Scratch testing has been adopted to investigate or rank the resistance to abrasive and grooving wear. Two different approaches are described here:

- One method employs scratch testing to estimate the removal coefficient of materials and uses this number and the hardness of the material in the fully strain hardened condition to make a criterion better correlated to the abrasion resistance than a plain hardness value
- Second method employs the concept of specific grooving energy to obtain rankings of competitive grooving resistant materials

Correlation Between Scratch Hardness and Abrasion Resistance. It is known that the abrasion resistance of pure metals is very closely proportional to their indentation hardness, *H*. However, this in not necessarily the case for alloys in which the hardness values are varied by heat treatments (Fig. 7). However, Zum Gahr (Ref 21, 22) has shown that the proportionality is more prominent if an increase in hardness is obtained by heavy work hardening of the material (H_{def} in Fig. 7b), instead of by heat treatments. It is possible to assess H_{def}, for example, by measuring the hardness of microchips formed under abrasion. Additional improvement of the linear relation is achieved by using the H_{def} value and further compensating for the material removal (that is, considering the ability of the material to respond to the engagement of a scratching tool by forming ridges rather than wear fragments or microchips). Because it is difficult to measure the removal coefficient during abrasion, Zum Gahr employed a scratch test to make an estimate. Single scratches on initially flat surfaces were made using a scratch diamond with an attack angle of 90°, a tip radius of 8 μm (320 μin.) and loaded by 2 N (0.2 kgf). The cross-sectional geometry of the grooves was subsequently measured and the removal coefficient calculated according to Eq 1. The acquired value, f_{ab}, is not identical to the average removal coefficient of real abrasion, which corresponds to more complicated abrasive element shapes and is performed on surfaces of irregular topography, and so on. Furthermore, because the f_{ab} value is determined by single-pass scratching, the ability of the ridges to withstand deformation from a subsequent scratching event is not considered. Still, this estimate of the removal coefficient has been shown to have good relevance, and a substantially improved proportionality is shown by plotting the abrasion resistance versus H_{def}/f_{ab} (Fig. 7c). Comparing Fig. 7(b) and 7(c) also shows that if two materials have the same H_{def}, the composition with the lowest f_{ab} value will have the best abrasion resistance.

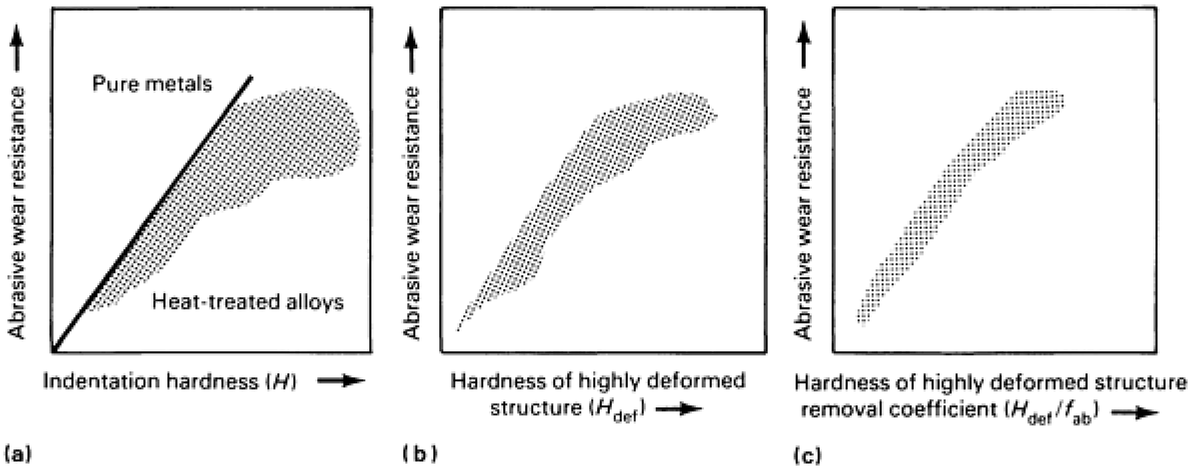

Fig. 7 Plots showing the correlation between abrasive wear resistance and selected hardness parameters. (a) Indentation hardness. (b) Hardness of a highly deformed structure. (c) Hardness of a highly deformed structure divided by the removal coefficient, f_{ab}. The individual results are continued to the shaded areas.

Specific Grooving Energy. Vingsbo *et al.* (Ref 1, 2) have used a pendulum tester and the concept of specific grooving energy to rank materials relative to resistance against grooving wear. In the pendulum test, a series of grooves of increasing size are produced, the corresponding mass losses, *w*, are weighed, and the consumed amounts of energy, *E*, are recorded. The specific grooving energy is defined as:

$$e = \frac{E}{w} \quad \textbf{(Eq 10)}$$

Figure 8 is a plot of log *e* versus log *w* and is used to rank different materials, based on the assumption that a high specific energy is directly related to a high resistance against grooving wear.

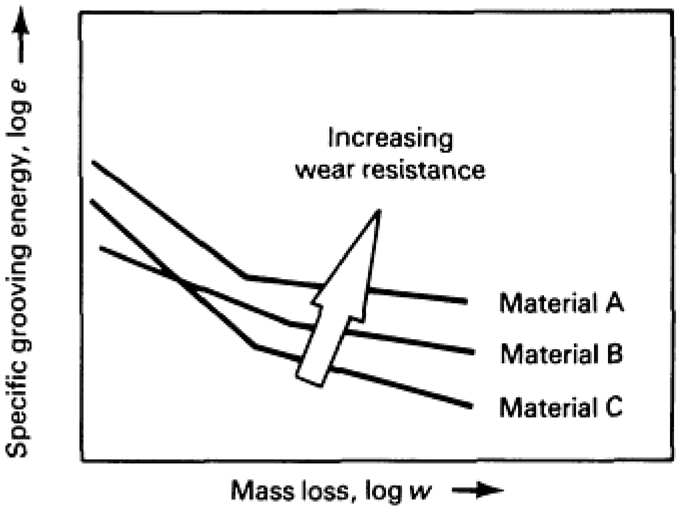

Fig. 8 Plot of specific grooving energy versus mass loss (abrasive wear) for three different materials

Based on Fig. 8, *e* will vary with *w* (groove size) not only relative to material, but also relative to groove size (that is, the character of the abrasive attack). Thus, a material that has the best resistance against coarse grooving wear does not necessarily have the same ranking relative to careful grinding or polishing.

Additional advantages of the pendulum technique are:

- Low experimental scatter
- A wide groove size interval
- Scratching speeds typical of wear parts in many service applications (for example, mining equipment, road grading blades, or excavator teeth)

Scratch Adhesion Testing of Thin Hard Coatings

Thin, hard wear-resistant coatings are today successfully employed in various engineering applications. However, if the adhesion of the coating to the substrate is insufficient, premature failure of the coated part may occur because of coating detachment by interfacial delamination or fracture. Thus, evaluation of coating adhesion is a key issue, and relevant test methods are sorely needed. Despite the publication of more than twenty methods on adhesion testing available in the literature, the authors of three independent review papers (Ref 23, 24, 25) on adhesion testing have all arrived at the conclusion that the only methods applicable to hard well-adherent coatings are the laser photoacoustic shockwave test (Ref 26) and the scratch adhesion test (Ref 27). Today, the scratch test is by far the most widely used because it is easy to perform and also yeilds comparatively fast results. A contributing factor to the popularity of the scratch test is the availability of commercial equipment (Fig. 9) from several manufacturers (Ref 28, 29). As of today, the scratch adhesion test is not standardized but standard initial work in terms of round-robin experiments have been performed (Ref 30, 31).

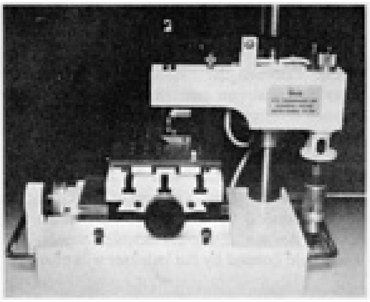

Fig. 9 A typical commercial scratch testing apparatus.

Test Equipment and Procedures. During the scratch test, a diamond stylus is made to slide over the coated surface (Fig. 10). The applied normal force, F_N, is increased stepwise or continuously (Fig. 11) until the coating is detached. The normal force that produces coating failure is known as the "critical normal force," $F_{N,C}$, and is used as a measure of the adhesion. Figures 2(a) and 2(b) show typical resulting scratches for a normal force $<F_{N,C}$ and $>F_{N,C}$, respectively. The onset of peeling can be monitored by optical microscopy, acoustic emission, and friction force measurements (Ref 32), and it has been suggested that the $F_{N,C}$ transition is directly associated with the sudden increase in the friction force and acoustic emission readings (Ref 28, 29).

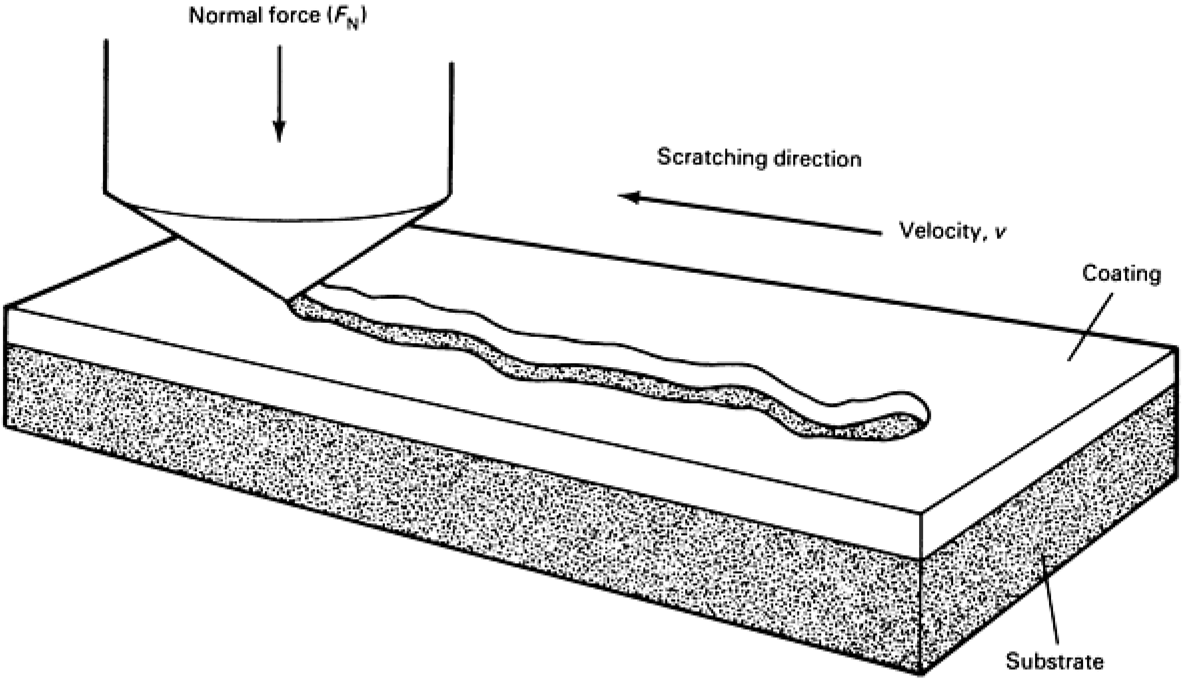

Fig. 10 Schematic showing typical deformation generated by diamond stylus sliding over a coated surface

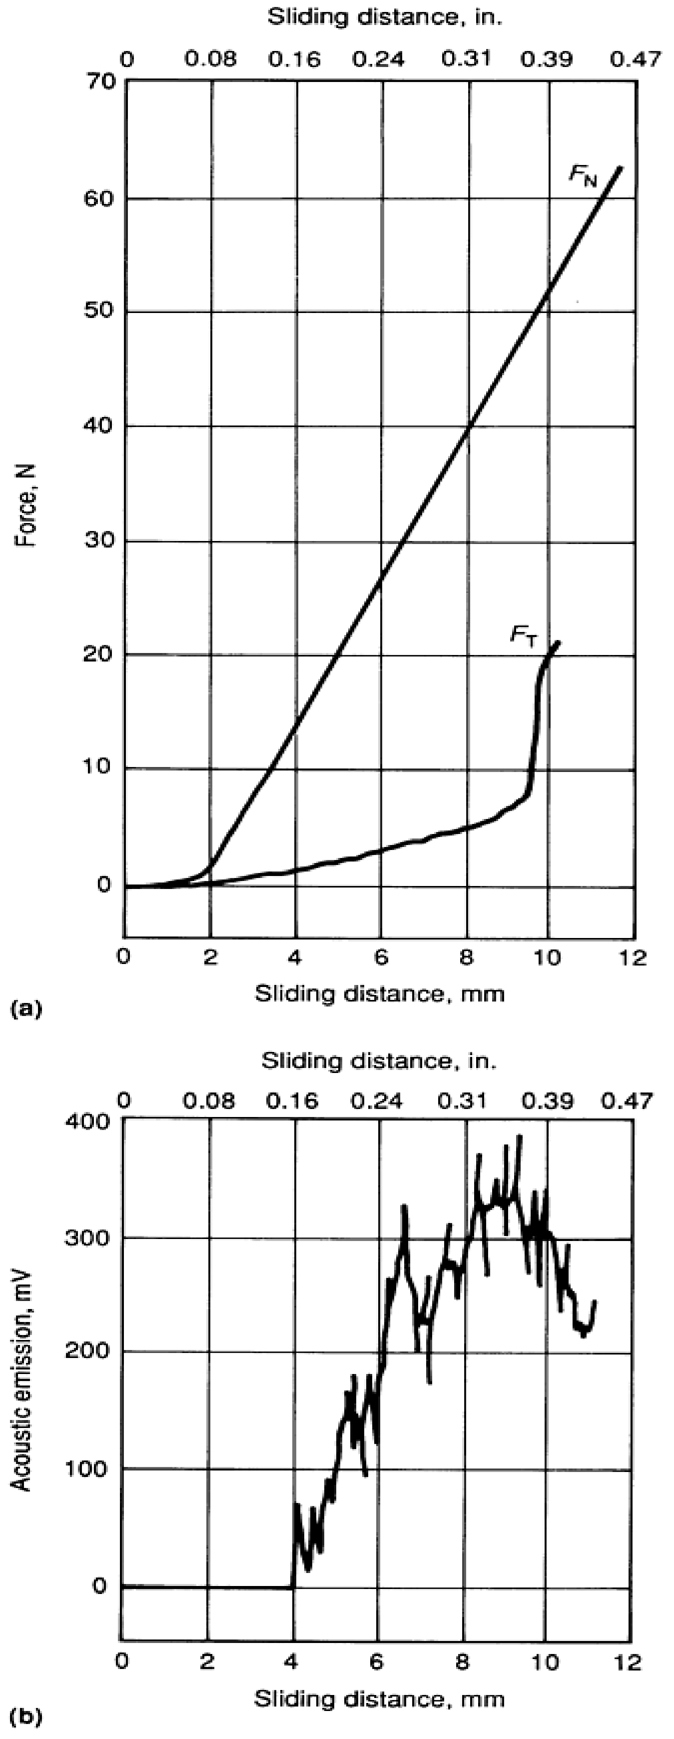

Fig. 11 Monitoring of peeling of a coating during a scratch test by two methods. (a) Friction force measurement. (b) Acoustic emission testing. Source: Ref 23

The most straightforward method for monitoring scratch testing in continuous load tests is optical microscopy. The distance from the start of the scratch to the failure site can be measured and directly related to the normal force. In principle, any optical microscope can be used to perform this measurement, but a microscope integrated with the test equipment is obviously advantageous.

The friction force detector (a strain gage transducer) detects the change in friction force when the coating is detached. Valli *et al.* (Ref 33) have found this method to be more sensitive in detecting coating failure, particularly for very thin (0.1 μm, or 4 μin.) coatings, than the other methods. A typical friction force trace is shown in Fig. 11. The acoustic detector (an accelerometer, basically measuring mechanical vibrations) is mounted above the stylus and detects the onset of coating detachment through the accompanying shock wave bursts (Fig. 11). However, neither of the latter two detection methods has proved completely reliable. Therefore, a posttest examination of the scratch should always be performed (Ref 23, 34).

Attempts have been made to line $F_{N,C}$ with the adhesion of the coating, using approaches ranging from pure plasticity theory (Ref 35) over elastic-plastic models (Ref 36, 37, 38) to models based on the release of strain energy during the removal of a coating (Ref 39, 40). The latest and most successful attempt has been made by Bull *et al.* (Ref 4), using the relation:

$$F_{N,C} = \frac{A_1}{\nu_c \mu_C} \left(\frac{2E_c W_{12}}{t} \right)^{1/2} \quad \textbf{(Eq 11)}$$

between adhesion and $F_{N,C}$. Here A_1 is the cross-sectional area of the scratch; v_c is the Poisson's ratio of the coating material; μ_C is the coefficient of friction at $F_{N,C}$; E_c is the Young's modulus of the coating; t is the thickness of the coating; and W_{12} is the work of adhesion. W_{12} is given by:

$$W_{12} = \gamma_1 + \gamma_2 - \gamma_{12} \quad \textbf{(Eq 12)}$$

where γ_1 and γ_2 are the specific surface energies of coating and substrate, respectively, and γ_{12} is the interfacial specific free energy.

However, the work of Bull *et al.* concentrates on one particular type of failure (ahead of the moving indenter), and the results will only apply when tensile stresses, which are normal to the surface, cause coating detachment. Because a number of possible failure mechanisms have been identified (Ref 34, 37), the number of coating/substrate systems that can be studied using this approach is limited.

Parameters Affecting $F_{N,C}$. Because the $F_{N,C}$ value is affected by numerous parameters related both to the testing conditions and to the coating/substrate systems being investigated (Ref 23, 28, 29, 34, 42), it cannot be directly related to the strength of the coating/substrate interface. In addition, the correlation between scratch test data and actual coating performance in practical applications is often poor. Attempts to quantitatively express adhesion in terms of critical normal force are also made more difficult. However, the influence of some parameters, such as temperature, humidity, and so on, still remains to be investigated.

Substrate Hardness and Coating Thickness. The influence of these parameters on the $F_{N,C}$ value has been thoroughly investigated (Ref 23, 28, 34, 43, 44, 45). It has been shown that the $F_{N,C}$ values increases both with increasing substrate hardness and with increasing coating thickness (Fig. 12).

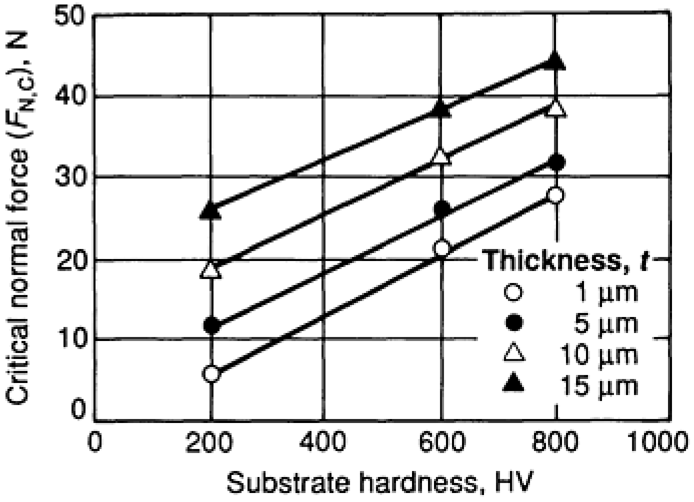

Fig. 12 Plot of critical normal force versus substrate hardness for selected thicknesses of chemical vapor deposition (CVD) TiC coatings on various steels. Source: Ref 28

Coating Surface Roughness. During scratch tests on commercially available inserts for cutting tools, it has been shown that the critical normal face may depend on the coating surface roughness. In particular, $F_{N,C}$ values determined on coated inserts with a high surface roughness (R_a ≥0.3 mm, or 12 μin., where R_a is the arithmetic average surface roughness) have no significance because such coatings have failures that occur mainly within the coating itself (cohesive failures) (Ref 42) and not at the coating/substrate interface.

Substrate Roughness Prior to Coating. The exact influence of substrate roughness on the $F_{N,C}$ value is difficult to determine because differences in surface roughness affect both the efficiency of the cleaning operation used and the adhesive properties of the coatings. However, studies have found (Ref 42) that the critical normal force have decreases with increasing surface roughness of the substrate (Fig. 13).

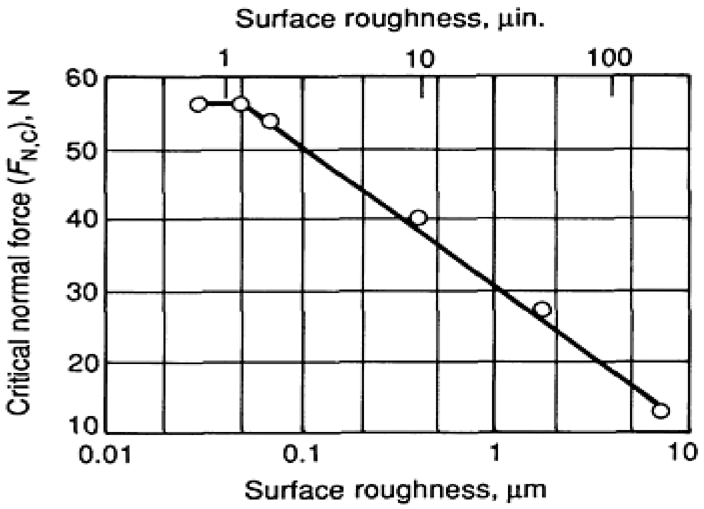

Fig. 13 Plot of critical normal force versus substrate surface roughness obtained for physical vapor deposition (PVD) TiN-coated high-speed steel (HSS) samples that have been subjected to different surface preparations.

Coating thickness was 2 μm (80 μin.). Source: Ref 42

Loading Rate and Scratching Speed. $F_{N,C}$ has been found to be independent of both loading rate (dF_N/dt) and scratching speed (dx/dt), provided that the ratio dF_N/dx remains constant (a "standard" dF_N/dx ratio is 10 N/mm). If the loading rate, dF_N/dx is kept constant, $F_{N,C}$ decreases when the scratching speed increases (Fig. 14a); when the scratching speed remains constant, $F_{N,C}$ increases with increasing loading rate (Fig. 14b). Furthermore, it has also been noted that a high loading rate results in a high experimental scatter.

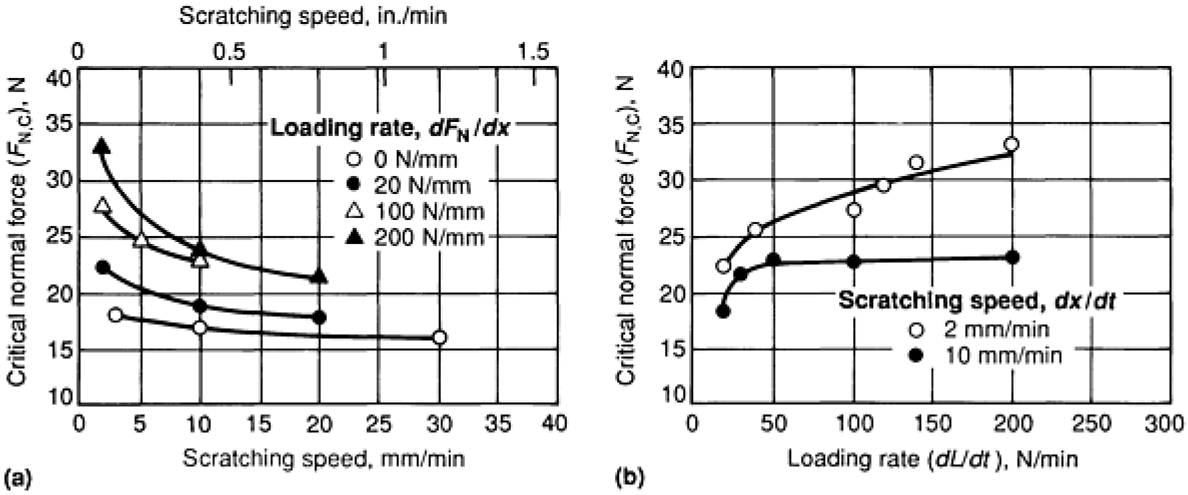

Fig. 14 Variation in $F_{N,C}$ measured on CVD TiC-coated steel. (a) Plot of $F_{N,C}$ versus scratching speed for selected loading rate values. (b) $F_{N,C}$ versus loading rate for selected scratching speeds. Source: Ref 42

Diamond Tip Radius. Theoretically, $F_{N,C}$ should be proportional to R^2 (Ref 42), where R is the diamond tip radius. However, experimental results vary from $R^{0.85}$ to $R^{1.55}$ for different dF_N/dx ratios and coating/substrate system. The most common R value is 200 μm (0.008 in.), which is given by the geometry of the HRC hardness test. Hamersky (Ref 46) has shown this to be the lowest value of R possible for accurate test results. However, his work was limited to aluminum films on glass substrates, and some doubt still exist about its relevance for hard coatings on hard substrates.

Friction Between Indenter and Coating. The friction between the indenter and the coating plays an important role (Ref 23, 28, 33, 42) because different friction coefficients yield different stress fields in the specimen ad thus will have different effects on the critical normal force.

Diamond Tip Wear. Obviously, the condition of the diamond tip will affect the scratch test results. As the diamond indenter wears, the stress field created by the indenter will change.

Surface Temperature Measurement

Francis E. Kennedy, Jr., Thayer School of Engineering, Dartmouth College

Introduction

SLIDING FRICTION results in a loss of mechanical energy, and past studies have shown that the vast majority of frictional energy is transformed into heat. This frictional energy dissipation takes place in the immediate vicinity of the real area of contact, where frictional interactions occur. The transformation of frictional energy into heat, a process known as "frictional heating," is responsible for increases in the temperatures of the sliding bodies, especially in the contact region. Frictional heating and the resultant contacting temperatures can significantly influence the tribological behavior and failure of sliding components. Surface and near-surface temperatures can become high enough to cause changes in the structures and properties of the sliding materials, oxidation of the surface, and possibly even melting of the contacting solids. Therefore, it is important to be able to predict and/or measure the temperatures of sliding contacts. Analytical methods for surface temperature determination are discussed in the article "Frictional Heating Calculations" in this Volume. This article will concentrate on experimental techniques for the measurement of surface and near-surface temperatures in contacting bodies.

A description of the geometric and temporal conditions under which such temperatures occur is useful background information. As shown in Fig. 1, there are three levels of temperature in sliding contacts. The highest contact temperatures, T_c, occur at the small (perhaps on the order of 10 μm diam) contact points between surface roughness peaks or asperities on the sliding surfaces. These temperatures can be above 1000 °C (1830 °F), but last only as long as the two asperities are in contact, possibly less than 10 μs. The asperity contacts are often confined to a small portion of the surface of the bodies, termed the "contact patch." An example of this is a typical elliptical Hertzian contact area several hundred micrometers in length between the ball and the ring in a rolling-element bearing. At any instant, there are usually several short-duration contact temperatures (T_c) at the various asperity contact points within a contact patch. The integrated (in space and time) average of the temperatures of all points within the contact area is the "mean contact temperature" (T_m). The mean contact temperature can be above 500 °C (930 °F) for severe sliding cases, such as in brakes, but is usually much lower. The temperature diminishes as the distance from the contact patch increases, and it generally reaches a rather modest "bulk volumetric temperature" (T_b) several millimeters into the contact bodies. That temperature is generally less than 100 °C (210 °F). It might be noted that the flash temperature originally discussed by Blok (Ref 1) and used in the article "Frictional Heating Calculations" in this Volume is defined as $T_f = T_c - T_b$.

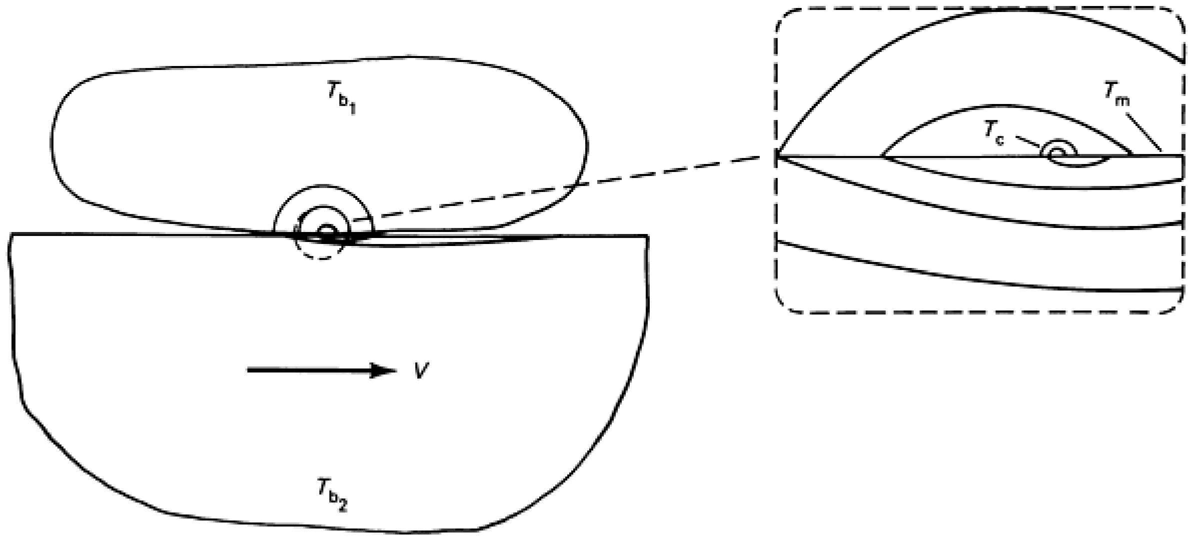

Fig. 1 Schematic diagram of temperature distribution (isotherms) around sliding contacts

Many experimental techniques for surface temperature measurement have been used, with varying degrees of success, to study the temperatures that result from frictional heating. Most of the techniques have geometric or temporal limitations that prevent their use for measuring all three levels of sliding surface temperature. The more successful techniques will be described below.

Metallographic Techniques

Examination of the microstructures of sections of bodies that have undergone frictional heating can provide information about the temperatures the bodies witnessed in service. Such metallographic techniques generally measure the microstructural changes that result from the surface and near-surface temperatures. These changes can be detected after metallurgical sectioning of the sliding body in a plane normal to the sliding direction. For some materials, etching of the near-surface region of the cross-sectioned body reveals a visible change in microstructure (Ref 2). For other materials, microhardness surveys are effective for determining the near-surface temperature distribution that the material witnessed in service (Ref 3). In either case, the temperature contours are constructed by comparing the hardness or structural appearance variations with those of standard reference specimens heat treated to known temperatures for known lengths of time (Ref 2).

An example of the use of this microstructural technique is shown in Fig. 2 (Ref 3). Figure 2 shows an etched cross section of a high-speed steel cutting tool after cutting iron for 30 s at a speed of 3 m/s (10 ft/s). The material beneath the cutting face of the tool was tempered as a result of frictional heating. Figure 3 illustrates the temperature contours developed by comparing the tempering effects in the tool with those in specimens of the same material (M34 high-speed steel) that were heated to known temperatures for the same length of time.

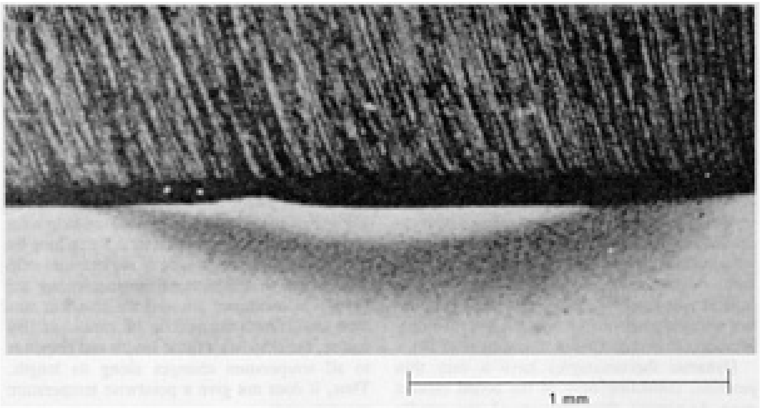

Fig. 2 Metallographic section through the cutting edge of a high-speed steel tool used for cutting iron for 30 s, with adhering chip. Section was etched in 2% nital for 30 s and shows heated region beneath rake face. Cutting speed: 3 m/s (10 ft/s). Source: Ref 3

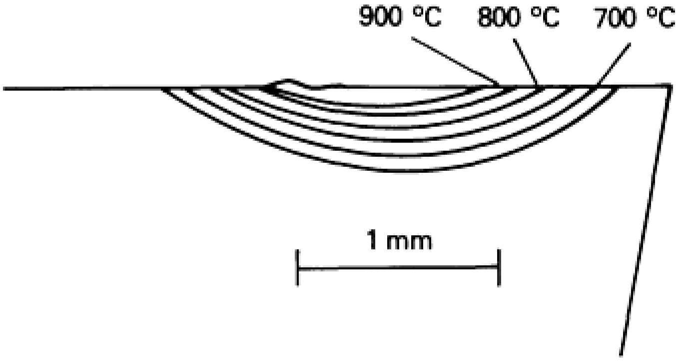

Fig. 3 Temperature contours for the cutting tool shown in Fig. 2. Source: Ref 3

Metallographic techniques generally require destruction of the sliding body for sectioning. Such postmortem investigations can yield substantial information about the mean surface and bulk volumetric temperatures that occurred in the sliding body during service. They can be used successfully only with materials that undergo a known change in microstructure or microhardness at the temperatures encountered in sliding. For the temperature contours to be accurate, the microstructural transformation of the material must be relatively unaffected by the contact stresses and temperature transients that occur at the sliding interface. Metallographic techniques cannot measure short-duration contact temperatures (T_c), nor can they measure temperature at a given instant during the sliding process.

Thermocouples and Thermistors

Thermocouples are probably the most commonly used sensors for measuring the temperatures caused by frictional heating. Their operation is based on the findings of Seebeck, who in 1821 demonstrated that a specific electromotive force (emf) potential exists as a property intrinsic to the composition of a wire whose ends are kept at two different temperatures. The simplest measuring circuitry for thermocouple thermometry involves wires of two dissimilar metals connected so as to give rise to a total relative Seebeck potential. This emf is a function of the composition of each wire and the temperatures at each of the two junctions. This circuit can be well characterized such that, if one junction is held at a known reference temperature, the temperature of the other "measuring" junction can be inferred by comparing the measured total emf with an empirically derived calibration table (Ref 4).

Embedded Subsurface Thermocouples. Generally, when the thermocouple technique is to be used to measure contact temperature, a small hole is drilled into a noncontacting surface of the stationary component of a frictional pair. The hole may extend to, or just beneath, the sliding surface. Cement is put in the hole; ceramic cement is used for components that encounter high sliding temperatures, and polymeric adhesive, such as epoxy, is used for lower-

temperature components. A small thermocouple is then inserted in the hole so that its measuring junction rests either at or just beneath the sliding surface. It is held in position by the cement, which also serves to electrically insulate the thermocouple wires from the surrounding material. Figure 4 is a diagram of a typical embedded thermocouple installation (Ref 5). Several such thermocouples can be embedded at different depths and a various locations along the sliding path to obtain information about surface temperature distribution and temperature gradients (Ref 6). Monitoring the thermocouples throughout a sliding interaction allows changes in surface temperature to be deduced.

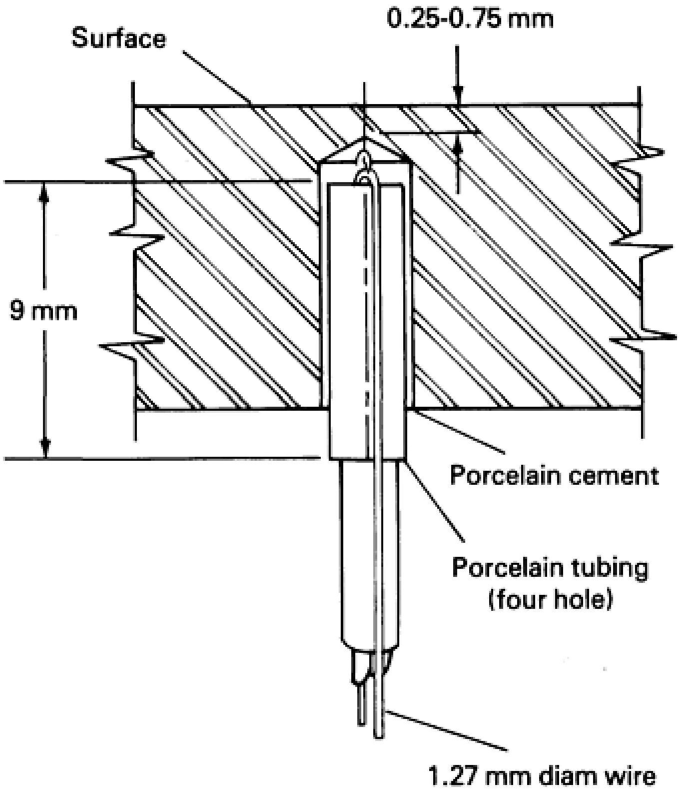

Fig. 4 Diagram of a thermocouple embedded in a brake pad. Source: Ref 5

Embedded thermocouples have been found to provide a good indication of the transient changes in frictional heat generation that accompany contact area changes (Ref 5, 6, 7). They cannot, however, provide a true indication of surface temperature peaks. Because of their mass and distance from the points of intimate contact where heat is being generated, subsurface thermocouples have a limited ability to respond to flash temperatures. A thermocouple can be made part of the sliding surface by placing it in a hole that extends to the surface and then grinding the thermocouple even with the surface. Even in that case, however, the finite mass of the thermocouple junction prevents it from the responding to flash temperatures of very short duration (Ref 7). Although these problems are not as severe with fast-response microthermocouples, the best use for embedded thermocouples is for measuring bulk temperatures within the sliding bodies. These bulk temperatures can be used effectively in determining boundary conditions for an analytical study or for calculating the distribution of frictional heat between the two contacting bodies (Ref 8). This is accomplished most easily if temperatures are measured at several depths beneath the sliding surface, enabling the determination of heat flux values.

Contact thermocouples consist of two separate insulated wires embedded in one of the sliding components but exposed at the contact surface. The deformation and frictional heating at the contact zone join the wires together, creating a thermocouple junction that responds to contact surface temperature. Such thermocouples have been used in several experimental studies of grinding temperature in the former Soviet Union (Ref 9) and elsewhere (Ref 10). An example of such a thermocouple is shown in Fig. 5 (Ref 10). In this design, separate flattened thermocouple wires are separated by insulating sheets of mica and are sandwiched between two halves of a split specimen (the workpiece). It is essential that the two thermocouple electrodes be insulated from each other and from the workpiece so that the thermal emf is not short-circuited (Ref 10). When sliding occurs at the hot junction, the two electrodes are welded together by the heat generated in the contact zone. The resulting thermocouple then indicates the temperature of the hot junction at the sliding interface.

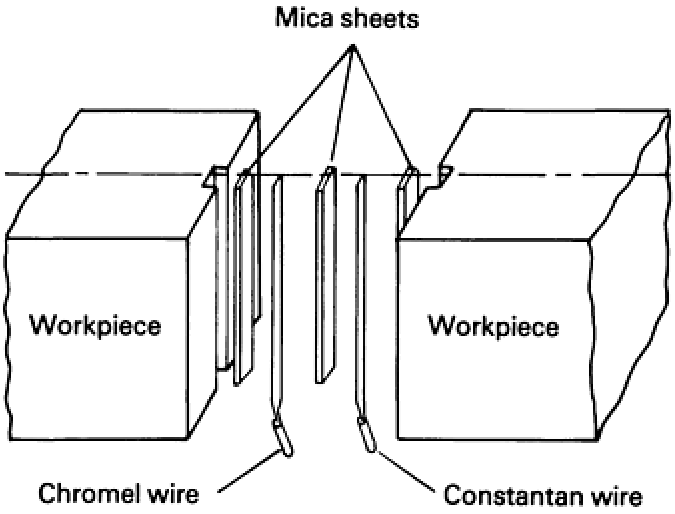

Fig. 5 Schematic diagram of a sandwiched contact thermocouple and split workpiece. Source: Ref 10

Contact thermocouples have proved effective in applications such as grinding (Ref 10) and brakes (Ref 11), but their accuracy remains questionable because of variable junction size and erratic transient response. Researchers have attempted to account for the thermal inertia of the thermocouple junction (Ref 10), but have not been completely successful.

Dynamic Thermocouples. In the dynamic thermocouple technique, sometimes called the Herbert-Gottwein technique, a thermocouple junction is formed at the sliding interface by the contacting bodies themselves. This method was originally developed to study contact temperatures at the interface between the cutting tool and the workpiece during metal-cutting operations (Ref 12). Later it was used to measure surface temperature in a variety of sliding contacts. Provided the two contacting materials are dissimilar and produce a well-characterized thermal emf as a function of temperature, the two rubbing materials can be used as part of a thermocouple circuit. An example of the use of the dynamic thermocouple technique is shown in Fig. 6 (Ref 13). In this application, a constantan ball served as one element of the thermocouple and a steel (iron) cylinder as the other. A measuring junction was formed wherever there was intimate contact between the ball and cylinder, and the measured temperature was the mean temperature at the contact interface (T_m).

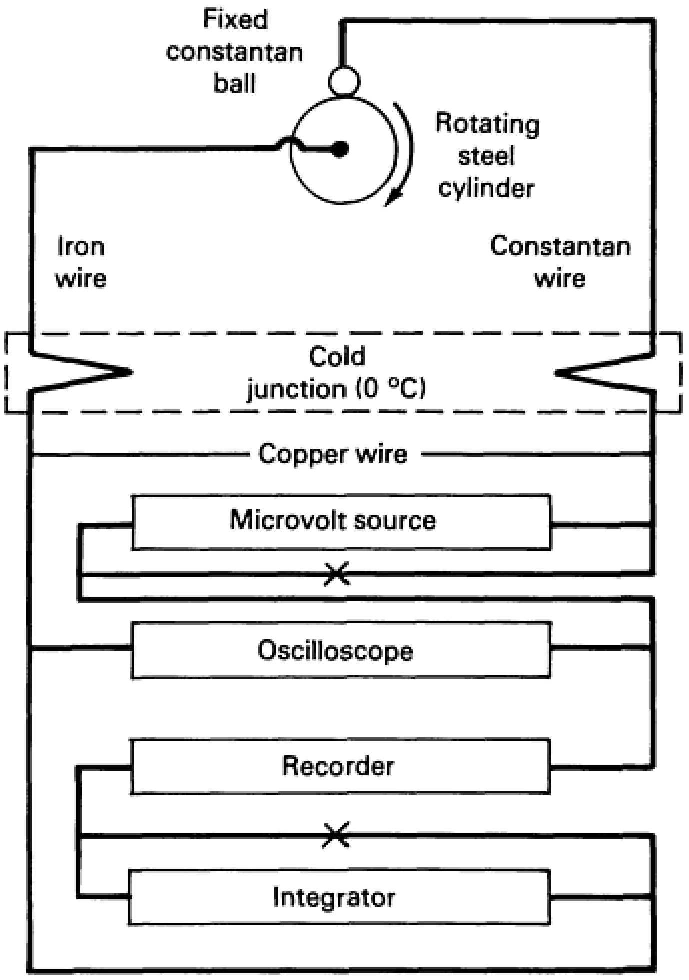

Fig. 6 Diagram of a dynamic thermocouple and monitoring circuitry. Source: Ref 13

In a modification of this technique, a single thin wire of constantan (or similar material) is embedded within the stationary sliding element, emerging at the contact surface. After the wire is insulated from the surrounding material with ceramic cement of epoxy, its end is ground smooth with the remainder of the sliding surface. In this way, a dynamic thermocouple junction will be formed whenever the end of the wire is in contact with the other surface, and the thermocouple location can be known with certainty (Ref 14).

Dynamic thermocouples have a very thin junction, consisting only of the actual contact zone. As a result, they can respond very rapidly to changes in surface temperature. Because they can respond to flash temperatures as well as to mean contact temperatures, dynamic thermocouples have been found to give higher measurements and faster transient response than embedded thermocouples (Ref 14). The measurements are often lower than theoretical predictions, however (Ref 13), and questions persist about the accuracy and meaning of the thermal emf produced by the thermocouple. The emf is produced by a weighted average of all temperatures across the sliding thermocouple junction, and that average may differ from the peak contact temperature (T_c), especially when the thermocouple junction contains more than one contact spot and the junction size changes with time (Ref 15). In addition, some electrical noise is frequently generated at the contact interface, and the thermocouple output must be discriminated from it.

Thin-Film Temperature Sensors. Over the past few years, microelectronics fabrication techniques, such as vapor deposition, have begun to be used to make surface temperature sensors. The advantage of such techniques is that very small sensors, with rapid response time, can be formed on surfaces.

One of the first vapor-deposited surface temperature sensors was a thermistor used to measure surface temperatures on gear teeth (Ref 16). The sensor consisted of a thin strip of titanium coated onto an alumina insulator on the surface of one of a pair of meshing teeth, as shown in Fig. 7 (Ref 16). The dimensions of the strip were approximately 500 μm wide by

2.5 mm long by 25 nm thick. The resistance of the titanium strip is sensitive to temperature, so monitoring the change in resistance allowed the transient surface temperature changes to be measured. By nature, the strip has a finite length and responds to all temperature changes along its length. Thus, it does not give a pointwise temperature measurement.

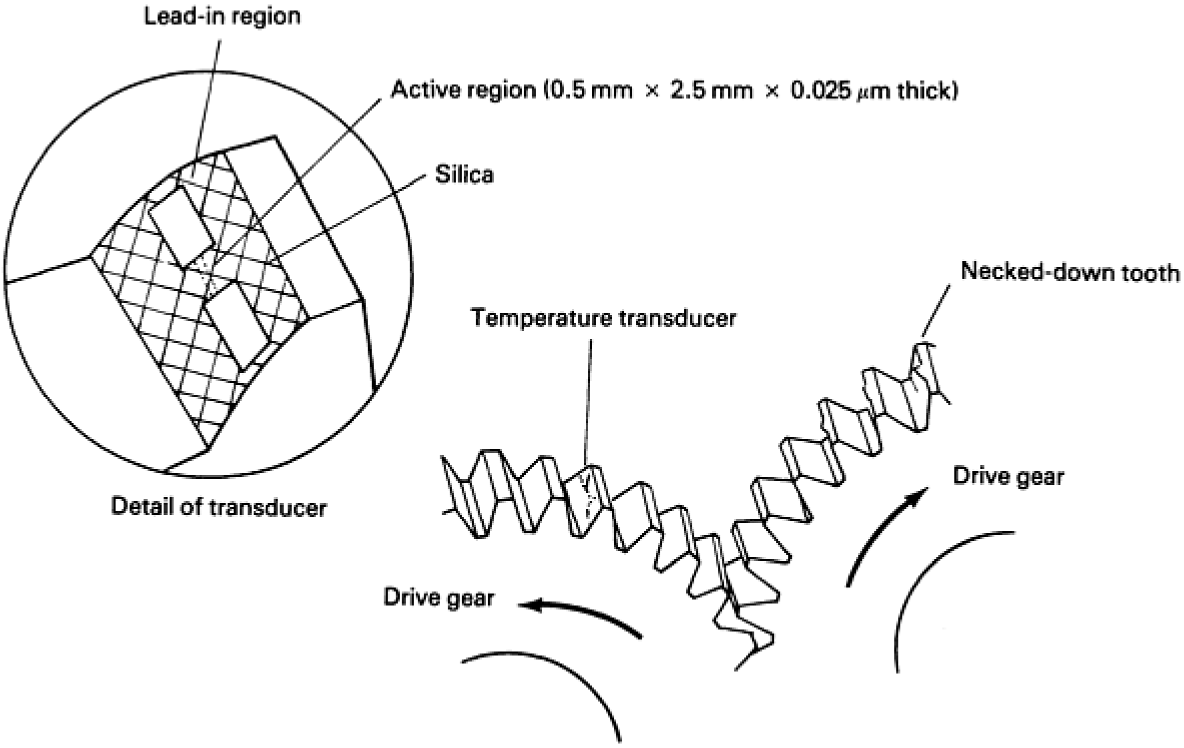

Fig. 7 Thin-film transducer (thermistor) for measuring surface temperature on gear teeth. Source: Ref 16

A more recent application of thin-film fabrication techniques in surface temperature measurement has been the development of thin-film thermocouples (TFTCs). Some of the earliest work on TFTCs described the use of vapor deposition to produce thermocouple pairs from thin films of nickel and iron, copper and iron, copper and nickel, copper and constantan, and chromel and alumel (Ref 17). Only recently have similar techniques been used successfully for measuring sliding surface temperatures (Ref 18). The production of a TFTC involves the deposition of thin films of two different metals, such as nickel and copper, sandwiched between thin layers of a hard, dielectric material such as Al_2O_3. A schematic cross section of a typical thin-film thermocouple is shown in Fig. 8 (Ref 18). The dielectric layer beneath the thermocouple junction is necessary to electrically insulate the TFTC device from the underlying metallic surface. Because of the softness of the thin metal films used for the thermocouple and connecting leads, a hard, protective layer must be deposited above the junction to limit damage to the TFTC device. The metal and dielectric films can be grown by physical vapor deposition techniques and can be less than 1 μm thick. Studies have shown that TFTC devices respond extremely rapidly (<1 μs) to a sudden temperature change and do not significantly disturb the heat flow from the sliding contacts (Ref 18). Such sensors can measure the temperature of the contact interface, especially when the protective layer is very thin, and the small size of the measuring junctions enables good indication of temperature at a specific point on the surface. If that point happens to be a flash temperature location, TFTCs can measure maximum contact temperature (T_c). As with all thermocouples or thermistors, however, thin-film devices cannot give a complete picture of surface temperature distribution, because that requires simultaneous measurements of temperature at a large number of points.

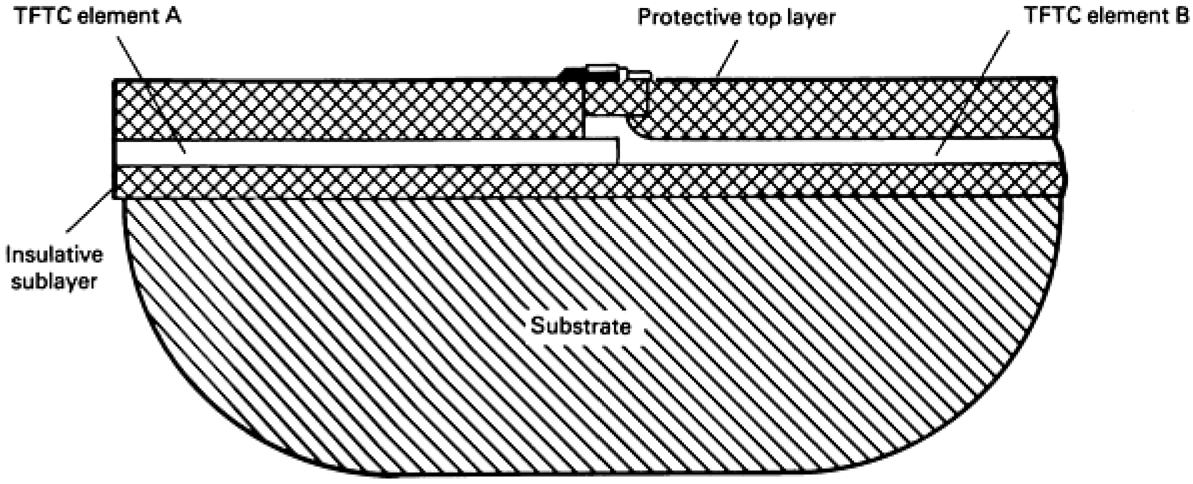

Fig. 8 Schematic cross section of a thin-film thermocouple. Source: Ref 18

Radiation Detection Techniques

Techniques involving the detection of thermal radiation have provided some of the most successful measurements of sliding contact temperatures. It is well known that any surface with a temperature above absolute zero is a natural radiator of thermal energy. The radiation emitted by the object is a unique function of its temperature, with the Stefan-Boltzmann law (Eq 1) showing that much more power is emitted by a body at high temperatures than at low ones:

$$\Phi = \epsilon \sigma T^4 A \qquad \textbf{(Eq 1)}$$

where Φ is the power (energy rate), T is the absolute temperature, σ is the Stefan-Boltzmann constant, A is the area of the heat source, and ϵ is the total emissivity of the surface emitting the radiation. ϵ is temperature dependent and is also very dependent on the characteristics of the surface. Some typical emissivity values at room temperature are listed in Table 1.

Table 1 Representative values of total emissivity of solid surfaces at 25 °C (77 °F)

Material	Total emissivity at 25 °C (77 °F)
Copper, polished	0.03
Copper, oxidized	0.5
Iron, polished	0.08
Iron, oxidized	0.8
Carbon	0.8

Source: Adapted from Ref 19

The radiation is composed of photons of many wavelengths, and, according to Planck's law, the monochromatic emissive power of a blackbody in a vacuum is:

$$W_{b,\lambda} = \frac{2\pi h C^2 \lambda^{-5}}{e^{Ch/k\lambda T} - 1} \qquad \textbf{(Eq 2)}$$

where λ is wavelength, C is the velocity of light in a vacuum, h and k are Planck and Boltzmann constants, respectively, and $w^{b,\lambda}$ is defined as the energy emitted per unit area at wavelength λ per unit wavelength in a small interval around λ. Integration of Eq 2 over all wavelengths leads to Eq 1 for the case of a blackbody (ϵ = 1). Planck's law (Eq 2) is plotted in

Fig. 9 for some representative temperatures (Ref 19). Note that $w_{b,\lambda}$ is very low at small and long wavelengths, so most emissive power is found at wavelengths in the range 1 μm < λ< 10 μm. For this reason, most successful attempts at measuring temperature by the detection of thermal radiation have concentrated on the infrared region of the spectrum (wavelengths of 0.75 to 500 μm). If the surface temperature *T* is high enough, radiation in the visible part of the spectrum (400 to 750 nm) can also be detected. Several different radiation measurement techniques have been successfully used to measure surface temperatures, including photography, pyrometry, thermal imaging, and photon detection.

Optical and Infrared (IR) Photography. A photographic technique utilizing infrared-sensitive film was developed by Boothroyd in 1961 for studying the temperature distribution in metal cutting (Ref 20). Similar methods were used in later studies of surface temperatures in machining (Ref 21), as well as for sliding components such as brakes (Ref 5) and in pin-on-disk sliding (Ref 22). In most cases, the camera is focused on the moving body as it emerges from a sliding contact, but in recent years successful photographs have been made through a transparent window to a sapphire/metal or sapphire/ceramic contact (Ref 22). Sapphire is a useful material for such studies; its mechanical and thermal properties are similar to those of steel, and it is essentially transparent to radiation in the visible and near-infrared regions (Ref 23).

A photograph showing hot spots on a tool steel pin sliding at high speed on a sapphire disk is presented in Fig. 10 (Ref 22). Temperatures of the spots were estimated to range from 950 to 1200 °C (1740 to 2200 °F). The temperature distribution is best determined by measuring the optical density of the developed negative. The system must be calibrated to determine the density-temperature relationship of the film in the test configuration. This is usually accomplished by photographing specimens of the same material that have been heated to known temperatures and then comparing the optical density of the test film to that of the calibrated film. The same magnification and exposure time must be used in both the calibration and the test photographs. When careful procedures are used, this method can provide good indications of the surface temperature distribution on a sliding contact. In general, however, methods involving infrared-sensitive film require exposure times (5 s or more) that are longer than the duration of flash temperatures, so they probably do not

give a true indication of the highest temperature in a sliding contact. Shorter exposure times (less than 1 s) can be achieved with normal high-speed color film, as in Fig. 10, but such film operates with visible light and thus is restricted to detection of high temperatures, perhaps 800 °C (1470 °F) or higher. Infrared film can respond to mean contact temperatures as low as 300 °C (570 °F), but even those temperatures occur only in rather severe sliding situations. An alternative is to use a modern infrared camera, which is essentially a scanning infrared detector.

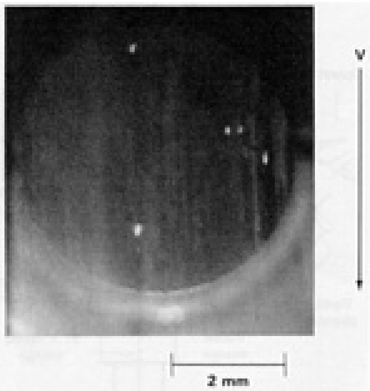

Fig. 10 Hot spots on a steel pin (6 mm, or 0.24 in., diam) sliding at 2 m/s (6.5 ft/s) on a sapphire disk with a load of 26 N (5.8 lbf). Photograph taken with back lighting after 25 min of sliding. Exposure time, 1 s. Source: Ref 22

Infrared detectors have been widely used and improved since Parker and Marshall (Ref 24) employed an optical pyrometer to measure the surface temperature of a railroad wheel as it emerged from a brake shoe. Early pyrometers used the eye as a detector to match the brightness of the subject body with that of a standard lamp incorporated in the instrument. Improved models that employed a photoelectric detector were later developed. The detector essentially integrates Eq 2 over all wavelengths within its spectral range and over the surface area viewed by the detector. Because the temperature is generally not constant over the field of view, the detector output is a function of the average temperature over the area.

To improve the accuracy of the temperature measurement and to approach a point measurement, most modern detectors are equipped with optics that limit the field to view to a small spot size, perhaps on the order of 100 to 500 μm diam. The result is an IR radiometric microscope. An example of which is shown schematically in Fig. 11 (Ref 25). This microscope uses a liquid-nitrogen-cooled detector made of indium antimonide (InSb), which has a spectral band of 2 to 5.6 μm. Infrared radiometric microscopes can measure transient temperature changes at a rate of up to 20 kHz or greater. They have been used effectively both with metallic components, where the detector is focused on a spot just emerging from the contact zone (Ref 25), and with transparent sapphire components, where the detector is focused through the sapphire onto the contact zone between the sapphire and the metal (Ref 26).

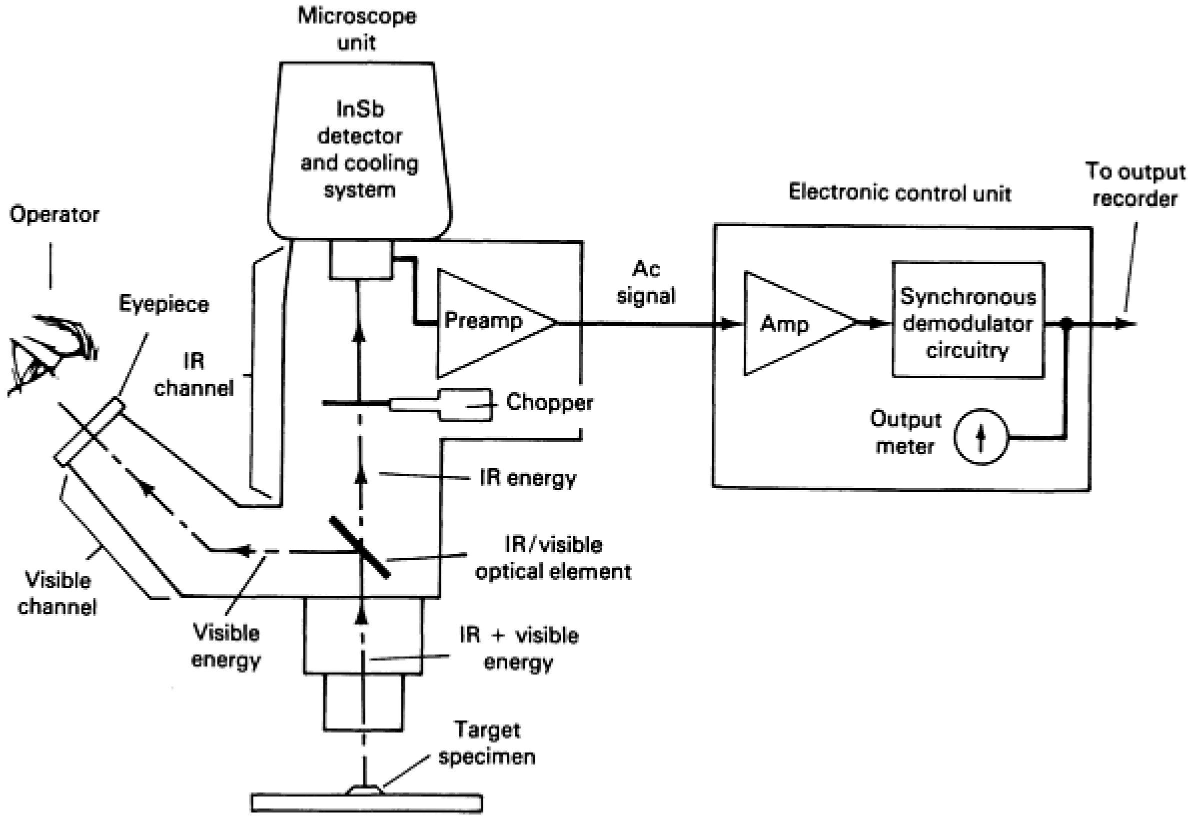

Fig. 11 Schematic diagram of an IR radiometric microscope. Source: Ref 25

By limiting the field of view to a single small spot, the IR microscope can miss many contact events occurring at other spots within the area of contact. To overcome this limitation, in recent years investigators have been using a scanning IR camera to study sliding surface temperatures (Ref 23, 27, 28). A scanning IR camera, or IR microimager, has a detector similar to that shown in Fig. 11, but the detector is optically scanned over the contact surface in either of two modes: line scan or area scan. In the line scan mode, a fixed line, perhaps several millimeters in length, is scanned continuously at a rate of up to 2500 line scans per second. In the area scan mode, the rotation of a prism advances the line for each scan to produce a field typically consisting of 100 scan lines. The output is a video voltage that is a function of the IR radiation detected at that instant. The output from a complete area scan for the case of a silicon nitride pin sliding against a sapphire disk is shown in Fig. 12 (Ref 23).

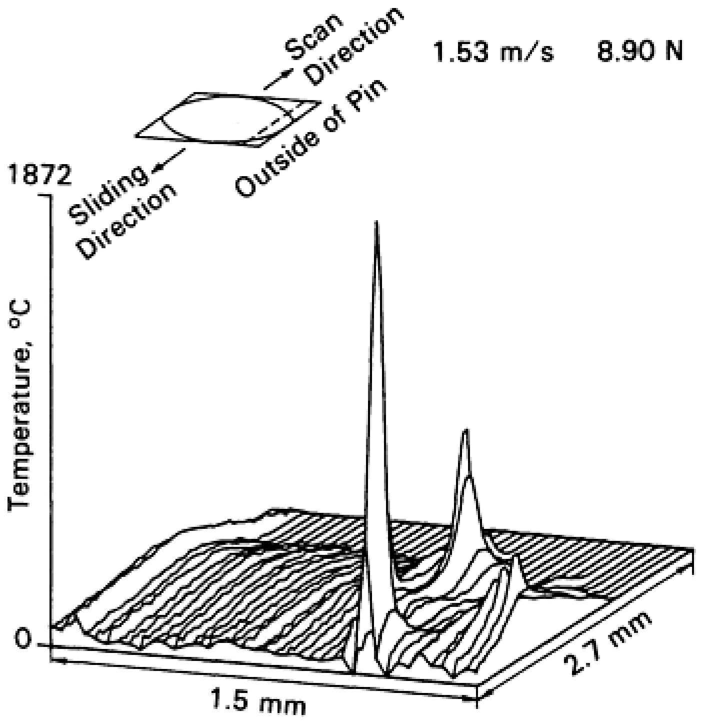

Fig. 12 Temperature distribution on the surface of a silicon nitride pin in sliding contact with a sapphire disk at a velocity of 1.5 m/s (5 ft/s) and a normal load of 8.9 N (2 lbf). Pin bulk temperature, 96 °C (205 °F). Area scan mode with IR scanning camera. Source: Ref 23

It should be noted that, even at a scan rate of 2500 lines per second, it takes 40 ms to complete an area scan composed of 100 lines. This is considerably longer than the duration of flash temperatures, so it is unlikely that a field plot similar to that in Fig. 12 is fully representative of the surface temperature distribution at any instant. However, it does give a good indication of the contact conditions within the target area and the approximate temperatures reached at the hot spots. A better indication of transient temperatures at a given point can be achieved in the line scan mode, by continuously sweeping over the same line. Even in that mode, however, the transient times of the temperature fluctuations have been found to be less than the time required to complete a single line scan (Ref 23), and the flash temperature intervals may, in fact, be less than the 5 μs or so between consecutive temperature measurements on the same scan line. Thus, measured contact temperatures may be less than actual flash temperatures, particularly if the hot spot is smaller than the spot size of the detector and is very short-lived.

Methods have been devised to correct for the instantaneous temperature averaging that occurs within an IR detector (Ref 23), but such techniques are only approximate. As stated earlier, an IR detector essentially integrates Eq 2, multiplied by the emissivity, over the area of the detector's target spot and within its spectral range to obtain the equivalent of Eq 1. If a small hot spot whose temperature is desired is contained within a larger target spot, the area of the spot must be known so that its contribution to the summed detector output can be determined. Because hot-spot areas are usually not known with certainty, the hot-spot temperature is inaccurately determined. A better technique, utilizing two separate detectors, was recently devised by Bair *et al.* (Ref 29). If the emitted radiation is split between the two detectors and a different band-pass filter is placed in front of each detector, different values of radiated power will be measured at each of the two wavelengths, and each will be a function of two variables: hot-spot area and temperature. The ratio of detected power at the two wavelengths can be used to determine the maximum temperature within the field of view (Ref 29). The hot-spot area can also be determined once its temperature has been calculated. The optical setup for this method is shown in Fig. 13, and a typical results is shown in Fig. 14, for a sapphire read/write slider against a thin-film magnetic disk (Ref 29). This method appears to hold much promise for future development.

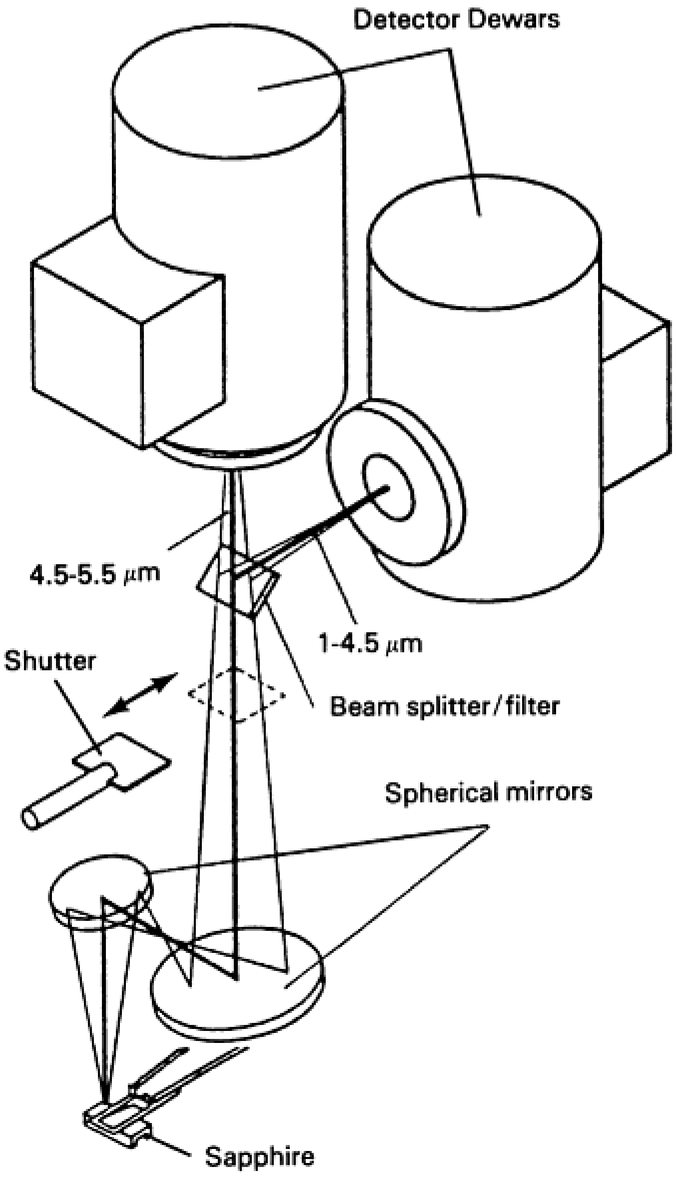

Fig. 13 Optical arrangement for an IR temperature measurement system with two detectors. Source: Ref 29

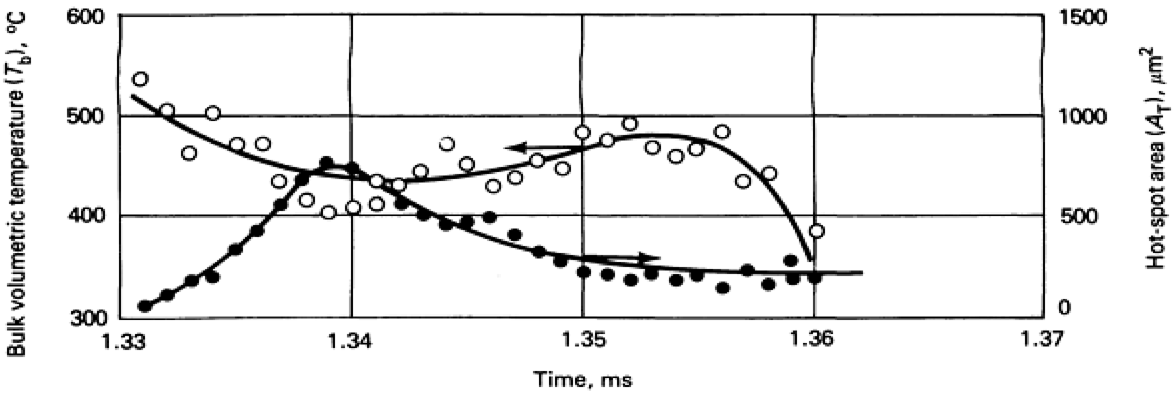

Fig. 14 Hot-spot temperature and area measured using an IR temperature measurement system with two detectors. Source: Ref 29

Uncertainty about the emissivity of contacting surfaces during the sliding process can lead to inaccurate temperature determination with any of the IR techniques. It is apparent from Table 1 that the total emissivity of a metallic (or nonmetallic) surface can vary considerably owing to oxidation, wear, or other changes in surface characteristics. To obtain an accurate temperature reading from a radiating surface, an accurate value of emissivity must be known at that temperature. This can be accomplished by carefully determining the emissivity of reference surfaces similar to the contacting surfaces at temperatures throughout the range of interest. There are also methods for measuring the emissivity and transmissivity of any lubricant between the surfaces (Ref 28). Despite these procedures, emissivity remains an accuracy-limiting variable in many IR measurements of sliding surface temperatures, especially when the emissivity changes during the sliding process (Ref 27). These difficulties have been partially overcome by the technique of Bair *et al.* (Ref 29), in which the calculated temperature is independent of the emissivity, provided the spectral distribution of emissivity remains unchanged.

Photon Collection. As an alternative to IR detectors, which generally respond too slowly to accurately measure flash temperatures in rapidly moving hot spots, a surface temperature measurement method was recently developed that uses a photomultiplier to collect photos emitted by hot contact spot (Ref 30). An experimental setup using this technique is shown in Fig. 15. Use of a photomultiplier with sensitivity to wavelengths in the 500 to 900 nm range allows detection of photons emitted from a hot contact between a moving surface and a transparent (sapphire) slider. Contact temperatures generally need to be at least 400 to 500 °C (750 to 930 °F) in order to generate photons with enough energy to be detected by the photomultiplier (see Fig. 9), but the response time of the photomultiplier is very rapid (less than 30 ns). Therefore, the technique can be used for detecting flash temperatures of very hot duration (2 μs or less) (Ref 30). However, it is not too useful for measuring mean contact temperatures, which are generally lower than 500 °C (930 °F). A further restriction is that the sliding test must be run in complete darkness to eliminate noise, which can dominate the output signal. This method is also subject to a limitation similar to that of most IR detectors; that is, the area of the spot emitting the photons must be known in order to accurately determine the temperature of the spot. Calibration of the relationship between output voltage and temperature can be accomplished using reference surfaces of the contacting materials at known temperatures (Ref 30).

Conclusion

The techniques described in this article have led to much useful information about the temperatures generated by frictional heating. Although each of the techniques is a useful engineering or research tool, each is subjects to some

limitations; therefore,no single surface temperature method can be used for all applications. Some techniques, such as thermocouples, give a measure of temperature at a single point, while others, such as IR imaging, give a field measurement. Response time varies considerably, from less than 50 ns for photon detection, to 1 μs or less for thin-film thermocouples, to several seconds for IR photography, to nearly a minute for metallographic techniques. Some methods are more useful as research tools than in studies using actual machine components. It is likely that a complete study of sliding surface temperatures in any real application would involve the coordinated use of several of the measurement techniques described above

Before beginning a surface temperature measurement task, the engineer should remember that the real area of contact in actual mechanical components is quite inaccessible and is made up of small spots that may remain in contact for a very short time. During that short contact time, the spots can get much hotter than the rest of the material within the nominal contact zone, attaining very high flash temperatures. Despite the progress that has been made in surface temperature measurement, it is difficult to accurately measure localized flash temperatures in actual mechanical components; this has led many investigators to rely on analytical methods for contact temperature determination. Experimental temperature measurements are often used in conjunction with analysis in order to provide necessary boundary condition information or to verify analytical predictions.

Surface Chemical Analysis

Austin L. Grogan and Stephen L. Rice, University of Central Florida; Mark Davidson, University of Florida

Introduction

THE TECHNIQUES AND METHODOLOGIES of chemical analysis that can be applied to problems in friction, lubrication, and wear are the focus of this article. The analytical techniques discussed are x-ray photoelectron spectroscopy, ion-scattering spectrometry, Auger electron spectroscopy, electron-stimulated desorption, and secondary ion mass spectrometry.

These techniques yield chemical information that is specific for the surface and near-surface regions of solid-state materials. They are therefore well suited to the types of problems often encountered in friction, lubrication, and wear. These techniques can also be used to obtain chemical information about bulk regions of a material when ion etching is employed to remove surface layers of the material. A brief description of infrared spectroscopy is also provided, because it can be utilized in conjunction with the surface analytical techniques described below.

X-Ray Photoelectron Spectroscopy (XPS)

XPS is a near-surface sensitive analytical technique based on the photoelectric effect, which was first indirectly observed by Hertz in 1887 (Ref 1). He noted that it was easier to generate a spark from an electrode when the electrode was illuminated with ultraviolet (UV) light. Thompson (Ref 2) was able to show that the results of Hertz are due to the emission of electrons that occurs with exposure to light, and Einstein (Ref 3) used these results to develop the theory of quantum radiation, upon which modern XPS is based.

The origins of XPS date to the late 1960s, as summarized in Ref 4 and 5, which describe the theory and applications in some detail. Because the energy of an emitted electron indicates both the species and the oxidation state of that species, the term electron spectroscopy for chemical analysis (ESCA) was coined. It has been suggested by Carlson (Ref 6) that the term ESCA be used in reference to all photoelectron spectroscopies (for example, XPS and ultraviolet photoelectron spectroscopy) and that XPS be used to refer to photoelectron spectroscopy that is excited by x-rays. This convention will be followed in this article.

Since the publication of Ref 4 and 5, the field of ESCA has expanded from an experimentally difficult technique that was routinely performed in only a few laboratories to a routine analytical tool. This has been due, in large part, to the development of vacuum technology and the availability of standard vacuum pumps and equipment. Presently, XPS has advanced to the point where it is now being considered for use in process control schemes (Ref 7). Commercial x-ray photoelectron spectrometers are now routinely available from numerous vendors with a variety of options, which often include other complementary surface analytical techniques in the same vacuum chamber.

XPS and Auger electron spectroscopy (AES) have now become the most routinely used surface analytical techniques in many fields. The probing depth of XPS ranges from 1 to 5 nm, and the detection limit typically ranges from 1 part per 100 to 1 part per 500, with a limit of 1 part per 1000 being approached under the most favorable of conditions. XPS has proved to be useful in such widely diverse areas as semiconductor technology (Ref 8), catalysis (Ref 9), electrochemistry (Ref 10), and materials research (Ref 11, 12, 13, and 14). Reference 15 provides the early history of ESCA. A more recent history is provided in the introduction in Ref 6. Examples of previous applications of XPS to problems in friction, lubrication, and wear are provided in Ref 16, 17, 18.

XPS Fundamentals. ESCA is based on the photoelectric effect, which is simply the ejection of an electron from an atom upon absorption of a photon. This process is shown in Fig. 1. If the energy of the photon is greater than the binding energy of the electron, then the electron is ejected from the atom. The energy of the electron is given by an energy balance (Ref 16):

$$KE = h\nu - BE - \phi \qquad \textbf{(Eq 1)}$$

where KE is the kinetic energy of the ejected electron, $h\nu$ is the energy of the photon, BE is the energy of the electron in the atom, and ϕ is the work function of the spectrometer (the energy required for an electron to escape its image charge).

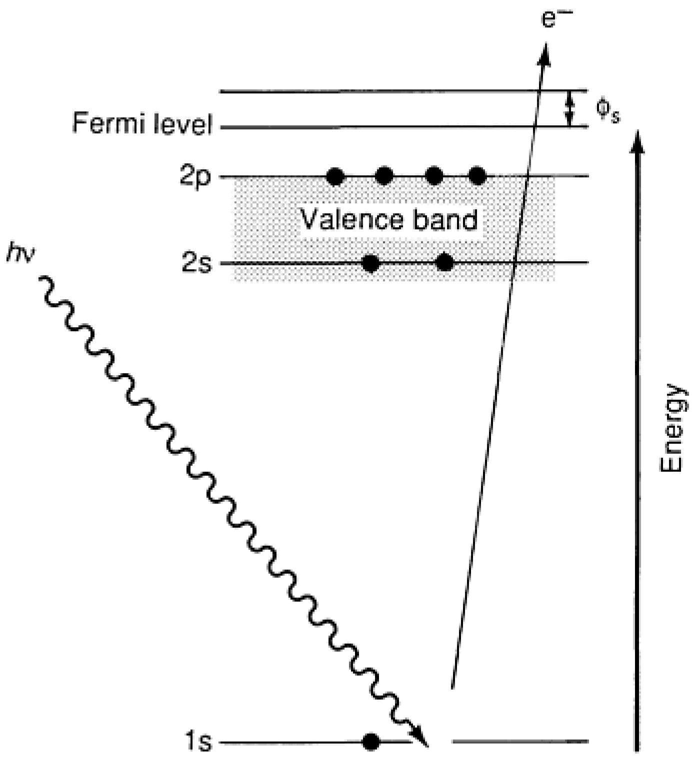

Fig. 1 Photoelectric effect

By supplying a flux of photons of known energy and measuring the energy of the ejected electrons, the binding energies of the electrons can be determined. The binding energies are indicative of the atoms from which the electrons came, and the flux of ejected electrons with a given binding energy is proportional to the number of atoms in the analyzed region. This information can be used to both identify and quantify the species present in the material under analysis. In addition, the binding energies of the core electrons can be shifted by changes in oxidation state. This shift is due to differing levels of screening of the core electrons by the valence electrons. By looking at these relatively small changes (0.1 to 10 eV) the chemical state of the analyzed species can be determined (Ref 4, 5, 14).

An example of this effect is shown in Fig. 2. These spectra were obtained from a TiO_2 (001) surface that had been sputtered (further described in the section "Auger Electron Spectroscopy"), annealed in ultrahigh vacuum (UHV), and then annealed in oxygen. The Ti 2p peaks widen and shift as the sputtering process selectively removes oxygen, and peaks from both Ti_2O_3 and TiO appear.

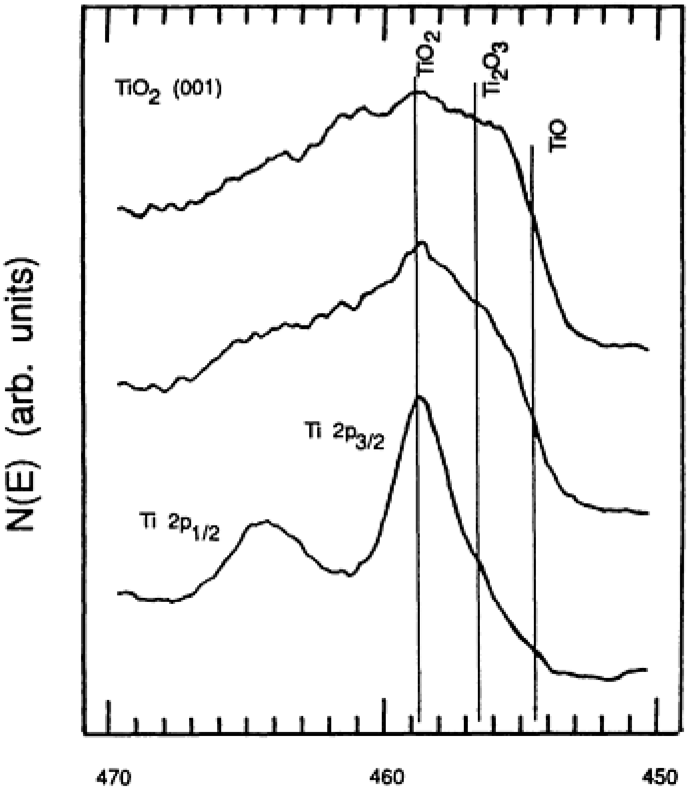

Fig. 2 XPS spectra from TiO_2 (001) surface showing Ti 2p peaks taken from (a) sputtered surface; (b) sputtered surface after annealing under vacuum at 400 °C (750 °F) for 1 h; (c) sputtered surface after annealing O_2 at 400 °C (750 °F) at 1.3 × 10^{-4} Pa (10^{-6} torr) for 1 h. N(E) = $N_{(E)}$. Source: Ref 19

The quantum mechanics of the photoelectric effect are much more complex than the simple theoretical explanation given here. In actuality,the energy balance may not give exactly the *BE* of the electron, because it assumes that the ion left behind is in its ground state (Ref 20). In practice, this occasionally gives rise to small background peaks called shake-up lines (Ref 21). For a thorough discussion of the theoretical basis for ESCA, see Ref 5, 6, 8, 20, and 22.

XPS Equipment. The experimental setup for XPS can be divided into four main components. There must be a source of x-rays, an electron energy analyzer, a UHV chamber in which to house them, and a sample to analyze. The vacuum chamber and associated pumps are standard items and are not discussed here, but the limitations and capabilities of the most popular options for each of the other three parts are described.

XPS X-Rays Sources. Conventional x-ray tubes that utilize either an MgKα or AlKα source (Fig. 3) represent the principal source of x-rays used in XPS. For most surface studies, the MgKα source is optimal, because of its higher intensity and narrower line width (Table 1), compared with other sources. The AlKα source is useful for observing higher binding energy lines, such as the Ge 2p lines at binding energies between 1230 and 1300 eV (Ref 21). Dual anode sources that give the researcher the option of the higher energy photons, if needed, are available. In addition, other anode materials are available with energies up to 8048 eV (CuKα), but for routine analysis, either the Mg or Al anode generally suffices.

Table 1 Energy, line width, and intensity values for several anode materials

Anode	Energy, eV	Line width, eV	Intensity
Mg	1253.6	0.7	1
Al	1486.6	0.85	0.5
Zr	2042.4	1.7	0.05
Cu	8048	. . .	. . .

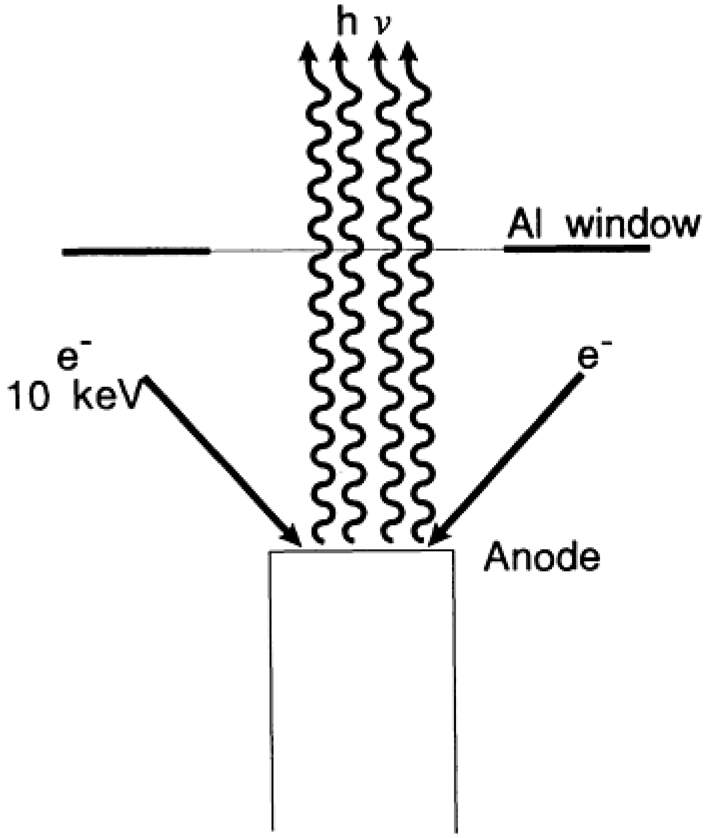

Fig. 3 Typical x-ray source, where electrons are accelerated to about 10 keV to the anode material, which then emits photons with energy characteristic of the anode material

As noted by Gardella (Ref 23) and Hercules (Ref 24), the conventional x-ray sources have great limitations with respect to energy and spatial resolution. The maximum energy resolution limitation of energy analyzers used in XPS systems is typically much less than the 0.7 eV natural line width of the MgKα x-ray source. Therefore, the energy resolution of the XPS data is limited by the x-ray source.

In addition, the x-ray spectrum emitted from the x-ray source contains minor x-ray lines (satellites) and a continuum background radiation called brehmsstrahlung. This prompted Fellner-Feldegg *et al.* (Ref 25) to develop a monochromatized x-ray source. These sources are now commercially available and have been used to measure line widths down to 0.34 eV. The monochromators have the additional advantage of providing focusing capabilities down to 150 μm. This allows the spatial mapping of surfaces with the power of chemical state determination provided by XPS (Ref 23).

Future developments in x-ray sources include high-flux rotating anode types that allow high energy resolution spectra to be obtained in 1 s. New anode materials will provide higher energy and narrower lines, and spots sizes as small as 1 μm (Ref 23).

Energy Analyzers. Two types of energy analyzers are often used in XPS spectrometers: the cylindrical mirror analyzer (CMA) and the hemispherical analyzer, both of which are the energy-dispersive type. The CMA consists of two coaxial cylinders with a potential placed between them (Fig. 4). The charged particles enter the region between the cylinders and are deflected by the electric field. The amount of deflection depends on the energy of the particle. Only those particles in a very narrow band can reach the detector. To make the spectrometer capable of the resolution necessary for XPS, two CMAs are placed in series (Ref 26). This configuration is called a double-pass CMA. The hemispherical analyzer is similar in operation to the CMA, but its geometry consists of two concentric hemispheres instead of cylinders.

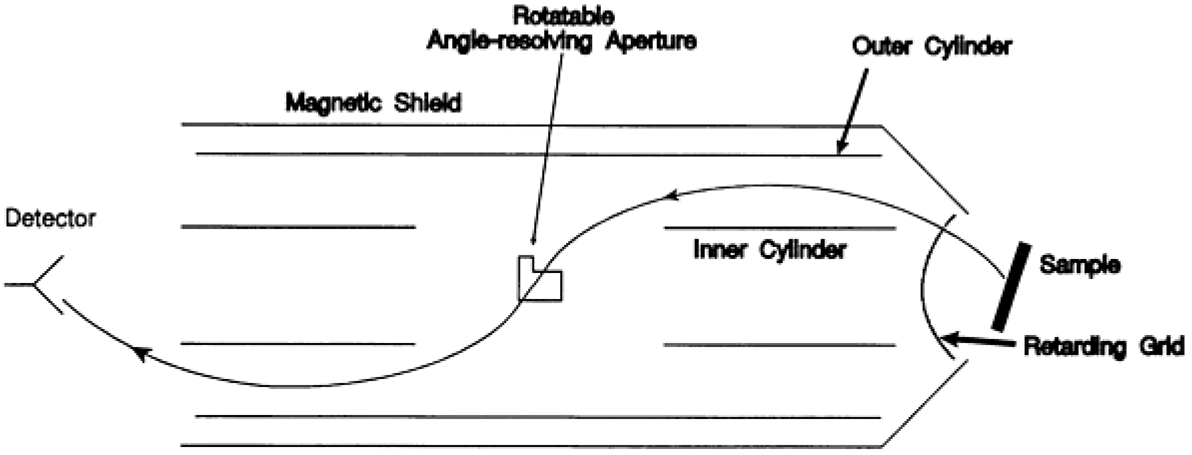

Fig. 4 Double-pass CMA showing charged particle path. Note that detection angle from sample can be varied by rotating central angle resolving aperture.

Both types of analyzers have advantages and disadvantages. The hemisphere generally has a higher throughput than the CMA for a given resolution. This can be important for XPS systems, because XPS signals typically have a low *S/N* ratio. Because the hemispherical analyzer has a higher throughput and, therefore, a higher signal for the same resolution, the XPS spectrum collected with the hemisphere will generally have a higher *S/N* ratio than that collected with the CMA for the same collection time. A spectrum with the same *S/N* can be collected with the CMA, but it will generally require longer collection times. However, the CMA is a more versatile instrument. Although angle-resolved XPS can easily be performed with the hemispherical geometry, the CMA can be equipped with an angular resolving aperture, which, unlike the hemispherical analyzer, allows the independent variation of excitation and detection angles. This is important for angle-resolved XPS and AES, which yield depth compositions nondestructively (Ref 14, 27), and for ion-scattering spectroscopy. The CMA is also better suited to collect AES data than the hemisphere. In general, the hemisphere is a better choice for a dedicate XPS instrument and the CMA is best for a multiple-technique instrument, especially if angle resolved experiments are desired. The CMA analyzer will be discussed further in the section Auger Electron Spectroscopy (AES) in this article.

Sample and Preparation. XPS requires a UHV environment to prevent arcing in the x-ray source, to prevent the photoelectron from being scattered from gas phase molecules, and to reduce accumulation of surface contamination during analysis. These requirements place some limitations on sample types, as well as preparation. The samples must have a low vapor pressure and be free from any contaminants, such as oil and fingerprints. As previously stated, the analysis is limited to the near-surface (1 to 5 nm) region of the sample. The addition of an ion gun allows sputter depth profiling, but the depth is limited to a few microns for a reasonable experimental time scales.

Preparation of the sample can be accomplished in several ways, depending on the nature of the sample. A common procedure for cleaning and mounting is as follows: The sample is ultrasonically cleaned in a series of solvents. Typically, the deionized water is first used to remove inorganic constituents, followed by cleaning in toluene, acetone, trichloroethylene, and then acetone and ethanol. This cleaning procedure sufficiently removes most contamination in the surface and near-surface regions.

If the desired, the final removal of remaining contamination can be accomplished by ion sputtering and/or annealing in the vacuum system. If the removal of surface oxide layers is required, such as in many single-crystal applications, the specimen can be etched with an appropriate acid. Buffered hydrofluoric solutions are commercially available for this purpose.

There are several methods for mounting samples such as powders. In one method, a sample of the powder is pressed between two soft metal foils, such as tin or indium. The foils are then separated and one of them is mounted for analysis. The authors have had mixed results with this method, because the substrate often appears in the spectra obtained, and the diversity in sizes of the "islands" of sample powder can lead to different charging levels, causing multiple peaks in the spectrum. The best results have been obtained by using a small aluminum cup to hold the powder. The powder is pressed into the cup with a pellet press and then the cup and powder pellet are mounted. This method is particularly useful when

the sample is a pellet to begin with and the average concentrations throughout the pellet are desired. The pellet can be ground into a fine powder and then pressed into an aluminum cup for mounting. Care should be taken to grind slowly, so as not to produce excessive heat.

XPS Spectrum. A sample spectrum obtained from a manganese dioxide powder is shown in Fig. 5. The horizontal scale is labeled as binding energy, and it should be noted that the spectrum is displayed with the binding energy increasing from the right to left. This is a customary way to display XPS spectra, because the data are taken as a function of kinetic energy, which increases from left to right.

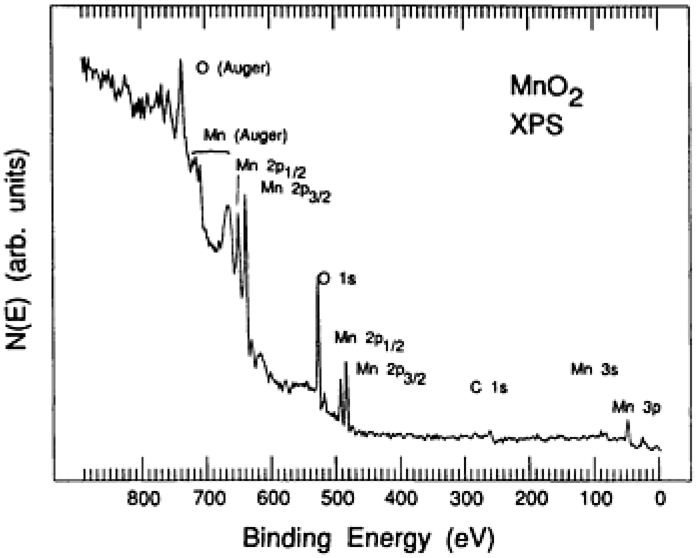

Fig. 5 Sample XPS spectrum of MnO_2 powder showing valence and core photoelectron peaks, as well as Auger peaks. N(E) = $N_{(E)}$

Several features are evident in the spectrum. The most noticeable trend is the overall increase in the background, from low to high binding energy. This increase is due to inelastic scattering of photoelectrons as they move through the sample. As the electrons scatter, they lose kinetic energy to the solid and thus contribute to the background towards low kinetic energy (high binding energy). This is evidenced by the sudden increases in the background at the photoemission lines. Below the kinetic energy level at which the electrons are emitted, there are more electrons that can inelastically scatter. Thus, the background increases suddenly and in proportion to the magnitude of the photoelectron emission.

The most important features in the spectrum are the peaks that are due to the photoemission of the core electrons. The energy and magnitude of these peaks are the basis for the qualitative and quantitative analyses of the sample, which are discussed in detail in next section. Also present in the spectrum are peaks that are due to Auger electrons created during the relaxation of the excited (core hole) that remains after the photoemission process.

The Auger process will be discussed in more detail in the section Auger Electron Spectroscopy (AES) , but it should be noted that the kinetic energy of the Auger electron is independent of the energy of the original excitation. This fact can be exploited in avoiding interferences between photoelectron lines and AES lines in the XPS spectrum.

If a dual anode x-ray source is available, the kinetic energy of the photoelectron peaks can be shifted by changing x-ray energies, but the kinetic energy of the Auger lines will remain constant and the interference will be removed. There are also peaks in the region of binding energies near the Fermi level (defined as zero binding energy) that are due to valence electrons. These features can be of considerable use in surface studies, although they are generally small in magnitude, because of the relatively low photon flux from typical x-ray tubes and their low probability of interacting with valence electrons. Useful valence band spectra can be obtained using UV light as an excitation source. This low-energy radiation couples well with valence-level electrons. Therefore, valence-level, rather than core-level, electrons are emitted. This technique, referred to as ultraviolet photoelectrons spectroscopy (UPS), is a powerful analytical technique, but the spectra are typically complicated to interpret because of Molecular orbital formation and chemical state effects. Therefore, UPS is not used on a routine basis for most applications.

Two small and less important features it the spectrum are x-ray satellites and shake-up satellite. X-ray satellites are a result of excitation of the photoelectron by a minor x-ray line with a slightly different energy than the main line. This results in a "shadow" peak on the low binding energy side of the photoelectron lines at a fixed binding energy offset with a magnitude proportional to the main photoelectron line (see Fig. 6) (Ref 28).

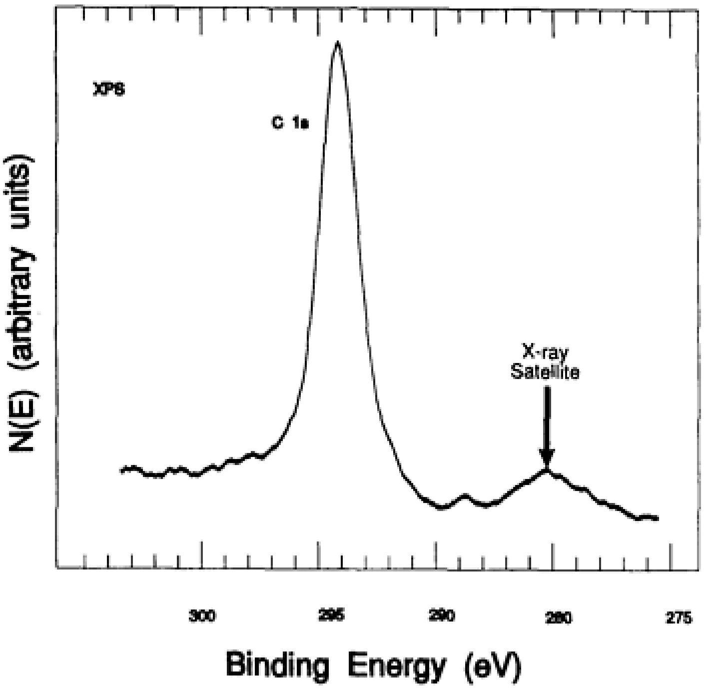

Fig. 6 Sample spectrum of C 1s photoelectron line showing x-ray satellite displaced 8.4 eV from main peak corresponding to most dominant satellite of Mg anode x-ray source. N(E) = $N_{(E)}$. Source: Ref 25

Shake-up satellites occur when the ion rear-ranges its outer electrons as the photoelectron exits in a way that leaves one or more of the valance electrons in an excited, rather than ground, state. Because this excitation energy is then not available to the photoelectron, a small peak appears at a slightly lower kinetic energy (higher binding energy). Both of these satellite peaks are usually ignored, although the shake-up peak is sometimes useful in chemical state determination when the shift in the core line is undetectable (Ref 29).

XPS Data Analysis. The first step in analyzing XPS data is to identify all species present. This begins with the calibration of the energy scale. The energy balance needs to be corrected for the spectrometer work function and sample charging. This is best accomplished by choosing some species in the sample as a reference. Adventitious carbon is often chosen, and its 1s peak is assigned a binding energy of 284.6 eV. However, this may not be a good choice, because the form of the carbon can vary widely from sample to sample. The inherent uncertainties in the spectrometer energy calibration generally limit the accuracy of the energy scale to about 0.1 eV, but this is adequate for chemical state identification of most species. Detailed descriptions of the energy calibration procedure are given in Ref 20.

After the energy scale is properly calibrated, all of the detectable species are identified by systematic identification of the peaks in the spectrum. This is usually best accomplished by first identifying the most prominent peak using reference spectra (Ref 21). Once the element from which the photoelectron line came is identified, all of the other lines, including Auger lines that are associated with that particular element, are located and identified. If any of the peaks (from that element) that should lie above the detection limit are not found in the spectrum, then the identification of the original peak is incorrect and another element is chosen. This process continues until all of the peaks in the spectrum have been identified.

Next, the identification of chemical state can be accomplished from more detailed spectra. The peak location is compared with reference data (Ref 22) and data are obtained from pure compounds. An example of the power of XPS to determine chemical states was shown previously in Fig. 2.

The quantitative analysis of XPS spectra is based on the theoretical description of the intensity (area under the main peak, plus the area under shake-up peaks, if present) of the photoelectron line, which can be accurately approximated by (Ref 5, 20, 21):

$$I_i = S_i N_i \qquad \textbf{(Eq 2)}$$

where I_i is the intensity of the peak of interest for species i, S_i is the sensitivity factor for peak i, and N_i is the concentration of species i in the sampled volume.

Sensitivity factors are tabulated for CMAs and hemispherical analyzers (Ref 21), but because the sensitivity factor is a function of the type of spectrometer, these tables may not be accurate for different types of spectrometers. The composition of the sampled region can be obtained by normalizing I_i/N_i for the major peak of each element present to the sum of the same quantity for all elements (Ref 7, 21). The accuracy of this method is typically on the order of 10%. Therefore, XPS is a semiquantitative technique with respect to composition determination. Matrix effects are primary factors that affect composition determination by using relative sensitivity factors. This is discussed more in the Auger Electron Spectroscopy (AES) section. As previously mentioned, the practical detection limit for quantification is 0.1 to 1 at %.

XPS spectra can yield structures that are composites of at least two individual peaks. This can can be the result of the presence of at least two elements in the sample that yield peaks with binding energies that are very close together. An example of this is excitation of Ta 4p and N 1s level electrons with a magnesium anode. The respective binding energies of these peaks are 403 and 400 eV (Ref 21). The details of the low-energy end of the Ta 4p structure and high-energy end of the N 1s structure can become obscured. A similar phenomenon can be observed when mixed oxidation states of a metal are present.

If, for example, the XPS spectrum of a metal consists of a doublet (two peaks), then the peaks are typically shifted to slightly higher binding energies as the degree of oxidation increases. If a sample contains the metallic species in addition to the metal oxide, then the two peaks associated with the oxide are typically shifted to slightly higher binding energies with respect to the metal. As a result, it is possible for the lower binding energy peak of the oxide to be very close to the higher binding energy of the metal. The result is a structure that is composed of two peaks.

Composite peak structures resulting from peak overlap are dealt with through either deconvolution or curve fitting techniques; the latter is probably the more popular of the two. It is important to note that neither technique can define a unique combination of single peaks that results in a given composite structure. Therefore, neither deconvolution nor curve fitting can yield a unique solution for the combination of individual peaks that results in a composite structure. A number of textbooks on spectroscopy, including those XPS resources cited in this article, describe deconvolution and curve fitting. For the purpose of this discussion, it is sufficient to point out that modern surface analysis software typically features curve-fitting routines to address the problem of peak overlap.

Ion-Scattering Spectrometry

Ion-scattering spectrometry (ISS) is based on energy analysis of ions reflected from a solid target material. The scattered species can be either inert or reactive in the most general sense, but inert species, such as argon and helium, are typically used.

The application of ISS as a surface-sensitive analytical technique is based on monitoring the kinetic energy of reflected probe ions for which the mass, incident energy, and angle of reflection are known. From this, the struck target atom mass can be determined and surface constituents identified. ISS can be applied to both electrically conductive and insulating materials, but can induce surface damage. Surface coverages near 0.01 monolayer are often detectable with ISS. At this point, ISS has not been employed in the field of friction, lubrication, and wear to the extent that XPS and AES techniques have.

ISS Fundamentals. Various articles that describe ISS fundamentals and applications have been published since 1970. Publications by Smith, Suurmeijer and Boers, and Taglauer and Heiland are excellent reference works (Ref 30, 31, 32).

In practice, the investigator is interested in using ISS to identify atomic species in the surface and near-surface regions. This is done by applying the laws of conservation of energy and momentum to the classical two-body collision model

(Fig. 7). Several points are pertinent for understanding the two-body collision process as applied to ISS. First, an incoming probe ion of mass, velocity, and energy values of M_1, V_0, and E_0, respectively, collides elastically with a target atom of mass, M_2. Second, following the elastic collision, the probe ion is deflected at some scattering angle, θ, with respective mass, velocity, and energy values of M_1, V_1, and E_1. The target atom recoils at an angle, ψ, with respective mass, velocity, and energy values of M_2, V_2, and E_2.

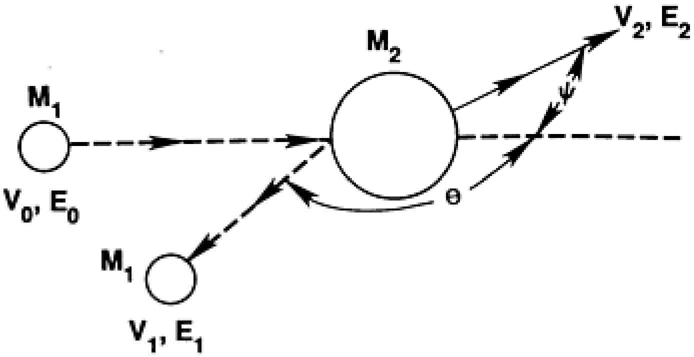

Fig. 7 Representation of two-body elastic collision between incoming atom of mass, M_1, velocity, V_0, and energy, E_0, with a target atom of mass, M_2, of initial velocity and energy of zero (stationary atom). θ and ψ represent the scattering and recoil angles, respectively.

Several equation forms are used to represent the two-body collision process. Such equations are the result of applying the laws of conservation of energy and momentum to the collision process. A typical form is that suggested by Suurmeijer and Boers (Ref 31). Specifically,

$$E_1/E_0 = \frac{1}{(1+\mu)^2}\left[\cos(\theta) + (\mu^2 - \sin^2\theta)^{1/2}\right]^2 \quad \textbf{(Eq 3)}$$

where $\mu = M_2/M_1 \geq 1$.

This form of the equation is for back scattering (that is, $M_2 \geq M_1$), as opposed to forward scattering when $M_1 > M_2$. When $M_1 > M_2$, the probe ions are not back scattered, but essentially, transfer all energy to the lighter target atoms, which recoil. It is this recoil energy that is measured in the case of forward scattering.

In practice, the forward recoil measurement is achieved by assuring a very shallow angle of approach between the target and incident ion beam and arranging the detector in a forward position in a manner such that the signal is being collected at a very shallow angle. This technique allows for detection of very light elements, with reasonable resolution when heavy probe ions are used.

Analytically, the forward-scattering process can be described by:

$$E_2/E_0 = \left(\frac{\mu}{(1+\mu)^2}\right)\cos(\psi) \quad \textbf{(Eq 4)}$$

where ψ is the recoil angle of the target mass, M_2, and $\mu = M_2/M_1$.

The scattering of ions from a solid-state surface is often classified according to the energy of the primary (probe) ion beam. Classifications of low-, medium-, and high-energy ion scattering, or reflection, are typically used. The purpose here is only to be concerned with low-energy ion-scattering spectrometry (LEISS), because of its high surface sensitivity. The

low-energy range is approximately 100 to 10,000 eV, whereas the upper end of the high-energy range is typically considered to be on order of 3 MeV.

LEISS is truly a surface analytical technique in that ions are reflected within approximately one monolayer. Probe ions with energies greater than the LEISS energy range will penetrate the sample more deeply. The result is a back-scatter spectrum with less surface-specific information.

It is important to point out that higher-energy studies can be useful for applications of thin-film analysis and analysis of subsurface regions. In order to accomplish this with lower-energy ISS, ion sputtering must be employed for "layer-by-layer" removal of the target material (see the discussion on ion etching in the Auger Electron Spectroscopy (AES) section of this article).

ISS Equipment. The equipment required to perform LEISS includes an ion source, an energy analyzer, and a vacuum system. Because these requirements closely parallel those of related surface analytical techniques, such as XPS and AES, it is not surprising that these techniques are often housed within a common vacuum system.

In some cases, the ion gun used for sputtering, or ion etching, with AES and XPS can be used as the ion source for LEISS. Historically, relatively simple electrostatic energy analyzers have been employed for ISS (Ref 30). The commercially available cylindrical mirror analyzers and concentric hemispherical analyzers typically used for AES and XPS analyses, respectively, are now popular analyzers for ISS applications.

Neutralization of Ions. Not all primary ions that are reflected from a solid target material are detected in ion-scattering spectrometry, because many ions are neutralized before exiting the target material. The fact that the neutralization probability is high for ions originating beyond approximately the first monolayer is the reason for the high surface sensitivity of LEISS. Ions are observed directly, but neutral species cannot be detected unless they are first ionized. Unfortunately, it is difficult to quantify ion neutralization processes; therefore, it is difficult to obtain quantitative information on chemical composition with ISS.

The ISS spectrum amounts to a plot of signal intensity versus E_1/E_0 (E_0 is the incident ion energy and E_1 is the reflected ion energy). If a relatively low-energy primary ion (that is, from 500 to 1000 eV) is used to bombard a sample, a relatively sharp back-scattered peak, such as shown by curve A of Fig. 8, typically results. However, as the primary beam energy is increased, a corresponding amount of skew is typically observed on the low-energy side of curve A. This is shown by curves B and C, which represent curves for respectively higher primary beam energies.

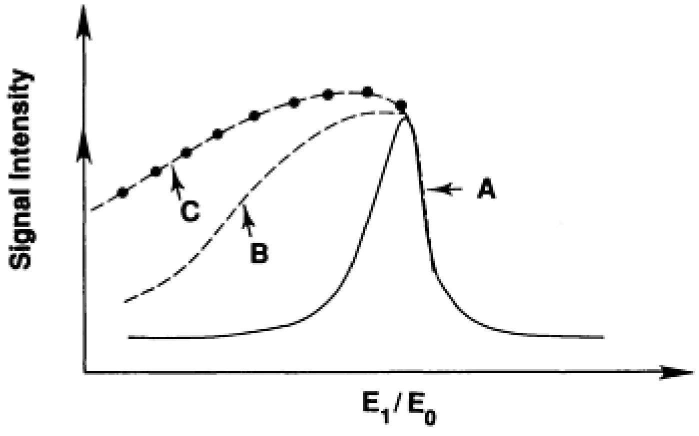

Fig. 8 Effects of deviation from single-event elastic collision model on ISS peak shape

The behavior of curves B and C, relative to A, can be explained as follows. The shape of curve A represents a low-energy beam that is reflected in a classical two-body fashion and is either elastic or very near elastic in nature. In other words, the low-energy beam undergoes true "single" scattering events. On the other hand, the higher-energy beam penetrates the sample more deeply before beginning the return path to the surface. As a result, "multiple" scattering events occur, and the energy loss of emitted ions finally escaping the surface is characterized by the broad low-energy components of

curves B and C. In fact, it is possible to observed distinct peaks at the low-energy end of the spectrum that are the result of species sputtered off of the surface, as opposed to ions that have been reflected.

The effects of multiple collisions can greatly affect the form of the ISS spectrum obtained. Interpretation of such results can be very involved; Ref 33, 34, 35 extensively discuss this topic.

In general, it is advisable for the investigator to employ the lightest possible primary ion and the lowest energies that are practical. As a rule of thumb, this means using He^+ as the ion probe, at energies up to 1000 eV. Again, results differ for the different systems and the literature should be consulted.

Resolution and Sensitivity. it is reasonable to contemplate the effects of varying the mass of the probe ion on the ISS spectrum. This is done analytically by differentiating E_1/E_0 of Eq 3 with respect to the target mass, M_2. To obtain higher mass resolution, the value of $d(E_1/E_0)/dM_2$ must be increased. Physically, this is achieved by choosing heavier mass values of M_1 for the scattering situation of $M_1 < M_2$. In fact, this idea has been employed to distinguish isotopes such as ^{63}Cu and ^{65}Cu (Ref 36). An excellent example increased mass resolution is the work presented by Smith (Ref 30), where a gold-nickel alloy with molybdenum contamination was studied. ISS was performed at E_0 = 1.8 keV for the primary ions of He^+ and Ne^+. The heavier Ne^+ primary ion was observed to result in increased peak resolution, compared with the lighter He^+ primary ion.

The sensitivity of the LEISS technique depends to some extent on the conditions of analysis. The relative intensity of a LEISS peak corresponding to an arbitrary atom, A, relative to another arbitrary atom, B, is given by:

$$\frac{I_A}{I_B} = \left(\frac{d\sigma_A}{d\sigma_B}\right)\left(\frac{C_A}{C_B}\right) \quad \text{(Eq 5)}$$

where I_i is the signal intensity of element *i*, $d\sigma_i$ is the differential cross section of element $_i$, and C_i is the surface concentration of element *i.*

The intensity, in turn, depends on the angles of incidence and scattering, and neutralization probability, as well as several other factors. Hence, by the geometry of the scattering experiment alone. It is possible to vary sensitivity, which can be as low as 0.01 monolayer (Ref 37). Spatial resolution is limited by the size of the ion beam, which is typically on the order of 1 mm (0.04 in.) in diameter.

ISS Applications. One application of ISS is well demonstrated by the behavior of polycrystalline platinum on a titania substrate. This example is particularly interesting, because under certain conditions it has been postulated that the titania substrate effectively encapsulates the polycrystalline platinum overlying titanium (Ref 38, 39, 40).

Supported transition metal oxide systems have enjoyed a great deal of attention over the years in terms of applications in heterogeneous catalysis. In the 1970s, supported platinum catalysts were extensively investigated to understand their role in methanation reactions. For such reactions, carbon monoxide and hydrogen are adsorbed on a catalytic surface and react to form methane.

Some investigators observed that when the catalyst is heated under conditions of sufficient vacuum, hydrogen and carbon monoxide no longer adsorb on the catalytic surface (Ref 41). The reason for the loss of adsorption has been a point of considerable debate. One hypothesis is that heating under reducing conditions results in the encapsulation of the metal surface by the supporting substrate, causing physical blockage of adsorbate sites. This hypothesis is sometimes referred to as the "encapsulation theory."

This theory is one of several posed to explain the behavior of reforming catalytic materials composed of systems containing platinum and titania. Under normal conditions, hydrogen and carbon monoxide are adsorbed on the platinum surface and methane is formed from their reaction. However, if the system is heated under sufficient reducing conditions, then adsorption of hydrogen or carbon monoxide is not observed. LEISS is an excellent technique by which to investigate the phenomenon, because encapsulation effects are expected to be surface-specific in nature.

The AES data shown in Fig. 9 are of a cleaned polycrystalline platinized-titania sample. The spectrum clearly shows that platinum, oxygen, titanium, and a small amount of graphitic carbon are present. Figure 10 represents ISS data for the

same sample. Peaks corresponding to single-event elastic scattering of He^+ from the sample show that oxygen, titanium, and platinum are present.

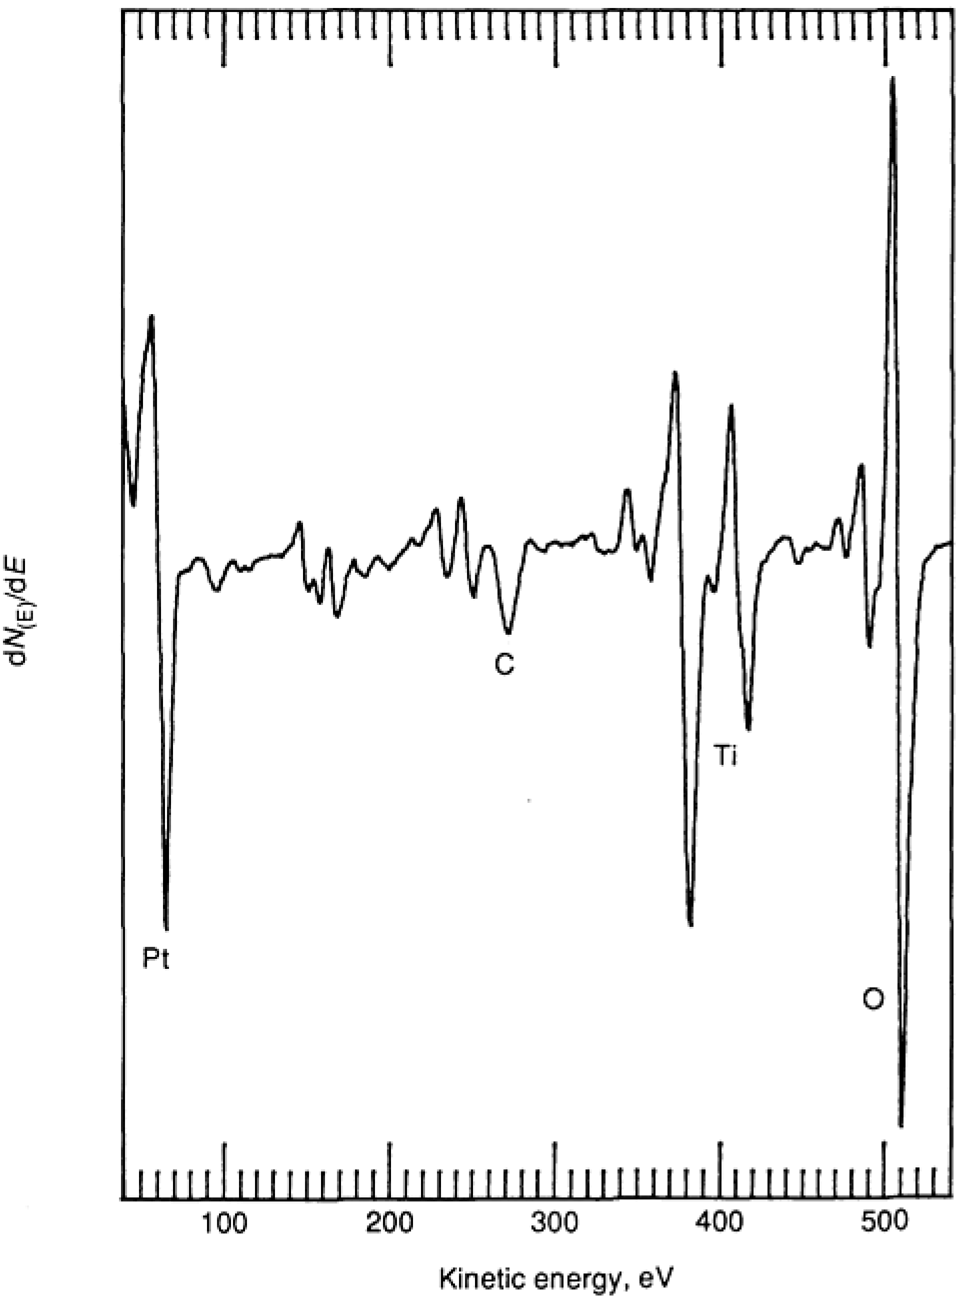

Fig. 9 AES spectrum of platinized-titania sample prior to annealing treatment

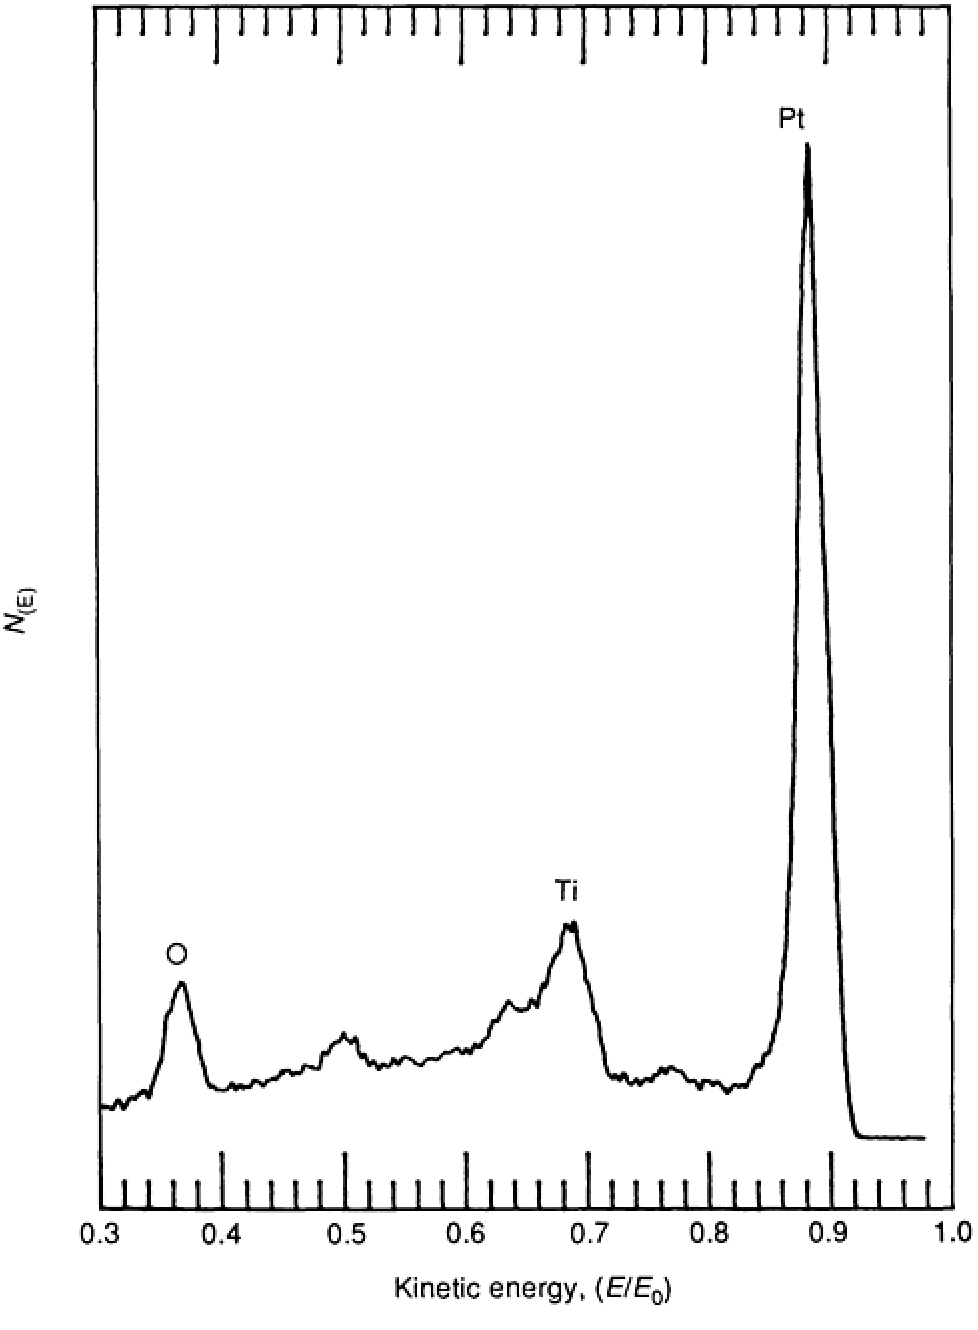

Fig. 10 ISS spectrum of platinized-titania sample prior to annealing treatment

Figures 11 and 12 are AES and ISS spectra of the same sample after annealing in ultrahigh vacuum (1.3 × 10^{-8} Pa, or 10^{-10} torr) at 500 °C (930 °F) for 1 h. Note that the relative amounts of titanium to platinum have changed, and are greater following the annealing treatment, which indicates that platinum is being overlayered by the titanium oxide substrate. Hence, ISS has been used in conjunction with AES to monitor surface and near-surface composition changes as a function of specific treatment conditions. In this case, the surface sensitivity of ISS makes the process of platinum encapsulation easy to observe.

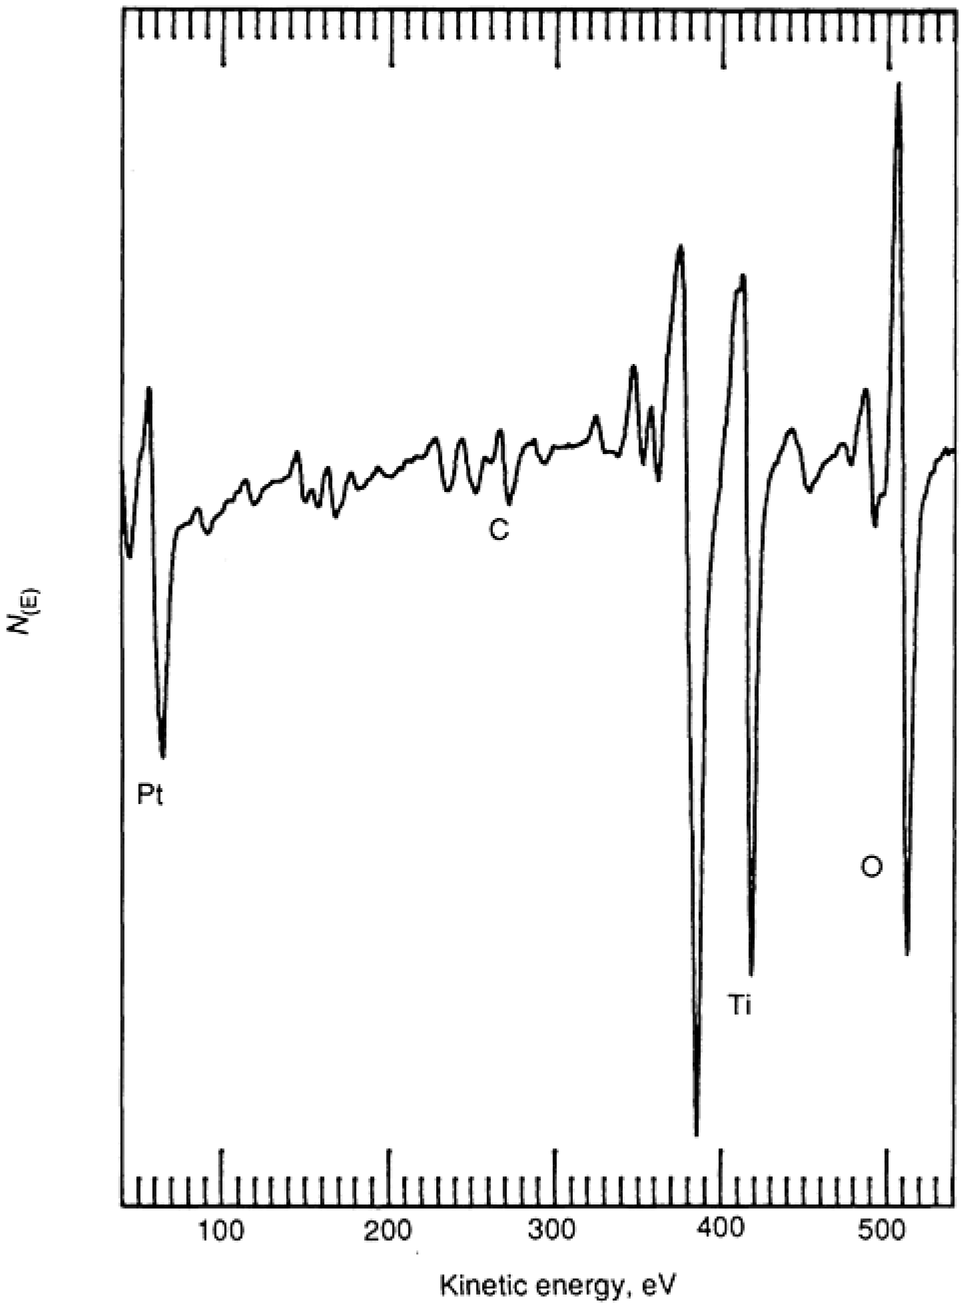

Fig. 11 AES spectrum of platinized-titania sample following annealing in vacuum for 1 h at 500 °C (930 °F)

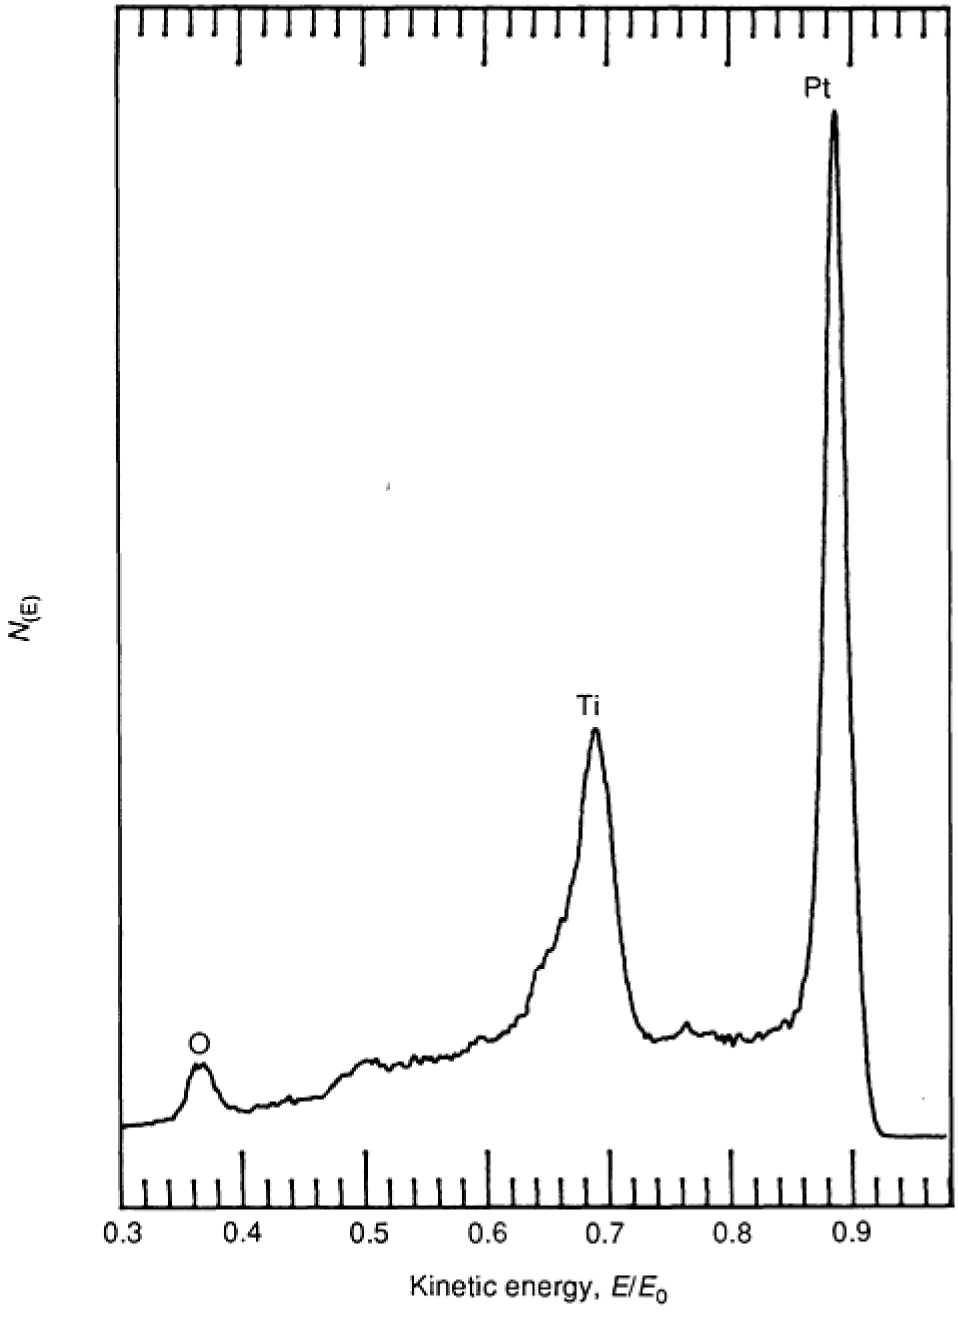

Fig. 12 ISS spectrum of platinized-titania sample following annealing in vacuum for 1 h at 500 °C (930 °F)

ISS can sometimes be applied to determine surface structure, as well as composition. For example, Niehus and Bauer (Ref 42) applied ISS to a study of oxygen adsorption on W (110). In this case, He^+ scattered at energies less than 500 eV was observed to be scattered only from the outermost atomic layer of the surface. It was therefore possible to distinguish the unreconstructed surface, consisting only of oxygen atoms, from the reconstructed surface, consisting of oxygen and tungsten atoms. Such structural studies are often done in conjunction with low-energy electron diffraction (LEED), which is a technique for structural determination. Reference 40 describes this technique.

Thus, ISS is an important analytical tool because of its high degree of surface sensitivity. In addition, it is sometimes possible to acquire structural information, especially in conjunction with techniques such as LEED. Disadvantages are the inability to obtain chemical state information and surface damage. ISS can be particularly useful in wear studies to investigate material transfer, particularly if small amounts of material are transferred and/or material transfer is restricted to very outer surface regions.

Auger Electron Spectroscopy (AES)

AES is a nonradiative spectroscopy that is based on measuring the kinetic energy of secondary electrons emitted from a solid surface when the solid is subjected to an appropriate energy source. The source is typically an electron beam with energies that range from 2 to 10 keV. However, photons and ions can also stimulate Auger electron emission from solid-state materials. The escape depth of an Auger electron depends on the energy of the electron, but is typically within a depth of five monolayers, with a detection limit of approximately 1 part per 1000. AES has probably been applied to problems in friction, lubrication, and wear more than any other surface analytical technique. Representative applications are described in Ref 43, 44, 45.

AES Fundamentals. Auger electron emission depends on the initial removal of electrons from the inner shells of an atom. This process is often referred to as core-level ionization. When a core-level vacancy is generated in an atom, the atom undergoes an electronic rearrangement, or relaxation process, through which an electron in a higher-lying energy level (lower binding energy) drops down to fill the core-level vacancy.

In the case of the Auger transition, the energy associated with this transition is imparted to a third electron is expelled from the solid, and is known as the Auger electron. The Auger $KL_{2,3}L_{2,3}$ emission process is shown in Fig. 13.

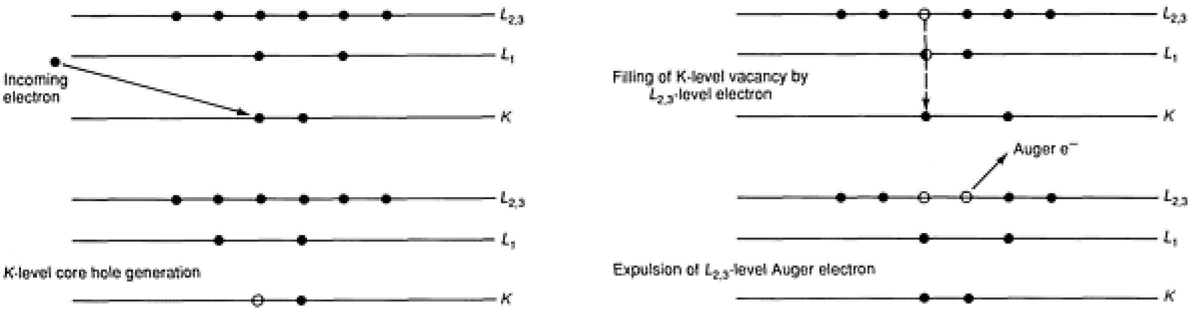

Fig. 13 Energy-level diagram at Auger $KL_{2,3}$, $L_{2,3}$ electron emission process

It is important to note that when a core-level vacancy is generated, it is also possible for the excited atom to relax via x-ray emission, as opposed to the radiationless Auger process. The emission process of an x-ray photon is the basis for electron probe microanalysis (EPMA), which is sometimes used in conjunction with AES. Unlike AES, EPMA is not a surface-sensitive technique.

Auger transitions are typically described in terms of conventional x-ray notation. A detailed discussion of this notation can be found in Ref 46 and 47. In short, x-ray notation is based on the principal quantum number, n, the orbital momentum quantum number, l, and the spin quantum number, s. The reader may recall that electrons with the same value of n occupy the same energy level or shell where n can take on the values of 1,2,3,. . .. Each principal energy level (designated by n) has one or more sublevels associated with it. The sublevels are designated by the letter, l, which is called the angular momentum quantum number. The allowed values of l are 0,1,2,3 . . . (n - 1) where n is the principal quantum number. Lastly, the spin quantum number represents the spin orientation of the electrons and this quantum number can take on a value of $s = \pm\frac{1}{2}$.

In x-ray, the principal quantum number assigned to an electron is designated by an upper case letter. In this notation system the designation of energy levels by K,L,M,. . . corresponds to values of n = 1,2,3, . . . for the principal quantum number. Next, each upper case letter is assigned a numerical suffix value, each of which represents a specific combination of angular and total momentum values. The total momentum is designated by the letter j and is the sum of the orbital and spin momentum (that is, $j = l + s$). A suffix value of l specifies $l = 0$ and $j = \frac{1}{2}$, while a value of 2 specifies $l = 1$ and $j = \frac{1}{2}$, a value of 3 specified $l = 1$ and $j = \frac{3}{2}$, and so on. For example, the x-ray notation of L_1 means $n = 2$, $l = 0$, and $j = \frac{1}{2}$, while the L_3 notation means $n = 2$, $l = 1$, and $j = \frac{3}{2}$.

Electron Escape Depth. The probability that an electron will be emitted from a solid, following generation, is related to the mean free path, λ, and the below-surface depth where the electron originates. Specifically, the probability of escape, *P*, can be written as:

$$P = \alpha \exp\left(\frac{-z}{\lambda}\right) \quad \textbf{(Eq 6)}$$

where *z* is the depth below the surface, λ is the mean free path of the electron, and α is a proportionality constant. In turn, the mean free path is a function of the energy of the electron. This path is relatively insensitive to the material through which the electron is moving and depends only on the energy of the electron. As a result, universal curves have been developed to graphically show the relationship between electron mean free path and electron kinetic energy. Such curves can be obtained from Ref 46.

As the Auger electron emission process begins, it is clear that several things can happen to the electron as it travels through the solid. The further the electron travels, the greater the probability that it will interact with other electrons in the solid. If this happens, the Auger electron will lose energy and eventually emerge at some energy less than the initial level. Clearly, only Auger electrons originating in the surface and near-surface regions eventually escape the solid and are recognized at characteristics Auger energies. These electrons that leave the solid and are then detected originate from an average distance, *Z*, below the surface, where *Z* is typically less than 10 monolayers (Ref 47). As a result, the AES spectrum peaks associated with these electrons are often referred to as elastic peaks.

It is important to point out that energy loss processes also occur as the result of interaction of emerging electrons with phonons and plasmons. Discussion of these phenomena can be found in Ref 48.

AES Equipment. Chemical analysis by AES involves the measurement of characteristic energies of electrons emitted from the surface and near-surface regions of solid-state materials. Hence, the fundamental requirements of the overall process consist of an appropriate energy source to stimulate Auger electron emission, a UHV system to maintain sufficiently low pressures, and an analyzer to measure energies of emitted Auger electrons.

The electron gun typically contains a tungsten filament that produces electrons through thermionic emission. In the case of scanning Auger instruments, beam sizes on the order of 1 μm are possible. The electron gun can theoretically be positioned in any manner that proves to be practical. However, for energy analysis, many systems employ cylindrical mirror analyzers that house the electron gun coaxially.

The vacuum system, which must be operated in the UHV range, has a stainless steel "bell jar" for the main chamber. System base pressures are typically on the order of 1.3×10^{-8} Pa (10^{-10} torr), with pressures during operation being slightly higher. Operational pressures in the range of approximately 6.5×10^{-8} to 1.3×10^{-6} Pa (5.0×10^{-10} to 1×10^{-8} torr) are typically encountered.

Three types of pump systems are usually employed to bring the system down to the desired pressure. Either mechanical roughing pumps or liquid nitrogen sorption pumps are used to initially start the pump-down process. Pressures on the order of 0.13 Pa (10^{-3} torr) are typically achieved with this primary pumping process. Next, turbomolecular pumping is typically employed to achieve pressures on the order of 1.3×10^{-3} Pa (10^{-5} torr), followed by ion pumping, which brings the system into the UHV range.

Eventually, contaminants accumulate until it is no longer possible to obtain the desired system base pressure. In this case, the system must be baked to remove adsorbed contaminants from system components, at which point they are pumped away. Procedures for baking vary from system to system and equipment manufacturers should always be consulted during the first baking procedure. Failure to execute this procedure correctly can result in equipment damage.

Energy Analyzer. The most popular type of analyzer for AES applications is probably the cylindrical mirror analyzer, previously discussed in the section on XPS. The CMA consists of two coaxially arranged cylinders. Electrons from the target material are electrostatically focused such that only electrons with specific energies will successfully traverse the length of the analyzer and contact the electron detector at the back of the analyzer.

The focusing process is accomplished by applying a voltage across the two cylinders. The outer cylinder is biased at a negative potential relative to the grounded inner cylinder. An electric field results from the voltage application across the

cylinders. The strength of the electric field is related to the magnitude of the voltage potential difference across the cylinders. As the voltage difference is increased, the field strength is increased. Only electrons within the energy spread, ΔE, have appropriate trajectories to reach the detector. Each electron has an energy, E = eV, where e is the charge on the electron and V is the applied potential. The energy analyzer resolution for this situation is defined as $\Delta E/E$.

CMAs are available in two configurations: single-or double-pass (Fig. 14). The single-pass configuration is well suited to AES because the electron beam typically used as a probe is focused over a small area relative to the entrance area of the analyzer. Therefore, the transmission of electrons through the analyzer is significant, relative to that observed for XPS, which employs a more diffuse x-ray source for excitation.

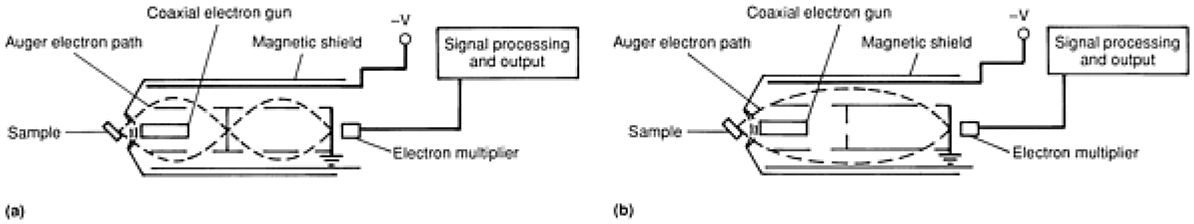

Fig. 14 Cylindrical mirror analyzer types. (a) Double pass. (b) Single pass

The double-pass CMA has found extensive application when AES and XPS are performed together. As already noted, additional focusing capability and resolution requirements are necessary for XPS, which means that this technique requires the double-pass CMA. Systems dedicated exclusively to XPS often employ analyzers of hemispherical geometry (Ref 46). The larger area over which the signal is collected with this geometry, relative to the CMA, results in detection enhancement and is therefore very attractive for XPS application.

The AES spectrum is a representation of the distribution of energies of Auger electrons emitted from a material of interest. This energy distribution is represented by displaying signal intensity, $N_{(E)}$, as a function of Auger electron kinetic energy. Therefore, AES data appear in the form of $N_{(E)}$ versus Auger electron kinetic energy, as shown in Fig. 15. This $N_{(E)}$ spectrum was obtained by subjecting a copper sample to a 5 keV electron beam. The spectrum shows that copper, oxygen, and carbon are present. Copper is characterized by three peaks in the range of 750 to 925 eV and one low-energy peak occurring near 50 eV. Oxygen and carbon are single peaks occurring at intermediate energy values. An important aspect of data in the $N_{(E)}$ form is that the signal is typically small and is contained on a large secondary electron background.

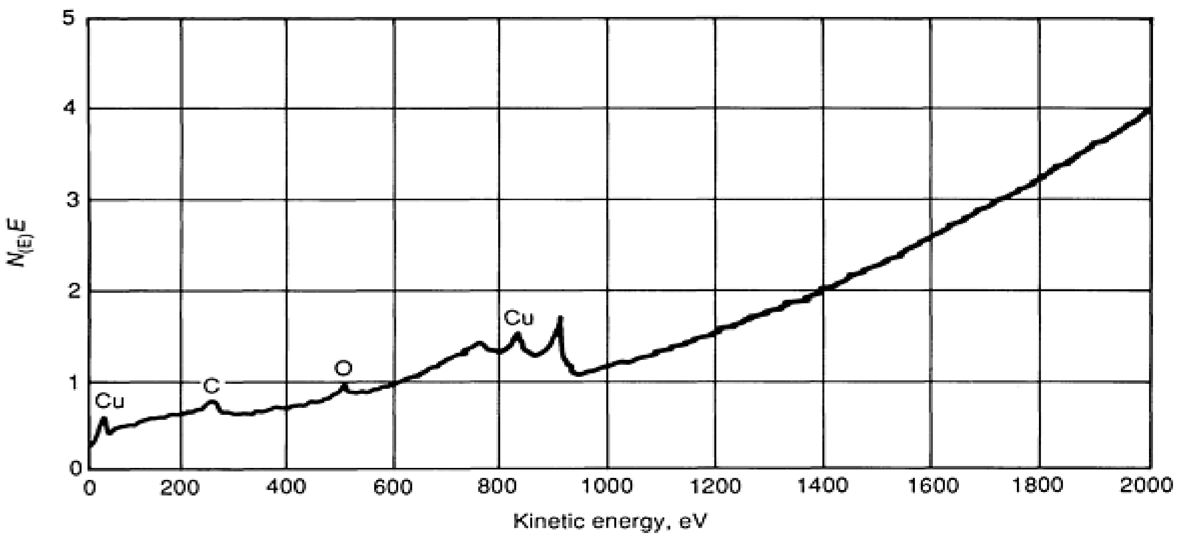

Fig. 15 AES spectrum of copper sample displayed in $N_{(E)}$ mode

The interpretation of AES data presented in the $N_{(E)}$ mode is greatly enhanced by differentiation of the $N_{(E)}$ signal. This mode of display is referred to as the d$N_{(E)}$/dE mode. The $N_{(E)}$ data in Fig. 15 is shown in d$N_{(E)}$/dE form in Fig. 16. The peak-to-peak height of signals in the d$N_{(E)}$/dE mode is proportional to the number of atoms from which Auger electrons originate to yield the signal.

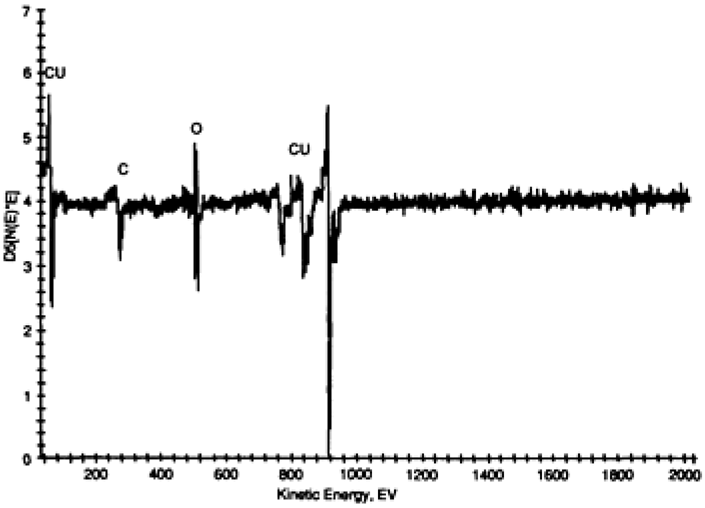

Fig. 16 AES spectrum of copper sample displayed in derivative d$N_{(E)}E$/dE mode. D5[N(E)*E] = d$N_{(E)}E$/dE

Qualitative analysis can be performed by measuring the kinetic energy of electrons over a range that encompasses emissions from all atoms of interest. In practice, the most useful range of electron kinetic energies is probably 30 to 2000 eV. Once an initial survey scan is completed, it is often useful to perform subsequent scans over more-narrow energy regions that contain peaks of interest. The smaller energy window will enhance the resolution of peaks in this region with respect to features that are not as easily observed in the more-compressed 30 to 2000 eV scan.

Quantitative results for compositional analysis are often extracted from AES data. The reader should realize that methods of quantification typically utilized in practice are best described as semiquantitative. This is because reference data are typically based on signal intensities obtained for pure reference materials. When the element is present in the more complex matrix environment of a compound, the behavior of emitted Auger electrons can be expected to be different. This is primarily manifested through complicated scattering events and changes in the inelastic mean free path. Scattering events can be significant because electrons that have encountered scattering events can sometimes contain sufficient energy to induce Auger transitions. The inelastic mean free path, which is the characteristic path length traveled by the Auger electron before it is inelastically scattered, is certainly subject to matrix effects.

As discussed in Ref 46, a linear relationship is the simplest form of relationship between the AES signal intensity of an atom of interest in pure form and in a matrix with other elements. For instance, the atomic fraction, X_i, of an atom, i, in a matrix is given by

$$X_i = \frac{I_i}{I_i^p} \qquad \textbf{(Eq 7)}$$

where I_i is the Auger signal intensity observed for the atom in the matrix and I_i^{p} is the intensity of the pure component. It should be clear that pure component intensity values for an element of interest must be either available or measured for a given set of operational conditions. In any event, a standard representing each element of interest must be measured at some point. This typically requires either preparation or acquisition of a large number of standards.

In practice, the composition of a material of interest can be determined in a couple of ways. One method of obtaining compositional information is to compare element peak intensities for a material of interest to intensities obtained from pure element standards. Alternatively, relative sensitivities of pure elements with respect to a pure element standard can

be correlated through the use of elemental sensitivity factors. In this case, the atomic fraction of species *i* in a matrix of *N* elements is given by

$$X_i = \frac{(I_i/S_i)}{\sum_{i=1}^{N} (I_i/S_i)} \qquad \textbf{(Eq 8)}$$

where X_i is the atomic fraction of species *i*, I_i is the signal intensity of species *i*, and S_i is the elemental sensitivity of species *i*.

It is important to point out that when data are collected in the derivative mode, I_i is the peak-to-peak height, and when data are collected in the $N_{(E)}$ mode, I_i is the peak area. It should also be noted that inaccuracies are inherent in the sensitivity factors because they are derived for pure elements and do not include matrix and chemical effects. Even though they are not commonly employed for outline analysis, techniques have been developed to evaluate matrix effects through the application of matrix factors (Ref 46).

Ion Etching (Sputtering). A very useful feature of most surface analysis equipment is the ability of ion etch, or sputter, the surface of a sample of interest. This process consists of eroding away the surface in a layer-by-layer fashion. The two primary uses of ion etching are acquisition of depth-dependent composition information (depth profile) and removal of contaminants from the surface of a material of interest.

The process of ion etching involves ion bombardment of a target surface with sufficient energy to break atomic bonds in the solid and remove chunks of the surface from the solid target. Ions are generated for this process by electron-atom collisions in a pressurized gas. It is usually desirable that the gas be chemically inert. Therefore, ions of the noble gases are typically employed, with Ar^+ being used most often. Once the Ar^+ beam is generated, it is delivered to the target with energies that typically range from 2 to 5 keV, with a beam diameter on the order of a couple of millimeters. Depending on the specifics of the equipment employed, the ion beam can either be applied to one spot or rastered over an area.

AES depth profile information is usually reported in the form of atomic concentration, or atomic fraction, versus sputtering time. Absolute depth values are usually not convenient to determine and can actually be very difficult to determine, depending on the particular system. Usually, ion etch rates, or sputter rates, are reported relative to a known sputter rate. In other words, a material of known thickness is selected, the time required to sputter through this thickness is recorded, and then rates for other materials are reported with respect to this rate. In most instances, the reference material used is Ta_2O_5. Historically, this choice has been made because of the ease with which the oxide film thickness can be controlled during formation (Ref 46).

Consider the AES depth profile data shown in Fig. 17. These data were acquired by sputtering with Ar^+ at 2 keV. The data are for a BiO_x-Auglass thin-film system prepared by thermally evaporating gold on a glass substrate, followed by the evaporation of bismuth over the gold. Subsequently, the sample was subjected to a treatment to oxidize the bismuth. This system was chosen to demonstrate the depth-profiling technique with AES, because the layered structure allows the clear identification of changes in composition through the layers of the thin-film system.

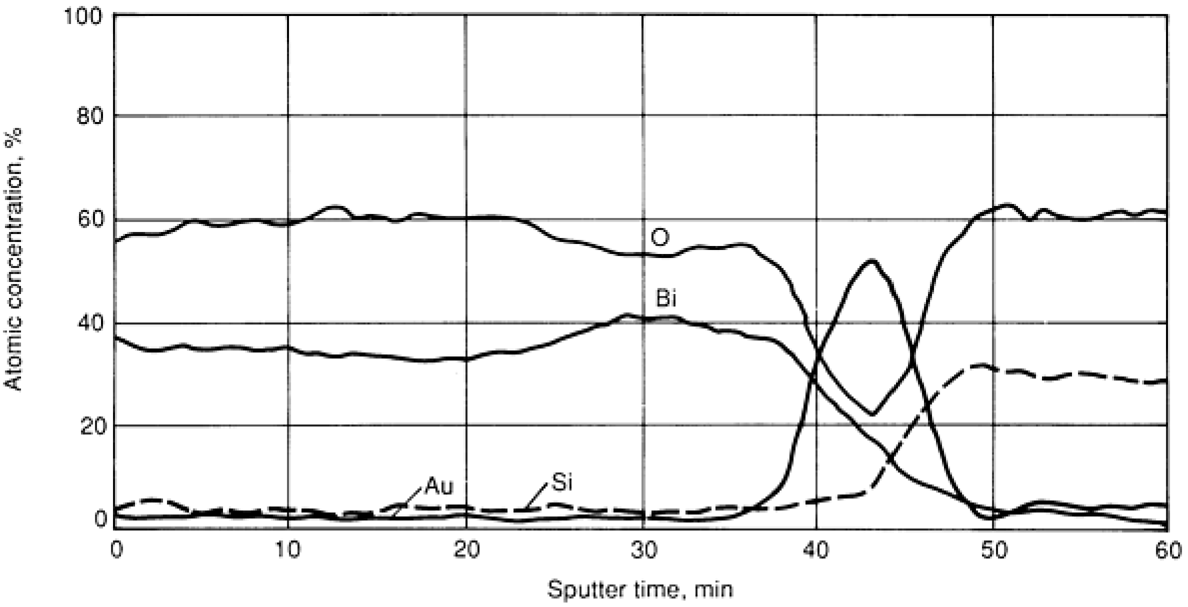

Fig. 17 AES depth profile of BiO_x-Au system on glass

It is imperative that the reader understand the complexity of the atomic processes that result in ions being etched from the surface. References 46 and 47 provide detailed descriptions of these processes. However, the potential limitations of ion etching can be summarized here. First, ion etching induces changes in the composition of the target material in local areas where etching is occurring. The degree of alteration of the true composition profile depends on the specifics of the system and conditions. Second, ion etching rates are subject to matrix, as well as grain boundary, effects. Again, the extent of these effects depends on the particular case, but can be substantial. Third, ion etching can induce surface roughness, which can affect subsequent analytical information. Last, it should always be remembered that ion etching is a destructive technique by nature and precautions should be taken if this presents a problem.

Effects of Chemical Environment on AES Spectrum. Changes in the chemical environment of an atom can affect the AES spectrum with respect to that atom. Such perturbations of the atomic environment are typically observed as shifts in the location of AES elastic peaks and/or changes in the prestructure of these peaks.

Shifts in the measured kinetic energy of AES electrons result when electron transfer occurs between atoms. The greater the extent of electron transfer, the greater this effect is expected to be. Therefore, chemical effects for systems exhibiting ionic bonding character should be important. In fact, chemical shifts of several electron volts can be observed for this particular situation. The effects of chemical shifts show in the AES spectrum as peak shifts to higher kinetic energies for electronegative atoms and as shifts to lower binding energies for electropositive atoms.

A classic case of chemical effects in the AES spectrum can be seen by comparing spectra for aluminum and alumina. In this case, both AES elastic peak locations and prestructures are significantly different. Reference 49 compares these spectra.

AES Applications. AES and related surface analytical techniques have enjoyed widespread application in many areas, although applications have been more extensive in areas such as catalysis than in areas such as friction, lubrication, and wear. However, as suggested earlier, AES has probably been applied to friction, lubrication, and wear problems more than any other method of surface analysis.

From the discussion thus far, it is clear that AES can be used to identify chemical constituents and to determine their relative abundance in terms of atomic fraction. In some cases, qualitative information about oxidation states can be obtained by AES peak structure. Changes in the shape of an AES peak can indicate a change in oxidation state. For example, a comparison between Fig. 9 and 11 shows that the AES Ti 387 eV peak shape is changed following annealing in vacuum (reducing conditions). Therefore, titanium oxide reduction can be qualitatively identified by the shape of the Ti 387 eV peak. This phenomenon has been discussed in detail by Hoflund *et al.* (Ref 50).

Consider the scanning electron micrograph shown in Fig. 18. The micrograph shows a wear track area on an aluminum 1100 surface that has been worn against an annular silicon carbide counterface in a distilled-water environment. The wear test was performed with a new test configuration that has recently been reported (Ref 51). Representative areas, both within and external to the wear track, will be analyzed as an example of the application of AES.

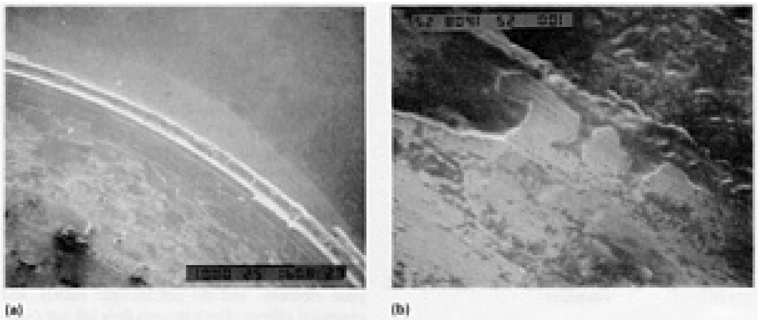

Fig. 18 Electron micrographs. (a) Wear track edge of worn aluminum 1100 sample. (b) High-magnification shot inside wear track

Figure 19 is an AES survey spectrum acquired using an Auger electron spectrometer with secondary electron imaging capabilities. The survey scan was acquired within the wear track region with electron beam voltage and current values of 5 keV and 1.67 μA, respectively. In fact, these parameter values were maintained for all data presented in this section.

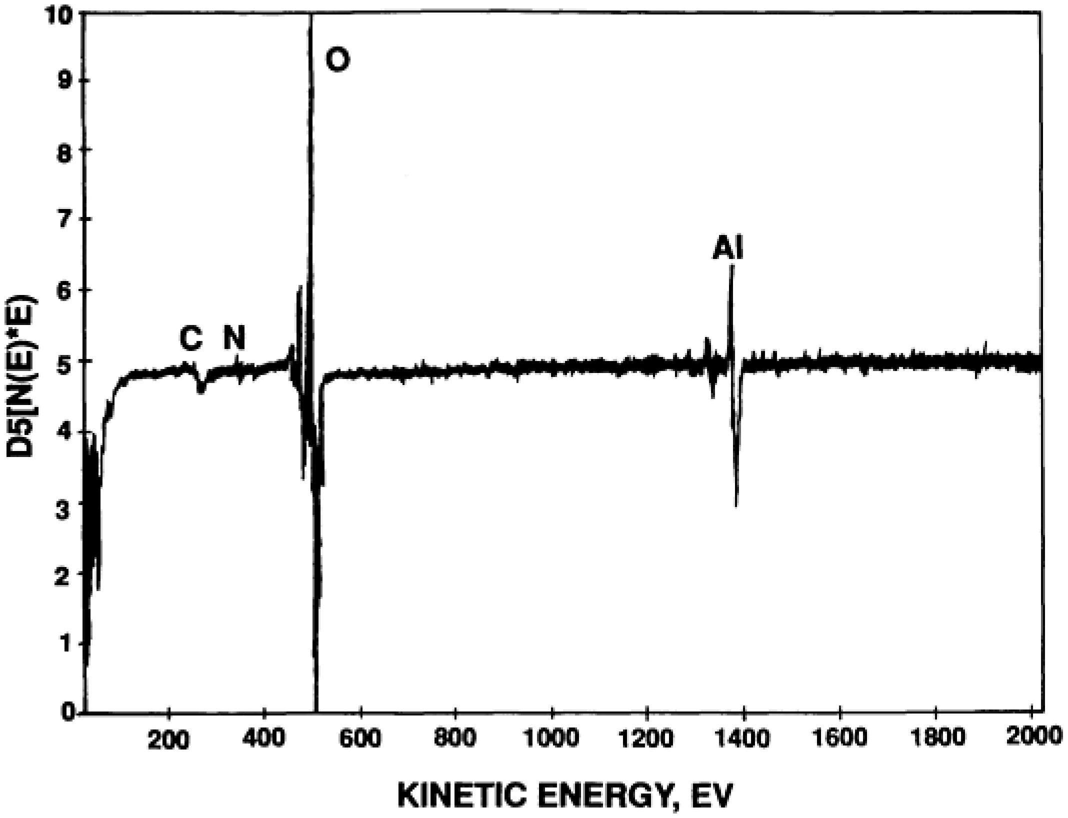

Fig. 19 AES survey spectrum of wear track region of aluminum 1100 sample. D5[N(E)*E] = d$N_{(E)}E$/dE

The data in Fig. 19 show that the surface and near-surface regions of the worn area typically contain small amounts of carbon and nitrogen, in addition to aluminum and oxygen. The carbon peak is expected to occur at 242 eV, oxygen at 503

eV, aluminum at 1396 and 68 eV, and nitrogen at 376 eV (Ref 43). The atomic fractions of aluminum, oxygen, and carbon are 0.62, 0.31, and 0.07, respectively. The small amount of nitrogen has been neglected in the calculation. The "oxide character" of metallic systems is often of interest. For this reason, the atomic ratio of oxygen to aluminum (O/Al) is noted to be 0.50.

In order to compare the composition of the specimen in regions below the wear track to the above-discussed composition in the surface and near-surface regions, ion etching was performed to effect material removal. Figure 20 shows the result of an AES survey scan acquired following ion etching for 10 min with 4 keV Ar^+. The AES spectrum shows that carbon and nitrogen have been completely removed. Only oxygen and titanium occur in this region. The small amount of argon shown by the AES signal at 215 eV is the result of Ar^+ being embedded in the specimen during ion etching. The (O/Al) value is 1.3, which is considerably more than the value of 0.50 obtained at the surface. The respective atomic fractions of aluminum and oxygen are 0.44 and 0.56. An analogous set of data was obtained for areas external to the wear track to allow a comparison between the worn area and a typical area of the specimen not subjected to the wear process.

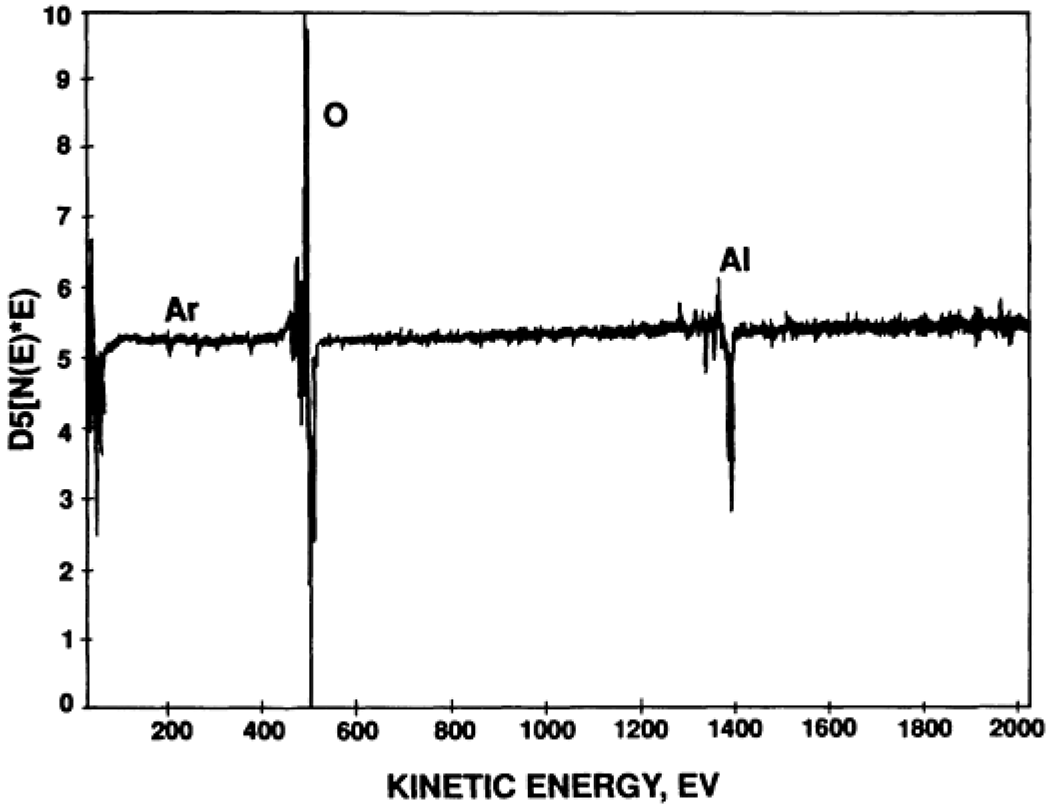

Fig. 20 AES survey of aluminum 1100 wear track region following sputtering with Ar^+ for 10 min at 4 keV. D5[N(E)*E] = d$N_{(E)}E$/dE

Figure 21 shows that chlorine, carbon, and a small amount of nitrogen, in addition to oxygen and aluminum, are present in the surface and near-surface regions. Note that the amount of carbon is considerably more than was observed in the wear track area. It is difficult to identify a single carbon source in this case. Carbon is a common component of most surfaces before the sample is cleaned by light ion etching and/or heating. Chlorine was present on the surface of some of the as-received material and therefore shows up here for the region external to the wear track area. This suggests that chlorine, nitrogen, and a considerable amount of carbon are removed during the wear process in the deionized water environment. The respective atomic fractions of aluminum, oxygen, carbon, and chlorine are 0.42, 0.24, 0.33, and 0.01. The (O/Al) value is 0.57.

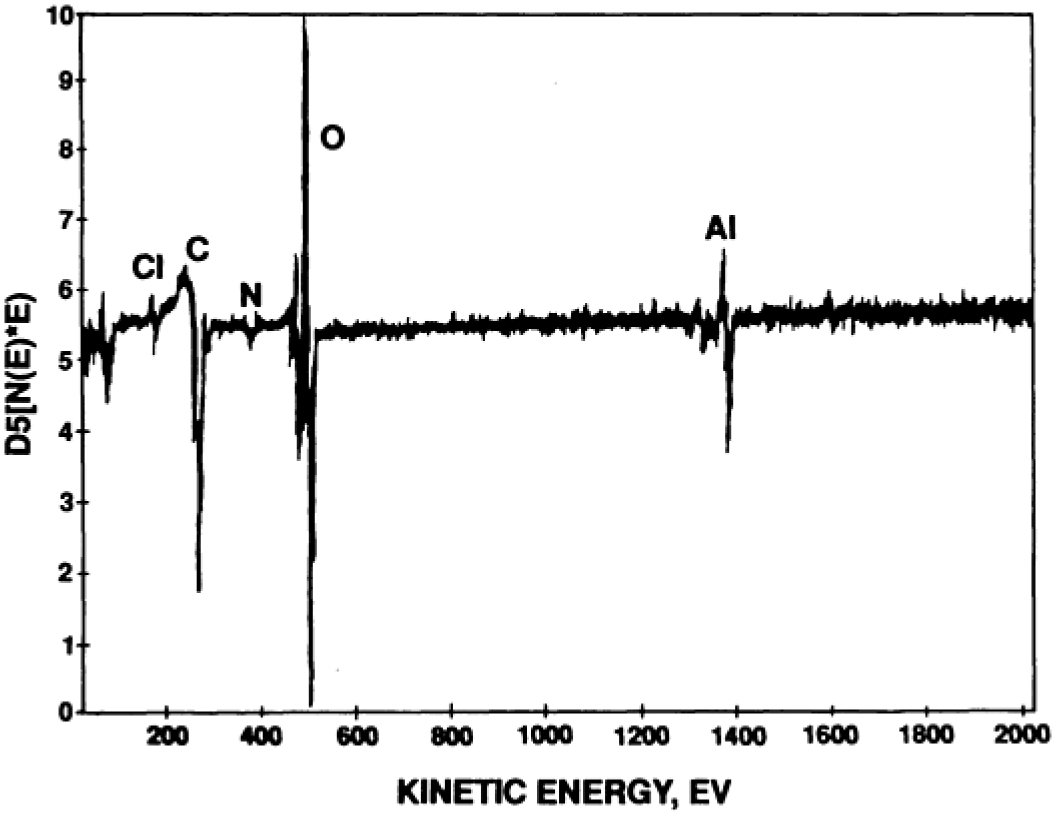

Fig. 21 AES survey spectrum of region external to wear track. D5[N(E)*E] = d$N_{(E)}E$/dE

Figure 22 demonstrates ion etching for 10 min with 4 keV Ar^+. The spectrum shows that chlorine and carbon have been effectively removed. As previously observed, argon appears in the spectrum after being embedded during the ion etching process. The (O/Al) value is 0.52, which is close to the value of 0.57 obtained prior to ion etching.

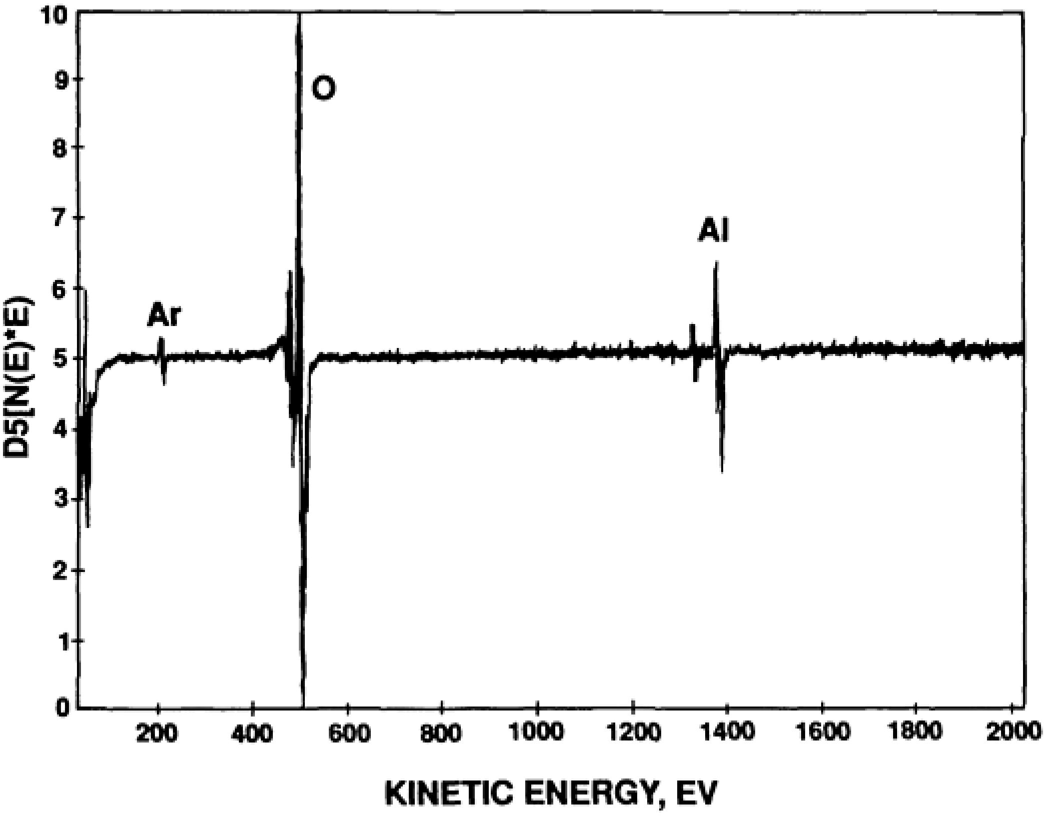

Fig. 22 AES survey spectrum of region external to wear track following sputtering with Ar^+ for 10 min at 4 keV. D5[N(E)*E] = $dN_{(E)}E/dE$

This example represents typical results obtained following evaluation of a number of sample areas, both inside and external to the wear track area. Probably the most interesting observation is that the (O/Al) value is consistent in moving from the surface and near-surface regions toward bulk regions, as deduced from the analysis of the specimen in regions external to the wear track. These (O/Al) values of 0.57 and 0.52 are also in the neighborhood of the 0.50 value observed for the surface and near-surface regions of the wear track. On the other hand, the (O/Al) value of 1.3 observed following ion etching in the wear track region is considerably higher. Even though a mechanism has not been proposed or tested here, the AES data indicate that the wear process could result in oxygen transport to interior regions of the specimen, resulting in increased (O/Al) values.

Finally, a point of caution should be observed when comparing composition data. The accuracy of data is probably at best on the order of 10%. Therefore, if it is determined that the atomic fraction of an element in a material of interest is 0.50, it should be viewed as 0.50 ± 0.10. This means that the composition should be interpreted as ranging from 0.45 to 0.55. This uncertainly stems from uncertainties in relative sensitivity factors that arise from complications such as matrix effects.

AES limitations are described below in terms of electron beam, nonconductive samples, and the overlapping of peaks.

The electron beam, typically used as the probe in AES, has several drawbacks. For instance, localized damage can occur through electron-stimulated desorption processes. As a result, composition can be altered in the subject area.

Nonconductive samples may "charge up" under the electron beam and yield spurious results. Major characteristics of surface charging are peak shifting and distortion. If the instrument has secondary imaging capabilities (scanning Auger), points of charging can sometimes be identified by their brightness.

Several procedures are commonly used to deal with the analysis of materials that demonstrate poor electrical conductivity. Higher beam voltages can sometimes be employed to alleviate the problem. Also, if shallow contact (grazing) angles are established between the electron beam and the solid, then surface charging can be minimized because this arrangement maximizes secondary electron emission from the surface. It is important to note that conventional

conductive coating techniques such as those employed with scanning electron microscopy (SEM) are not practical with AES because of the surface sensitivity of AES measurements. Also, it is sometimes possible to raster the electron beam to the extent that localized areas of charging are avoided or at least minimized.

Peak overlap is usually not a major problem with AES, but it can occur and should be addressed. This problem can be a combination of differences in relative sensitivities and concentrations of the elements involved. For instance, if the characteristic peak(s) of one constituent is very near the peak location of another constituent, and the signal intensity of one is considerably less than the other, then the constituent with the higher sensitivity can mask the peak of the other. This is especially true if chemical elements with low sensitivities are present in small concentrations.

Consider the peaks of chromium that occur at 529 eV and 489 eV in the ($dN_{(E)}/dE$) mode and the primary peak of oxygen that occurs at 503 eV in the ($dN_{(E)}/dE$) mode (Ref 49). These peak locations are such that overlap and masking can occur in some situations. For example, consider the Auger spectrum shown in Fig. 23. The spectrum is of a chromium catalyst material composed of mixed oxides of chromium and tin. Note that oxygen dominates the spectrum in the region where oxygen and chromium occur. The amount of chromium is so small, relative to oxygen, that the primary chromium peaks cannot be distinguished. In this case, one alternative would be to utilize other methods, such as XPS, to examine the chromium. It is convenient to use an x-ray source to stimulate Auger transitions when peak overlapping occurs. The resulting transitions will typically be easily distinguished (see Fig. 5).

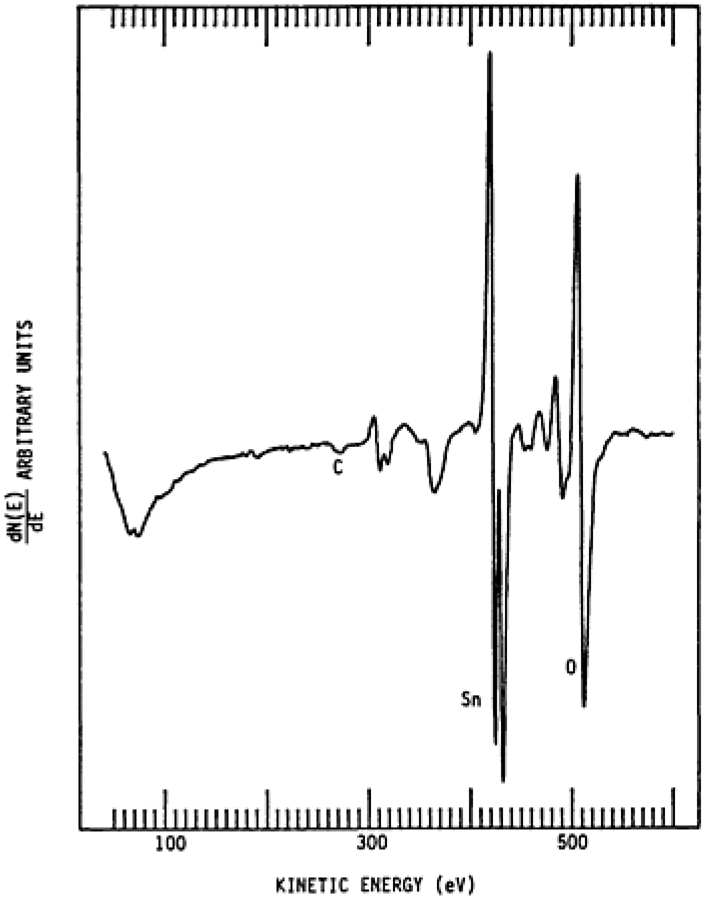

Fig. 23 AES spectrum of cleaned polycrystalline tin oxide sample

Electron-Stimulated Desorption (ESD)

Electron-induced desorption of ions is the basis of ESD. The technique, which has only recently been applied to chemical analysis, offers the advantage of hydrogen detection with minimum surface damage, compared with secondary ion mass spectroscopy (SIMS), which is an alternative technique that is usually used for hydrogen detection. A major disadvantage of ESD is that the data are generally difficult to interpret beyond the simple identification of low molecular weight ions.

The detection limit of ESD varies considerably, depending on the particular situation. In general, the detection limit of ESD is greater than that of XPS and AES. Some adsorbates, such as fluorine, can be detected when present in concentrations near 1 ppm. ESD has not been specifically applied to friction, lubrication, and wear problems at this time, to the knowledge of the authors.

ESD Fundamentals. The desorption of an ion by electron stimulation involves electronic transitions and is not the result of thermally stimulated desorption, or momentum transfer from electrons in the incident electron beam to surface atoms of the solid. Many mechanisms have been proposed for ESD, and Ref 52 provides an excellent review of this material.

Two mechanisms, in particular, have received considerable attention: the Menzel-Gomer-Redhead (MGR) model (Ref 53) and the Knotek-Feibelman (KF) model (Ref 54). The MGR model is based on electron ejection from a bonding orbital, leading to an antibonding state. This is an unstable configuration relative to the bonding state, prior to electron ejection. An excited adsorbate state can result from the antibonding state.

The MGR model can be depicted as shown in Fig. 24. Curve G represents a potential energy curve for a surface atom, such as an adsorbate atom, vibrating in the ground state in proximity to the solid surface. For the sake of discussion, the solid is assumed to be a metal and is designated by (M). The adsorbed atom is designated by (A). Curve (M + A)* represents an antibonding state of (A) following excitation by electron loss from a bonding orbital. Curve M + A* represents an excited state of (A), and the $M^- + A^+$ curve represents an ionized state where the positively charged adsorbate can desorb if the appropriate energy configuration exists. The arrow in Fig. 24 indicates how a transition from the ground state to the ionized state results in desorption of an ion. Note that the arrow intersects the potential energy curve of $M^- + M^+$ in the repulsion region. Therefore, this potential energy becomes the kinetic energy of the desorbing ion.

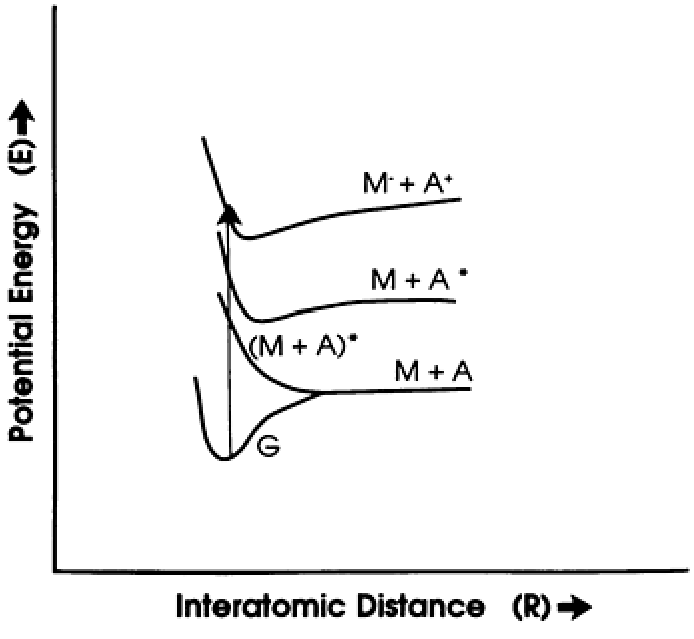

Fig. 24 Menzel-Gomer-Redhead (MGR) model of electron transition leading to ion desorption by ESD. Source: Ref 53

The KF model is characterized by an initial core-level ionization. This is followed by an interatomic electron transfer to fill the core-level vacancy, and this interatomic transition is also associated with the loss of at least one electron to the surroundings (vacuum). Note that the process described is an Auger process, and that interatomic, rather than intraatomic, electron transfer has been specified. This can occur when the atom in which the initial core-level vacancy occurs is present in an oxidation state such that no valence electrons are available to fill the core-level vacancy. An example is titanium in the +4 oxidation state. In this case, the metallic ion has been ionized to a noble gas configuration. This situation is shown in Fig. 25.

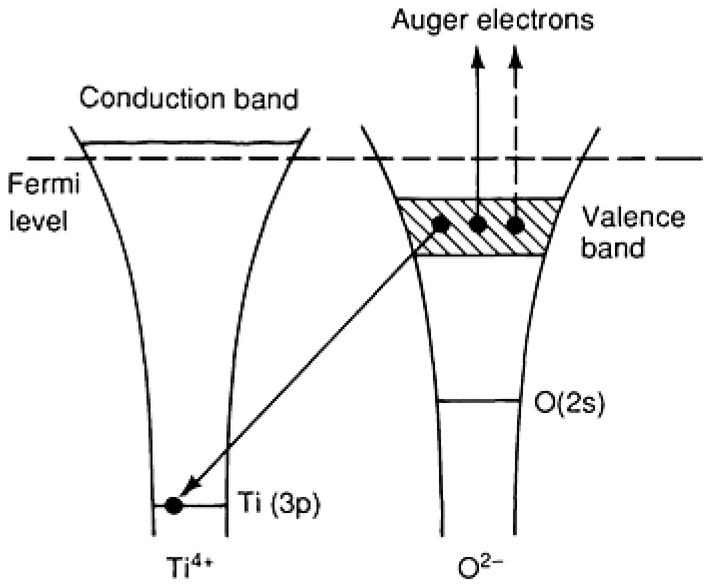

Fig. 25 Knotek-Feibelman (KF) model for ESD using TiO_2 as example. Depicted is interatomic electron transfer between oxygen and titanium. Source: Ref 54

ESD Equipment. The equipment required for ESD is analogous to that required for AES: an electron source, a method for detecting ion energies, and sufficient vacuum. ESD also requires a method of mass analysis to identify masses associated with specific energies. Historically, numerous types of system configurations have been employed for ESD studies. Quadruple mass analyzers are most commonly used.

However, ESD has been performed recently in conjunction with Auger and related spectroscopies. In this case, the electron gun utilized for AES is used for ESD, and the cylindrical mirror analyzer can be configured for ion energy analysis of positively charged ions (Ref 55). With this particular configuration, ion energies ranging from 0 to 20 eV can be detected. A disadvantage is that mass resolution is poor when the CMA is applied as a mass analyzer for species of mass greater than approximately 15 amu.

Traum and Woodruff (Ref 55) originally devised a method to operate the CMA as a time-of-flight mass analyzer and Gilbert *et al.* (Ref 56) have developed a pulse-counting circuit for operating the CMA in the time-of-flight regime. These articles are suggested as initial references for those interested in using the CMA analyzer as a time-of-flight mass analyzer.

ESD Spectrum. The measurement of the energy of ions being desorbed from a surface is sometimes referred to as an electron-stimulated desorption-ion energy distribution (ESDIED) spectrum, which represents the relative number of ions with a particular kinetic energy. An example spectrum for a cleaned polycrystalline tin oxide sample is shown in Fig. 26. Note that this spectrum appears to be the convolution of at least two peaks. At this point, time-of-flight analysis must be performed for each peak of interest in the ESDIED spectrum, so that chemical species associated with each peak can be identified. Peak values of 1.9 eV and 3.5 eV are assigned for the ESDIED spectrum shown in Fig. 26.

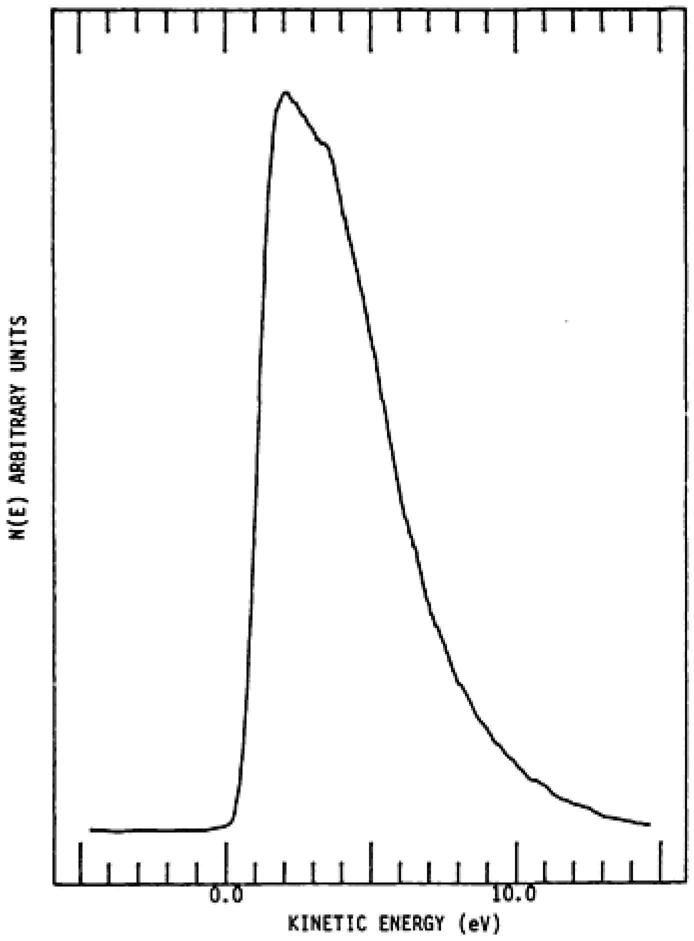

Fig. 26 ESDIED spectrum of cleaned polycrystalline tin oxide sample

Figures 27 and 28 contain time-of-flight data for the 1.9 and 3.5 eV ESDIED peaks, respectively. As shown in the spectrum, the lower-energy peak is associated with H^+, whereas the very small peaks at the higher energy end of the spectrum are associated with O^+ and OH^+. It should be noted that the presence of O^+ and/or OH^+ is not clear at this point because the signal is very low. However, it will be shown later that the assumption of some O^+ and/or OH^+ activity in this region is justified.

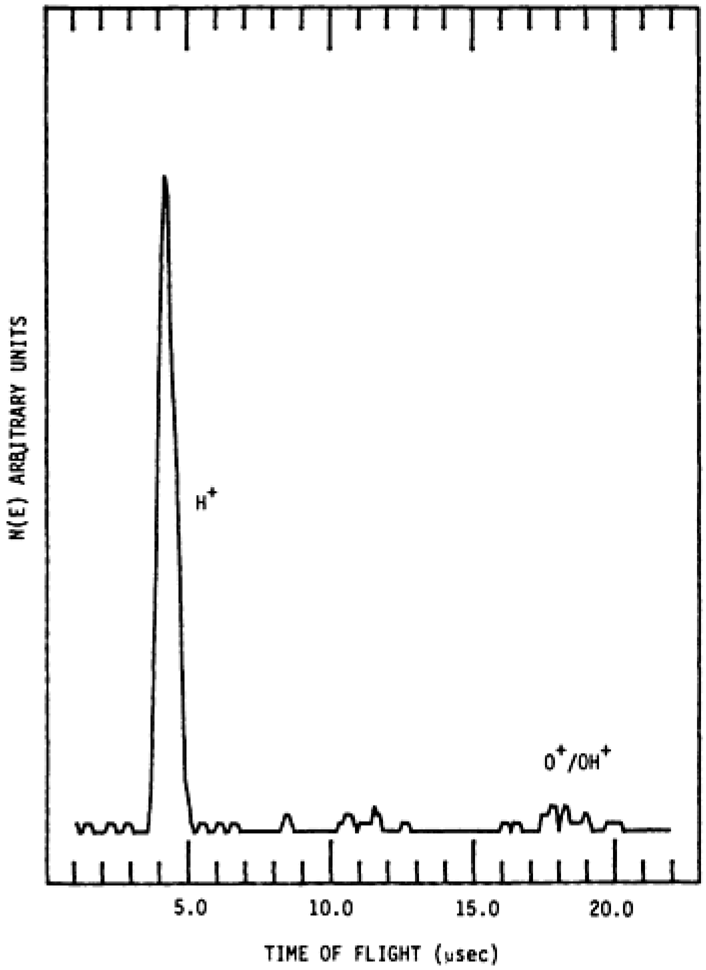

Fig. 27 Time-of-flight data for species composing the 1.9 eV ESDIED peak

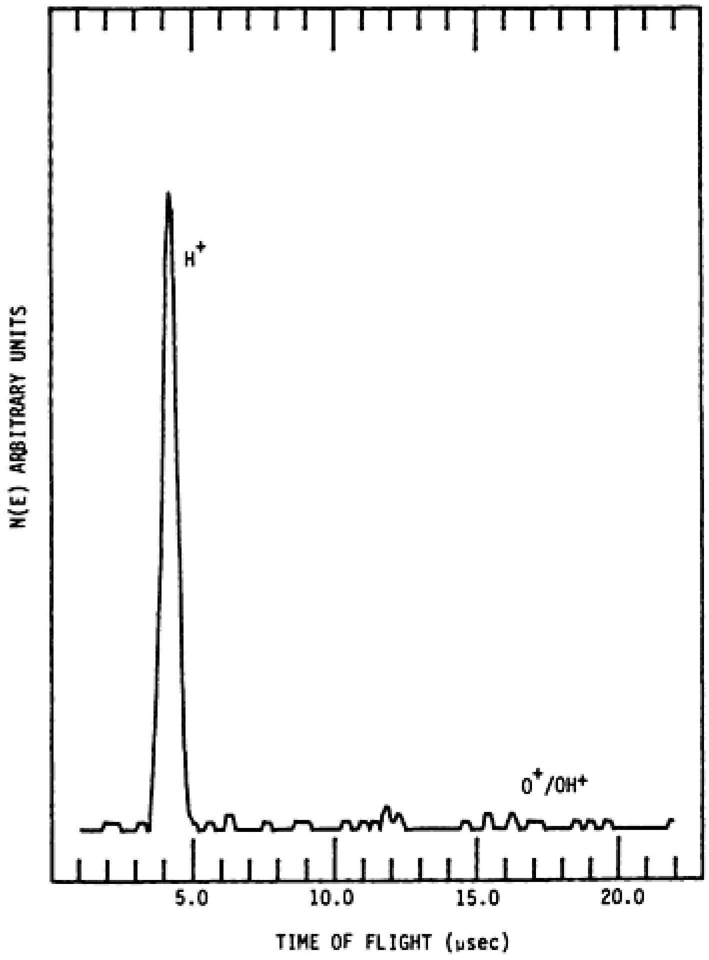

Fig. 28 Time-of-flight data for species composing the 3.5 eV ESDIED peak

It has been shown (Ref 55) that the time-of-flight of an ion is proportional to its mass. The relationship is time-of-flight = 4.2 $\sqrt{m}$, where *m* is the mass of the ion. Hence, flight times of 4.2, 16.4, and 16.9 μs are expected for H^+, O^+, and OH^+, respectively. Time-of-flight data for the 3.5 eV ESDIED peak also shows that H^+ is being desorbed, but that O^+ and/or OH^+ are probably not.

ESD Applications. The data acquired for the polycrystalline tin oxide sample discussed in the previous section is discussed further here. Consider the ESDIED and time-of-flight data shown in Fig. 29. The data were acquired after annealing for 30 min at 600 °C (1110 °F) and 9.3 × 10^{-7} Pa (7.0 × 10^{-9} torr). Note that the 1.9 eV ESDIED peak is very small relative to the higher-energy peak around 4.3 eV. The time-of-flight data of Fig. 30 and 31 show that O^+ and OH^+ are both desorbed, and the 4.3 eV peak has more O^+ than OH^+, relative to the 1.9 eV peak.

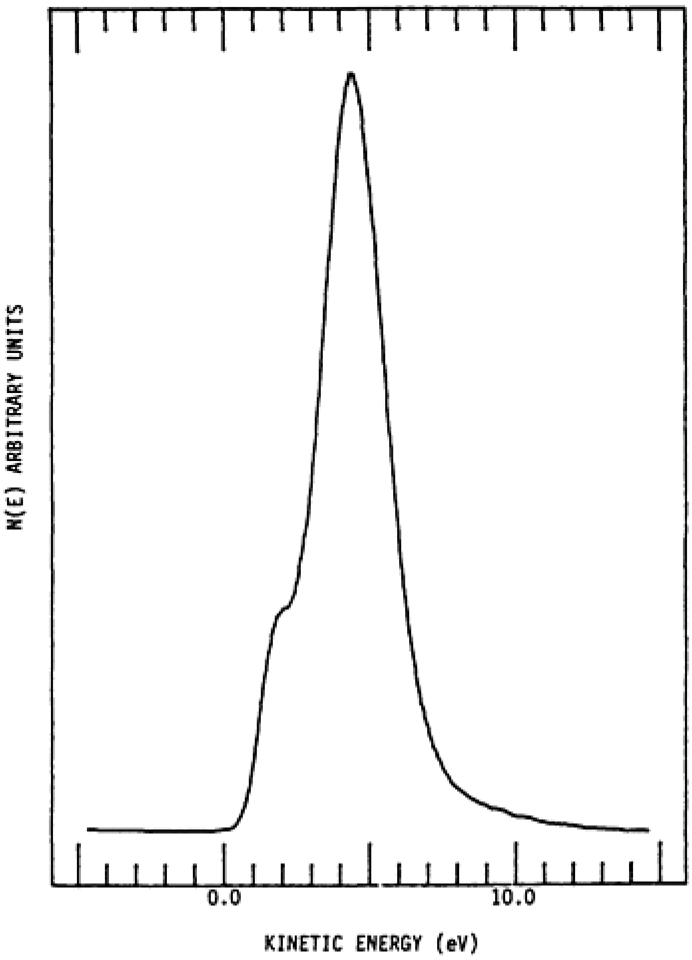

Fig. 29 ESDIED spectrum for polycrystalline tin oxide sample following annealing in vacuum for 30 min at 600 °C (1110 °F)

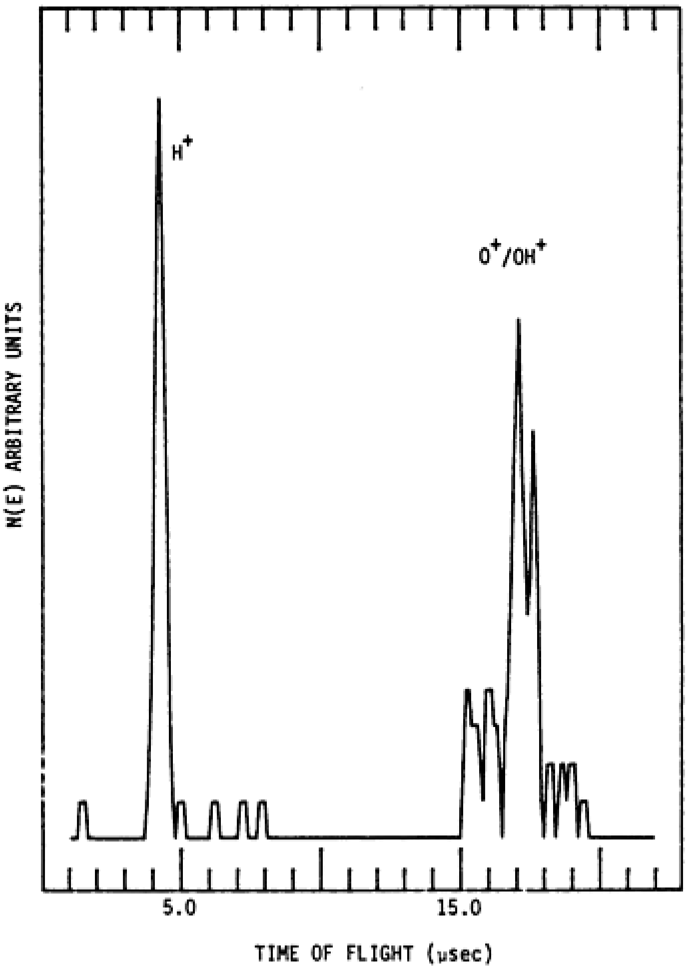

Fig. 30 Time-of-flight data for species composing the 1.9 eV ESDIED peak following annealing in vacuum for 30 min at 600 °C (1110 °F).

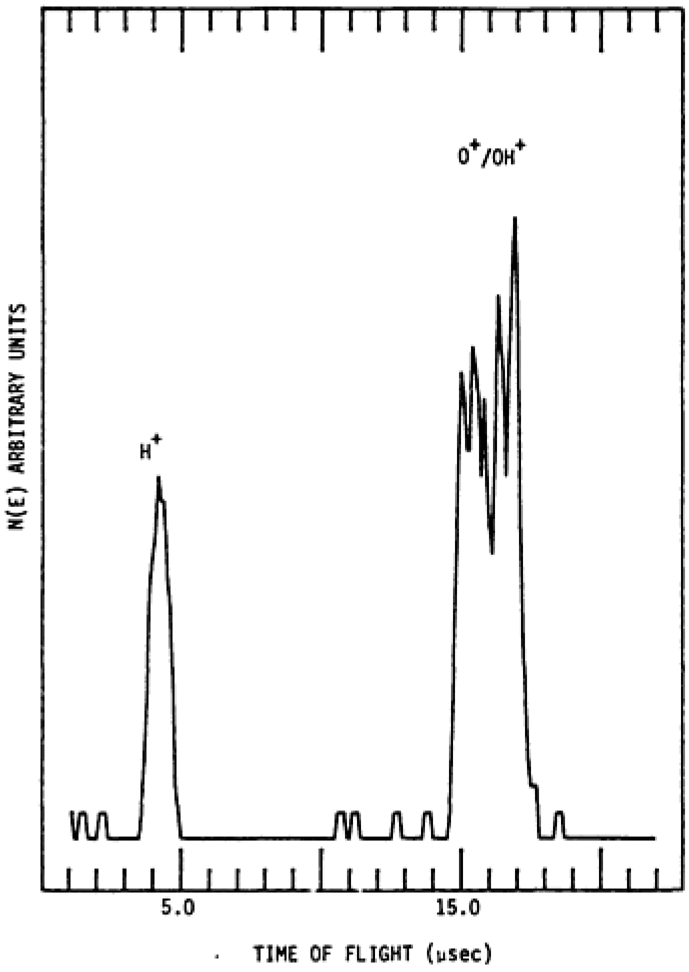

Fig. 31 Time-of-flight data for species composing the 4.3 eV ESDIED peak following annealing in vacuum for 30 min at 600 °C (1110 °F)

The ESD data can be explained by the following considerations. First, it is necessary to realize that tin oxide undergoes dehydration for the annealing conditions used. This has been shown by Cox (Ref 57) using valence band ESCA. If it is noted that the O^+ and OH^+ desorption signal is very small prior to annealing, but significantly larger following annealing, it is clear that the surface O^+ and OH^+ for the clean sample, prior to annealing, are not active with regard to desorption by electron stimulation. However, the O^+ and OH^+ that remain after dehydration are amenable to desorption by electron stimulation. Therefore, oxygen and hydrogen not associated with water of hydration have been distinguished because these bonding states are active with respect to ESD, whereas those associated with water of hydration are not.

It is possible to test this interpretation by exposing the sample to an oxidizing atmosphere. This was accomplished by annealing the sample in oxygen for 1.5 h at 400 °C (750 °F) at 1.3×10^{-4} Pa (10^{-6} torr.) The ESDIED and time-of-flight data are shown in Fig. 32 33 34. The 1.9 eV ESDIED peak has increased in size relative to that observed for the previous 600 °C (1110 °F) annealing treatment. The relative amounts of O^+ and OH^+ being desorbed have also decreased again, compared with data collected following the 600 °C (1110 °F) annealing treatment.

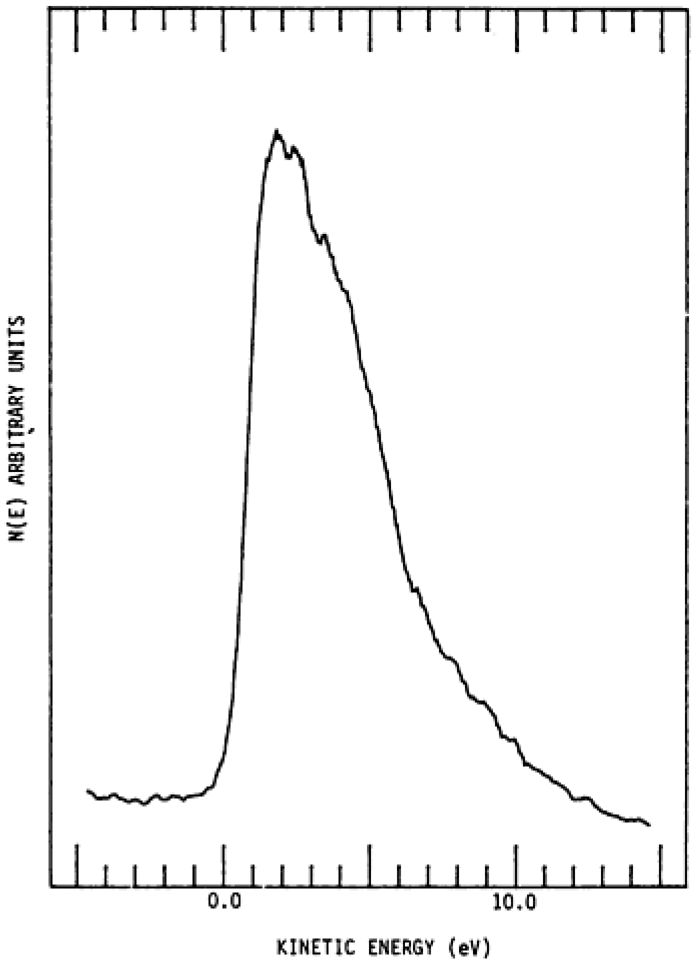

Fig. 32 ESDIED spectrum for polycrystalline tin oxide sample following annealing in oxygen for 90 min at 400 °C (750 °F)

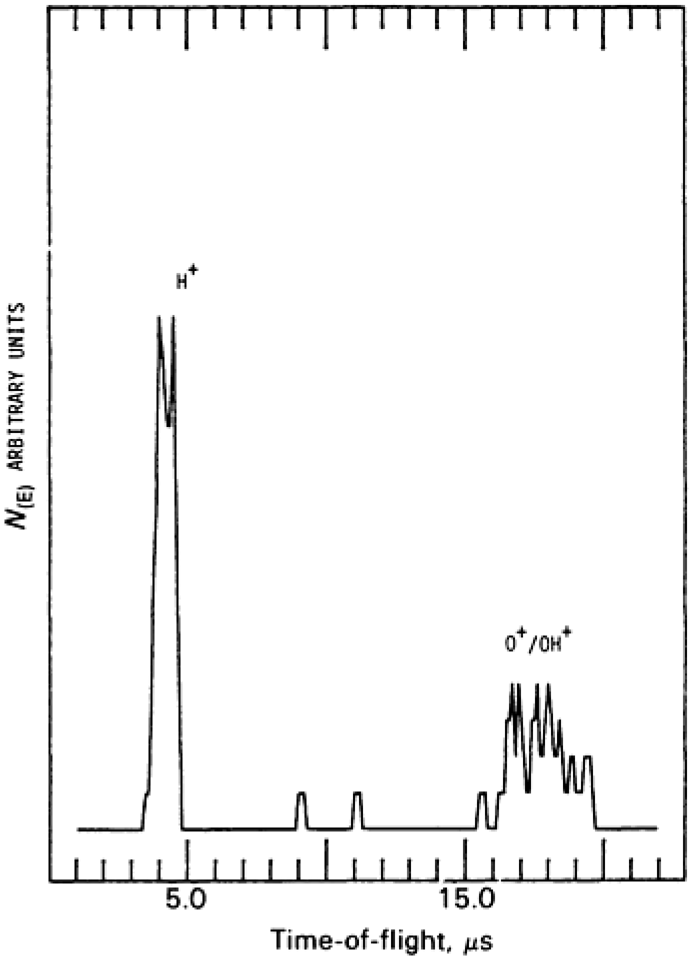

Fig. 33 Time-of-flight data for species composing the 4.3 eV ESDIED peak following annealing in oxygen for 90 min at 400 °C (750 °F)

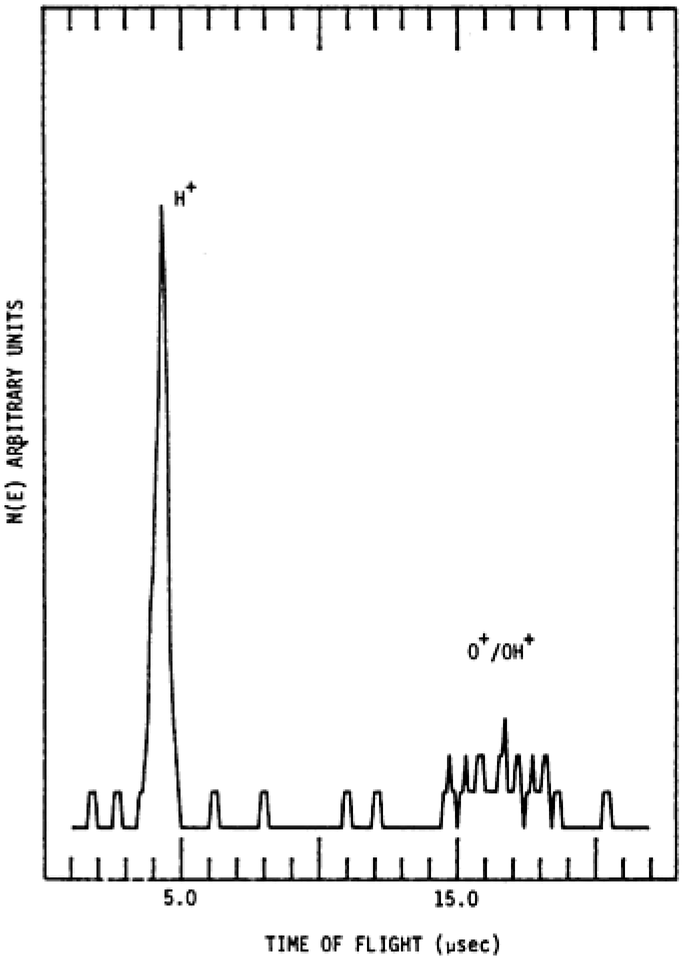

Fig. 34 Time-of-flight data for species composing the 4.3 eV ESDIED peak following annealing in oxygen for 90 min at 400 °C (750 °F)

It is reasonable to expect oxygen supplied to the sample during the oxidation treatment to become associated with vacancies generated during the dehydration process. Therefore, it can be concluded that the 1.9 eV ESDIED peak is associated with water of hydration, and the higher-energy ESDIED peak is associated with other species, such as oxygen bound to tin, in the lattice structure.

Thus, oxygen and hydroxyl groups associated with water of hydration are not active with regard to desorption by electron stimulation, relative to oxygen and hydroxyl groups associated with other bonding situations. ESD has been used to distinguish these oxygen and hydrogen types.

ESD is a valuable technique because it enables hydrogen detection and it can be used with minimum modifications to existing AES equipment. The major drawback is that data interpretation beyond identification of desorbing species is often difficult. An alternative to ESD is discussed next.

Secondary Ion Mass Spectrometry (SIMS)

SIMS is an analytical technique that has become very popular over the past few years. Enhanced element sensitivity and hydrogen detection capability (order of ppm) are two advantages of SIMS that AES and XPS techniques do not offer. Its primary disadvantages are that it is inherently a destructive technique and quantitation is more difficult, relative to techniques such as AES and XPS.

Specific examples of the application of SIMS to studies of wear, lubrication, and friction are somewhat limited, when compared with techniques such as AES. An excellent example of the application of SIMS to study material transfer

resulting from abrasive contact between a ceramic and several metals is described in Ref 58. SIMS is particularly suited to such studies if the amounts of material transferred are expected to be very small.

SIMS Fundamentals. The SIMS process is performed by bombarding the surface of a solid target material of interest with a beam of energetic ions. The ions composing the bombarding beam are referred to as primary ions. These ions can be delivered to the target surface at energies up to approximately 40 keV. The result of collision processes between primary ions and the target surface of interest is the emission of negative, positive, and neutral species. The term "species" is employed to indicate that ions or agglomerations of atoms bearing a net charge can be emitted from the surface. The species emitted from the surface are analyzed in terms of their mass-to-charge ratios (m/e). Therefore, only charged species can be analyzed. Neutral species that have been sputtered from the surface must first be ionized before analysis is possible.

It is important to point out that charged species leaving the target surface as a result of sputtering constitute only a small portion of all sputtered atoms leaving the surface. This typically ranges from a few hundredths of a percent, up to approximately 1%. Discussions of analytical descriptions of secondary ion yield and parameters that influence the overall yield, such as ionization probability, are discussed in Ref 46 and 47.

SIMS can be performed in two modes. In one case, the primary ion beam is rastered over the surface covering an area of approximately 50 × 50 μm (2 × 2 mils) (Ref 46). This mode of analysis is referred to as static SIMS and is characterized by a relatively slow removal rate of atoms from the surface of the target material.

Alternatively, the primary ion beam can be focused on an area of submicron dimension and material removed at very high rates relative to static SIMS. This mode of operation is referred to as dynamic SIMS. Its sampling depth is on the order of 10^3 nm, whereas static SIMS is characterized by sampling depths of only a couple of atomic layers (Ref 46).

SIMS is often employed to obtain chemical depth profile information. Dynamic SIMS can achieve practical sputter rates, as well as maximum sensitivity (Ref 46). Therefore, this section focuses on this mode.

In most cases, the primary ion beam employed with SIMS is an inert gas. However, primary beam systems should be capable of generating both negatively and positively charged ions of reactive gases. Negatively charged ions, such as O^-, can be used as a primary beam source when sample charging is expected to be a problem. With versatility in the primary beam source, electrically insulating materials can be analyzed with a minimum of difficulties.

An additional advantage of the ability to implement several types of primary ion beam gases is the effect of secondary ion yield. This is because secondary ion yields are influenced by the charge characteristics at the surface. Ion yields are maximized when neutralization probabilities are low. Therefore, positively charged secondary species are less likely to be neutralized when electronegative atoms are present in surface and near-surface regions of the material from which secondary ions are being sputtered. For this reason, if oxygen is used as a primary beam source, rather than an inert gas, the emission of positively charged secondary ions can be expected to be enhanced. This point is discussed in Ref 47.

The SIMS spectrum consists of a representation of the signal intensity, or count rate, as a function of mass-to-charge ratio (m/e). Consider the SIMS data presented in Fig. 35. These data represent a SIMS survey scan for the surface and near-surface regions of a BiO_x-Au-glass thin-film system, such as that discussed in the AES section (see Fig. 17). The SIMS data in Fig. 35 contain several elements that do not appear in the film data in Fig. 17 (that is, elements in addition to Bi, O, Au, and Si). These additional elements are the result of trace contamination of the deposition chamber from previous deposition processes. This is an excellent example of the increased sensitivity of SIMS relative to AES.

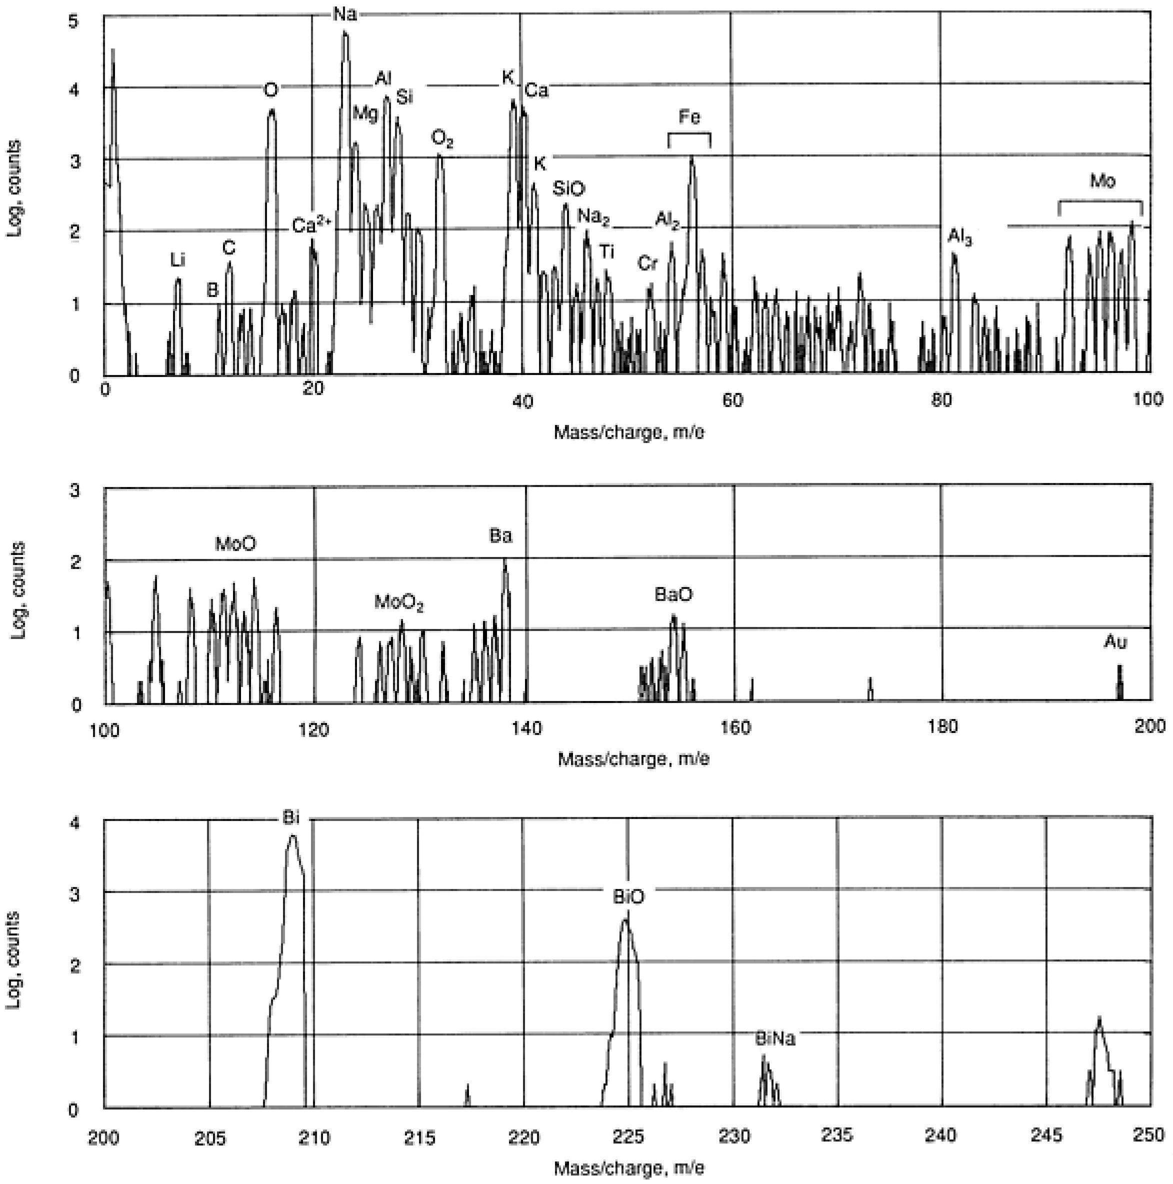

Fig. 35 SIMS survey of bismuth layer of BiO_x-Au-glass specimen

The reader should be aware that quantitation of SIMS data is a very complicated issue. The basis problem is the fact that the secondary ion yield can be significantly influenced by several phenomena that can be very complex in nature. The emission of secondary ions depends on the chemical and physical characteristics of the target surface, the primary beam characteristics, and the matrix characteristics of the target material.

The most direct method of quantitation is to compare SIMS results with a reference material of known composition for a given set of conditions for data acquisition. Of course, this involves the availability of reference materials for all anticipated matrix configurations that might be encountered. At best, this is inconvenient. It would therefore be helpful if a myriad of matrix configurations could be evaluated by simply extending data required for a minimum number of reference samples.

In principle, this could be accomplished by the ability to extend relative sensitivity factors obtained for a few reference materials to any arbitrary matrix configuration. This has been achieved by defining a parameter that characterizes the electronic properties of the surface of the target material (Ref 59).

It is of interest to note that data from internal standards have been employed to specify parameters of a model to predict relative atomic fraction values from secondary ion intensities (Ref 60). The model referenced here has been applied with a reasonable degree of success when one considers that it has been applied to a variety of materials.

SIMS equipment includes an ion source (ion gun), a UHV environment, and a detection system that consists of components such that energy and mass selection of the sputtered species occurs prior to the detector. References 47 and 59 provide a more detailed equipment description.

SIMS Applications. As previously mentioned, SIMS is a valuable technique in terms of detecting elements present in relatively small concentrations, as well as detecting hydrogen. These capabilities can be particularly useful in friction, lubrication, and wear problems involving materials that contain hydrogen and/or where small amounts of material transfer occur.

Material transfer examples include that which results when materials are in tribocontact and that which results from diffusion processes. Material transfer by diffusion is often difficult to substantiate, especially if the amount of mass transfer is relatively small.

For the purpose of demonstration, the interdiffusion of constituents composing a layered BiO_x-Al-glass system is discussed. This system is analogous to the BiO_x-Au-glass thin-film system previously discussed and is used here because the amount of interdiffusion associated with high-temperature oxidation of the BiAl-glass-layered structure is substantial and can be clearly identified.

Consider the SIMS depth profile data shown in Fig. 36 and 37. These data respectively represent results for a layered structure that was not subjected to high-temperature oxidation, and a layered structure that was. The secondary ions monitored are Al^+, Bi^+, O^+, and Si^+. The data clearly demonstrate that interdiffusion occurs among constituents of the bismuth layer, the metal layer, and the glass substrate. It is interesting to note that interdiffusion processes for this system were, in general, not nearly as observable with AES depth profiling as with SIMS. Again, this demonstrates the advantage of the increased sensitivity of SIMS, relative to other surface analytical techniques.

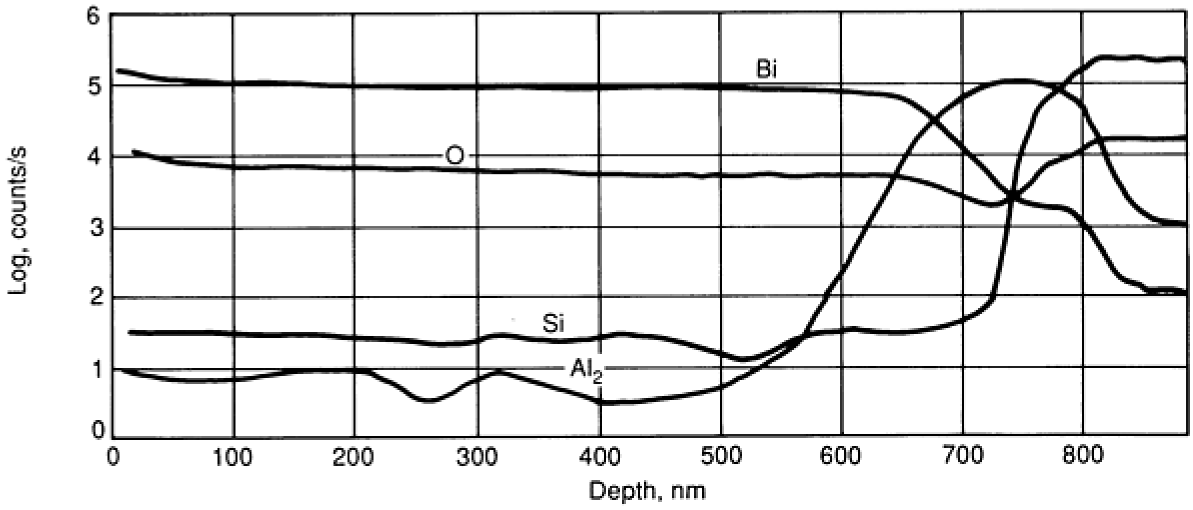

Fig. 36 SIMS depth profile of layered Bi-Au-glass specimen

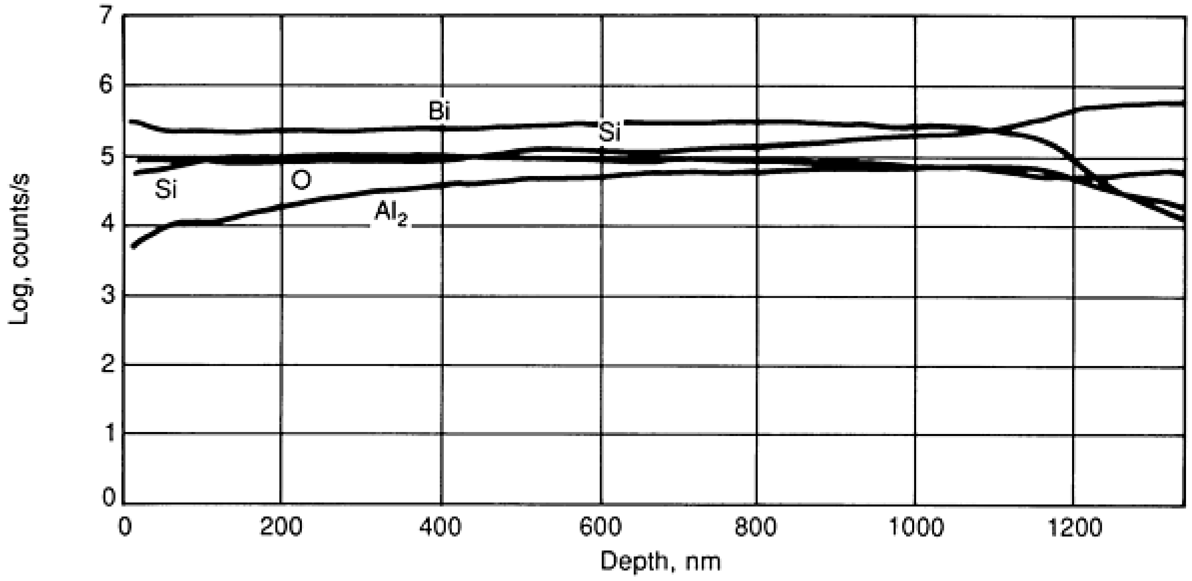

Fig. 37 SIMS depth profile of layered BiO_x-Au-glass specimen

It is important at this point to emphasize that care must be taken when evaluating data acquired near interfacial regions. This consideration is often applicable when mass transport by diffusion is of interest. The important point is that the sputtering process can produce mixing of constituents across the interface, which results in peak broadening in the composition profile. Such broadening can be interpreted as diffusion effects if sufficient care is not taken. The most practical way to avoid difficulty is to evaluate reference materials for comparison, as was done here by comparing a sample not subjected to high-temperature oxidation to a sample that was.

The capability to detect hydrogen can be very useful in friction, lubrication, and wear studies because such studies often involve systems that contain hydrogen. For instance, Sugita and Ueda (Ref 61) studied the wear characteristics of silicon nitride in water with respect to the material produced at the specimen-counterface interface. SIMS analysis showed that the worn surface contained silicon bonded to oxygen and hydrogen. Therefore, silicon was oxidized as a result of the tribocontact. The presence of hydrogen suggests that the oxidized silicon is hydrated to some extent. X-ray diffraction data were used in conjunction with the SIMS data to propose a mechanism of material removal for this system of silicon nitride rubbing against silicon nitride in a water environment. The mechanism proposed is one in which the silicon in silicon nitride is first oxidized and then converted to an amorphous form of silica hydrate, which is then removed by frictional forces associated with the rubbing of the two silicon nitride faces.

Thus, SIMS provides a means by which hydrogen can be detected and a means by which elements can be observed at very low concentrations. Its primary disadvantages are that it is inherently a destructive technique and chemical bonding information such as that obtained with XPS and AES is not available.

Infrared (IR) Spectroscopy

The IR spectroscopy technique should be mentioned because it is becoming more important in the study of the chemistry of solid surfaces; however, it will not be treated in detail in this article. Infrared spectroscopy has been employed for some time as a routine technique for determining the molecular structure of organic compounds, and therefore it is not a new technique.

IR spectroscopy is performed by subjecting the sample to a source of IR radiation. This source is sometimes referred to as an emitter. For practical purposes, the IR range is taken to be electromagnetic radiation within the energy range for 200 to 4000/cm. In practice, more than one type of emitter is required to cover the entire IR range. The electric field of the electromagnetic radiation can couple with oscillating dipoles of vibrating molecules. The result of this interaction, or coupling, of the electromagnetic radiation with vibrational energy modes of molecules is absorption of the radiation.

The IR absorption spectrum appears in the form of the percent of radiation transmitted through the sample (that is, not absorbed) as a function of IR radiation energy. Structures that are expected to be active with regard to IR absorption are those that exhibit a net dipole moment. Symmetric molecules, such as N_2 and O_2, are not expected to exhibit an absorption species for any relative position of the atoms (bond length). On the other hand, molecules such as HCl, NO, and CO are expected to exhibit characteristic absorption frequencies.

Problems in friction, lubrication, and wear can involve analysis of surface components that are present in coverages of considerably less than one monolayer. This is possible with IR spectroscopy, but most investigators employ the technique of multiple internal reflectance (MIR) spectroscopy for such studies. This technique offers increased sensitivity for surface components, allowing detailed studies of adsorbate-surface interactions. In fact, MIR spectroscopy can be used to determine the orientation of adsorbate molecules on solid surfaces. Both IR and MIR spectroscopy are discussed further in Ref 62 and 63.

X-Ray Characterization of Surface Wear

C.R. Houska, Virginia Polytechnic Institute and State University

Introduction

X-RAY DIFFRACTION and spectroscopy provide a variable-depth probe of the atomic arrangements and composition of near-surface material. Depending on the sample, x-ray wavelength, and experimental arrangement, quantitative data from about 10 nm to a number of μm can be provided. This range of penetration depth can be used to examine wear-modified and unmodified regions. Deeper penetrations allow unmodified material to be sampled as a reference for those changes taking place near the surface.

The first consideration is to examine the conditions that determine penetration depths for both x-ray diffraction (XRD) and x-ray fluorescence (XRF). Both kinds of data can be obtained using either commercially available equipment or specialized beamlines at synchrotron radiation facilities. Synchrotron beamlines allow more flexibility in the choice of wavelengths and provide highly collimated and intense beams that add to the capability to alter the penetration distance by adjusting the optical arrangement. Small glancing angles between the specimen surface and either the incident or diffracted beams are effective in probing closer to the surface.

X-rays can become totally reflected from locally flat surfaces at extremely low angles of incidence (<0.25°). Under these conditions, beam penetration becomes anomalous and limited to less than 8 nm. Penetration distance, Z_0^T, depends on the angle of incidence, θ_i, relative to the critical angle, θ_c; that is,

$$Z_0^T \approx \frac{\lambda}{2\pi(\theta_c^2 - \theta_i^2)} \qquad \textbf{(Eq 1)}$$

where π = x-ray wavelength (Ref 1).

An uncertainty or divergence in the angle of the incident beam, θ_i, can introduce a large uncertainty in penetration distance. A wavy or rough surface and an ideally parallel beam also leads to quantitative uncertainties because θ_i takes on a range of values. Because of these difficulties in determining penetration distance with total reflection, the subsequent discussion involves glancing angles that are greater than the critical angle. Above the critical angle, one can define penetration distances more simply using a large data file of absorption coefficients (Ref 2) and more conventional equipment.

Surface roughness introduces an additional complication. Near the surface, signal-producing material is removed. Where it exist, the beam paths differ from point to point at a fixed distance below the mean surface. A fluctuation in path length produces a net decrease in the measured signal (Ref 3). This problem has been studied using severely ground samples and a correction given in terms of a Gaussian distribution of asperities with correlation (Ref 4).

X-Ray Diffraction and Fluorescence from Flat Surfaces

Analyses of penetration distances are typically based on flat surfaces. The surface need only be flat over a distance that allows the incident and outgoing signal beams to see a locally flat region of the surface. Under these conditions, beam paths enter and leave near-surface material only once. Both diffraction and fluorescence signals are treated together with a common absorption term. XRF has one more absorption term, because of a difference in the incident and fluorescence wavelengths.

The following discussion refers to a differential element of irradiated area

$$A_e = \frac{A_0}{\sin(\theta + \omega)} \quad \textbf{(Eq 2)}$$

and thickness, d*Z*. The various terms, along with the tilt angle, ω, are illustrated in Fig. 1. A_0 is the cross section of the incident beam with incident angle, $\theta + \omega$, and intensity, I_0. If the signal angle is $\theta - \omega$, the fluorescent signal from an element at a depth, *Z*, is given by (Ref 5):

$$dP = I_0 Q_F \exp\left[\frac{-\mu_i Z}{\sin(\theta + \omega)} - \frac{\mu_s Z}{\sin(\theta - \omega)}\right] dV \quad \textbf{(Eq 3)}$$

with

$$dV = \frac{A_0\, dZ}{\sin(\theta + \omega)} \quad \textbf{(Eq 4)}$$

and

$$Q_F = \frac{N_i\, \sigma_i\, D_i}{4\pi R^2} \quad \textbf{(Eq 5)}$$

where N_i = number of *i* atoms/volume, σ_i = total atomic cross section of atom *i*, D_i = dimensionless absorption factor for fluorescent radiation in the path from sample surface to detector multiplied by the detector efficiency, and *R* = sample-to-detector distance.

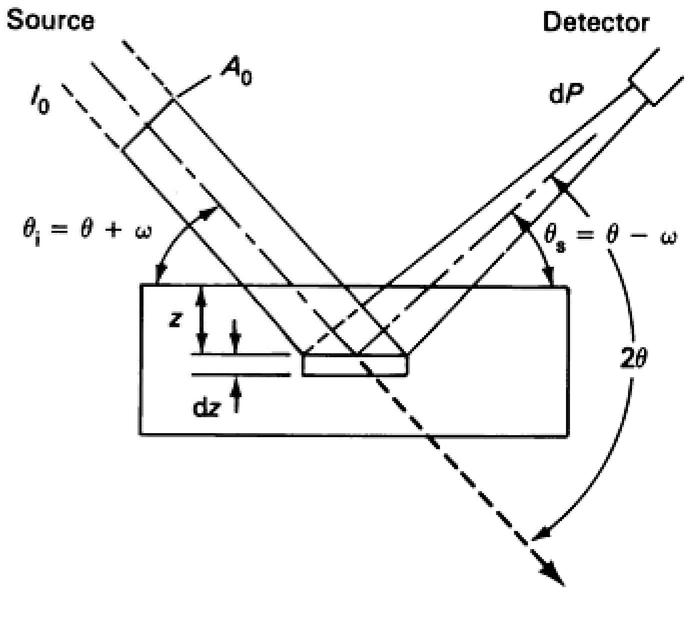

Fig. 1 X-ray optics illustrating: θ_i = angle of incidence, θ_s = signal angle, ω= angle of tilt from symmetrical arrangement, and 2θ = angle between signal and incident beam. Other quantities include A_0 = cross-sectional area of incident beam, and total volume of signal element is A_0/sin(θ + ω) multiplied by its thickness, *dZ*, located at a depth - *Z*. The detector is located at a distance *R* from the sample.

For a diffracting element, Q_D differs, depending on whether the volume dV contains a single crystal or a polycrystalline substance. Only a polycrystalline substance with a flat surface, which gives (Ref 6, 7)

$$Q_D = const.\ \frac{\lambda^3}{V_C^2} \left(\frac{1 + \cos^2 2\theta' \cos^2 2\theta}{(1 + \cos^2 2\theta') \sin\theta \sin 2\theta} \right) j\, F^2 \qquad \textbf{(Eq 6)}$$

will be considered. Here, θ is the Bragg angle for the sample, V_C is the volume of the unit cell, θ' is the Bragg angle of the monochromator, if used, j is the multiplicity, and F is the structure factor. If the thermal factor is known, it can be included as an additional term in Q_D.

The exponential term in Eq 2 is of primary interest because it determines beam penetration. With a fluorescence signal, two linear absorption coefficients are required; that is, one for the incident beam, μ_i, and another for the signal as it leaves the sample, μ_s. For diffraction, the incident and signal wavelength are the same with $\mu_i = \mu_s = \mu$. The absorption coefficient depends on the material and wavelength.

With a homogeneous sample, the contributions from all layers are obtained by integrating Eq 3. One normally integrates to infinity for a thick sample, giving the effective penetration distance.

$$Z_0 = (\mu_i S)^{-1} \qquad \textbf{(Eq 7)}$$

where the path length factor is

$$S = \frac{1}{\sin(\theta + \omega)} + \left(\frac{\mu_s}{\mu_i} \right) \frac{1}{\sin(\theta - \omega)} \qquad \textbf{(Eq 8)}$$

The total signal for all elements becomes

$$\frac{P}{I_0 Q_i} = \frac{A_0 (\mu_i S)^{-1}}{\sin(\theta + \omega)},\ i = F \text{ or } D \qquad \textbf{(Eq 9)}$$

which is written so as to isolate the effective volume term on the right. The term on the left is the reduced integrated intensity, where P is determined by the total area under a peak.

If one considers a pair of rays entering and leaving the sample, penetrating to a distance equal to the effective penetration distance, Z_0, the beam is reduced by e^{-1} purely from sample absorption. The accumulated signal from all elements between the surface and Z_0 relative to an infinitely thick sample is $1 - e^{-1}$, or 0.63. As λ increases, the trend is for the penetration distance to decrease as the absorption coefficient usually increases. However, crossing an absorption edge causes a sudden change in the penetration distance (Ref 8). Another common way of decreasing the penetration distance is to decrease the angle of incidence below the Bragg angle, θ, with a fixed 2θ. This decreases S^{-1} for a particular Bragg peak as one goes toward smaller glancing angles. In fact, one can tilt the sample so that the glancing angle is one the signal side and obtain a similar decrease. The direction of tilt does influence the area of beam as it intersects with the sample and gives a higher effective volume at low angles of incidence and, therefore, more intensity.

Figure 2 illustrates changes in the effective penetration for a large in ω angles with CuKα (λ = 0.1542 nm), CrKα (λ = 0.2291 nm), a partially stabilized zirconia sample (PSZ), and the (111) and (400) Bragg reflections (Ref 9). A wavelength of 0.4 nm is also shown with the (111) set to illustrate an extreme wavelength that is only available at a synchrotron radiation beamline. Here, it can be seen that when the angle of incidence equals the signal angle, the effective penetration is a maximum at 0.42 μm, and can be further reduced to 0.02 μm for ± ω tilts of ~40°. This would give glancing angles below 2.9° for a Bragg angle of 42.9°. In other words, 63% of the Bragg peak would come from the region between the

surface and 0.02 μm. Changing λ from CrKα to CuKα, radiation increase the maximum penetration from 1.05 to 2.08 μm.

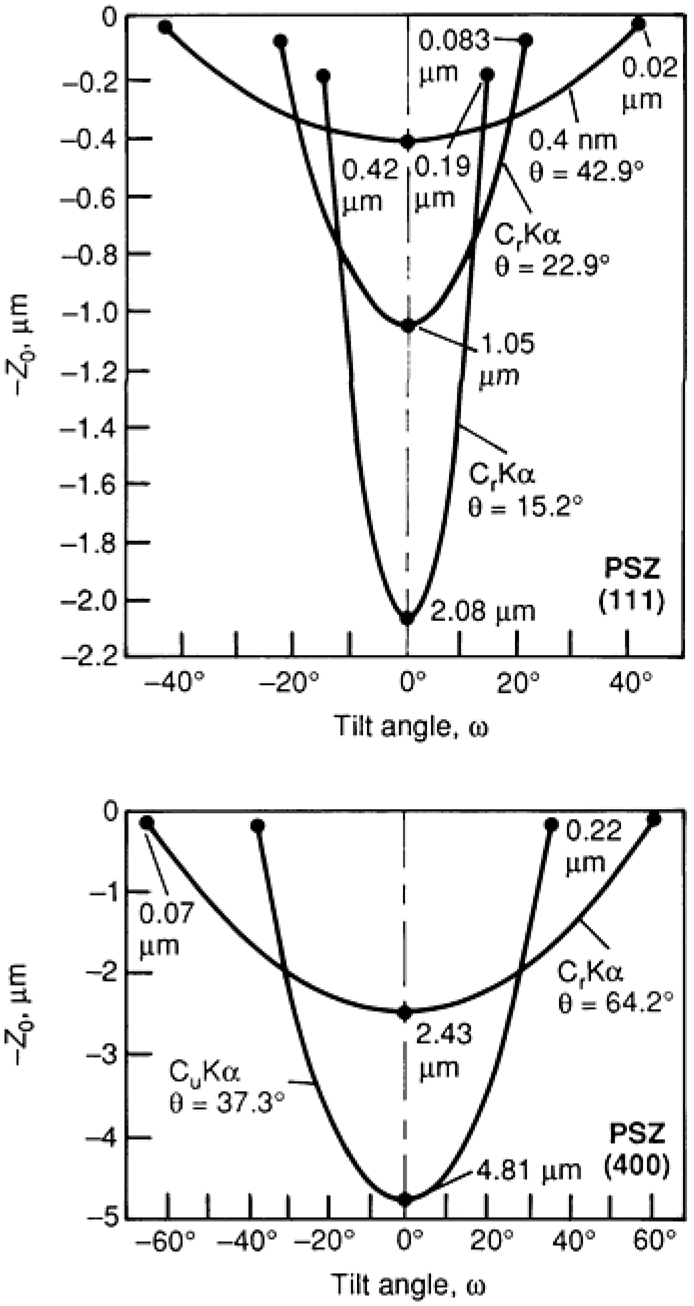

Fig. 2 Examples of effective flat sample penetration depths for (111) and (400) peaks with various wavelengths (0.4 nm, CrKα) and CuKα and tilt angle ω. All are based on the absorption in partially stabilized zirconia and its lattice constant. The maximum ω tilt is limited by θ and the critical angle for total reflection.

One would have to go to even lower glancing angles to attain 0.02 μm, which may not be practical with commercial x-ray systems. The relatively high absorption coefficient of zirconia tends to give limited penetration. A similar family of curves is found for the (400), but with larger penetration distance, because of the larger Bragg angle for the reflection θ. At a larger θ, larger ω tilts are required to attain glancing angle conditions. This larger range in ω is visible when the (111) family is compared with the (400).

X-Ray Diffraction and Fluorescence from Rough Surfaces

The Gaussian distribution is commonly used to describe the distribution of excursions (Ref 9, 10). It is also convenient to use for x-ray problems. With this distribution, the density of excursions from the mean surface plane between locations Z_1 and Z_1 + dZ_1 is

$$p(Z) = \frac{1}{\sqrt{2\pi}\,\sigma} \exp\left[\frac{-Z_1^2}{2\sigma^2}\right] \quad \textbf{(Eq 10)}$$

where σ is the standard deviation of the excursions.

The area fraction of sample at a distance Z_1 from the mean plane is

$$A_f = \frac{1}{2} \operatorname{erfc} \frac{Z_1}{\sqrt{2}\,\sigma} \quad \textbf{(Eq 11)}$$

This is the well-known error function complement shown at the right of Fig. 3. It is 0.5 at the mean plane, 0 for large positive excursions beyond about +2σ, and 1 for those deeper than -2σ into the sample.

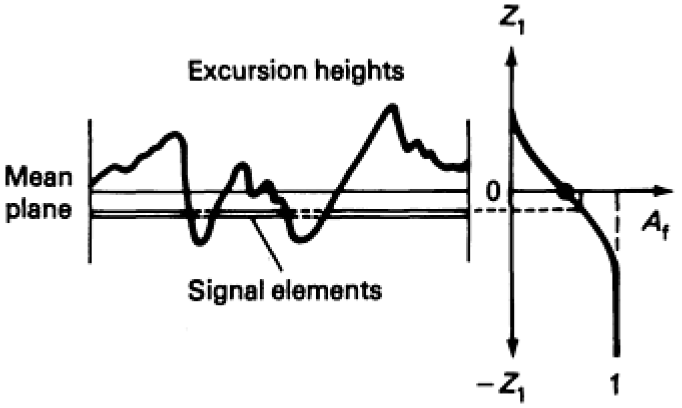

Fig. 3 Location of signal-producing elements about the mean plane of a surface with a Gaussian distribution of asperities. Area fraction, A_f, of occupied sampling plane is shown to right.

X-ray diffraction from polycrystalline samples requires that crystallites be oriented to satisfy Bragg's law. For polycrystalline samples, this usually turns out to be a small fraction of the sampling plane, unless one is using an oriented single crystal. Consequently, the statistical signal fluctuation from XRD can be large for material near the mean plane, unless the material has very small grains. This is not the case for x-ray fluorescence analysis, where all atoms near the surface have a finite probability to contribute a measurable signal.

With a real surface, the signal-producing elements are likely to be correlated with absorbing elements in either the entrance path or along an exit path out of the sample. This surface roughness problem has been treated using numerical calculations based on a Gaussian distribution with correlation (Ref 4). There is no simple analytical answer to this problem. Some general conclusions allow one to establish conditions where surface roughness calculations become unimportant. The x-ray theory contains a correlation parameter, τ_c, which indicates how quickly a surface excursion loses correlation with increasing distance, τ, from a neighboring point. A large τ_c causes neighboring points along the surface to look alike, whereas a small τ_c causes nearby points to be unrelated.

An estimate for the θ value, giving the maximum integrated intensity correction for roughness, can be obtained from

$$\theta_0 = \tan^{-1} \frac{2.4\sigma}{\tau_c} \quad \textbf{(Eq 12)}$$

Likewise, if one is not to exceed a maximum intensity correction of 15%, the following condition should be satisfied:

$$2.4\sigma \leq \mu^{-1} \quad \textbf{(Eq 13)}$$

The term 2.4σ can be related directly to the full width at the half maximum of the Gaussian probability distribution. A 15% correction would represent routine work. For precision work, the maximum σ given by Eq 13 should be decreased by one-half.

Equation 12 describes the condition of having the incident and signal beams oriented parallel to the mean slope of the surface. This shifts the correction to low angles when the correlation parameter τ_C becomes large, relative to σ. Both Eq 12 and 13 treat a sample having a statistically homogeneous distribution of signal elements. When strain gradients that are present near the surface are as large or smaller than 2.4σ, correlation between the signal elements and the exit and entry paths should be considered for a quantitative treatment of the data.

The roughness correction has been shown to go to zero at the extremes of $\theta \rightarrow 90°$ and $\theta \rightarrow 0°$ under symmetrical conditions (Ref 3). At these limits, the paths are either completely correlated or are uncorrelated. The statistical model previously cited (Ref 4) does not treat the case when an incident or signal ray is likely to see more than one asperity.

Experience with the examination of rough surfaces using x-rays is very limited. At this time, x-rays do not appear to give results as good as those obtained using profilometer data in order to determine the statistical parameters that describe real surfaces. At low glancing angles, either with the incident or the signal beam, one can lose quantitative accuracy of intensity data when Z_0 approaches the mean surface excursion distance. However, this need not be a problem for either qualitative chemical or phase identification. Routine approaches for identification problems are described in Ref 8.

Near-Surface Gradients

Equation 2 defines the reduced intensity in terms of a thin slab element having an irradiated area $A_e = A_0/\sin(\theta + \omega)$. For a single-phase homogeneous material free of strain, all elements can be treated as identical and either summed or integrated to obtain the full signal. This led to the integral result for the effective volume, Eq 9. If the surface has been disturbed mechanically, thermally, or chemically, and this produces a change in the spacing of diffracting planes that extends over those probe distances already discussed, the Bragg peaks become distributed over a range of 2θ angles. Peaks are no longer superimposed at the same position and can be treated as differential behavior. Both integral and differential gradients have been described in terms of a continuous distribution function, $H_i(Z)$, which describes the gradient of i with distance Z below the surface (Ref 11, 12). The subscript designates the kind of distribution; that is, residual strain, atom type, a particular phase, texture, grain size, or other structural disturbances distributed along a gradient. These can be defined as integral or differential gradients with respect to the signal elements, depending on whether the intensity is unshifted or shifted in 2θ.

A feature that exhibits a differential behavior displays a change in the ***d***-spacing with position along the gradient zone. Under these conditions, the diffraction angle 2θ between the incident and signals beams changes according to Bragg's law:

$$n\lambda = 2d(Z) \sin \theta(Z) \quad \textbf{(Eq 14)}$$

A change in d causes a distribution of intensity over a range in 2θ angles. The most often leads to an asymmetrical broadening of the Bragg peak, which can be produced by chemical or residual strain gradients. The intensity of the diffracted signal is again proportional to the effective volume or the area of sampling plane multiplied by its thickness, which is given by (Ref 13, 14):

$$\left(\frac{\mathrm{d}d}{\mathrm{d}Z}\right)^{-1} [\exp(-\mu Z S)]\mathrm{d}d \quad \textbf{(Eq 15)}$$

This depends on the d-spacing gradient, $\mathrm{d}d/\mathrm{d}Z$, over each element and leads to a redistribution of the Bragg intensity, along with 2θ axis or differential behavior. Equation 15 indicates that a small d-spacing gradient tends to give higher intensity.

A fluorescence signal "*i*" of a fixed wavelength at each position *Z* gives integral behavior over a gradient zone. When analyzed by a crystal or energy-dispersive detector, one finds that signals at different depths with a common λ superimpose. Therefore, the total signal is obtained by summing all measurable signals to some effective distance below the surface. Here, the signal is not dispersed at each depth -*Z*. Integral behavior is expected from a gradient in the volume fraction of crystal phases having fixed compositions. Here, the diffraction signals accumulate from the entire zone at fixed 2θ positions, giving relatively sharp peaks. The positions are simply determined from Bragg's law and the published lattice parameters and structures (Ref 8) of the various phases along a zone.

Texture can also be treated as an integral quantity because fixed lattice parameters produce an accumulation of diffracted signals from all parts of a zone. If a texture gradient exists over the probe distance considered, the variation in relative integrated intensity from one Bragg peak to another will vary, depending on the pole density gradient of the diffracting planes and the probe depth. A severe thermal-mechanical disturbance at the surface could produce crystallite reorientation and a measurable texture gradient. This problem has not been examined quantitatively.

A grain-size gradient in the range that produces x-ray diffraction line broadening (<100 nm) could give different line widths, again, depending on the gradient, probe depth, and instrument resolution. Because each diffraction peak occurs at the same 2θ position from different portions of the zone, it is considered to be integral behavior. A similar argument can be given for nonuniform strain, but without a uniform strain component. This might be produced by a gradient in the dislocation density. At high dislocation densities, the diffraction peaks become broadened at fixed 2θ positions. This leads to an integral behavior, with either line width or shape changing with probe depth.

There are normally inherent differences in our ability to accurately detect changes in differential and integral measurements. Conventional x-ray diffraction sources are typically of low intensity and require long counting times to attain statistical accuracies better than 5% when polycrystalline samples are used. Integral behavior is examined largely from changes in relative intensity measurements as they vary with different probe depths. Differential behavior further depends on changes in the intensity distribution with 2θ which is usually very sensitive to the gradient profile. The accuracy of the 2θ scale can easily be 1 in 10,000, making an XRD measurement of differential behavior highly accurate. The following sections provide examples of both integral and differential behavior using XRD.

Integral Gradient

The examination of phase gradients along a wear track of a partially stabilized zirconia disk by XRD provides an example of integral behavior. Three distinct crystal phases can be present in this material: cubic, tetragonal, and monoclinic. Linear, exponential, and stepped distributions have been considered (Ref 11, 12). The exponential distribution can be written as (Ref 11):

$$H_i(Z) = H_{0i} + H_{si}e^{-Z/b_i} \quad \textbf{(Eq 16)}$$

The various terms are illustrated and defined in the caption of Fig. 4. For each position *Z*, it is required that

$$\Sigma H_i (Z) = 1 \quad \textbf{(Eq 17)}$$

where all phases *i* are considered. The effective volume for each phase is obtained by integration

$$V(ij\lambda\omega) = \frac{A_0}{\sin(\theta + \omega)} \int_{-\infty}^{0} H_i(Z) \exp(-\langle\mu\rangle SZ)\, dZ \quad \textbf{(Eq 18)}$$

with

$$S = \frac{1}{\sin(\theta + \omega)} + \frac{1}{\sin(\theta - \omega)} \quad \textbf{(Eq 19)}$$

and the subscript *i* refers to the Miller indices (*hkl*) reflecting at an angle θ. The linear absorption coefficient averaged over all phases is $\langle\mu\rangle$. For the exponential distribution given by Eq 11, this simplified to

$$V(ij\lambda\omega) = \frac{A_0 H_{0i}}{S\langle\mu\rangle \sin(\theta+\omega)} \left[1 + \frac{b_i \langle\mu\rangle S(H_{si}/H_{0i})}{1 + b_i \langle\mu\rangle S}\right] \quad \text{(Eq 20)}$$

for a flat sample.

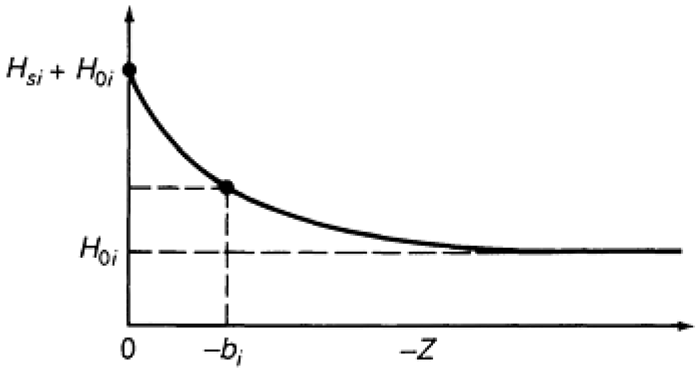

Fig. 4 Experimental near-surface area fraction distribution showing: undisturbed substrate limit, H_{0i}; surface area fraction, H_{si}, and location e^{-1} point in terms of $-b_i$

The quantity *S* is the path length factor given in Eq 8 with $\mu_s = \mu_i$. *S* becomes very large as $\omega \rightarrow \pm\theta$. Two cases are considered below.

In the first case, the beam samples only a small fraction of the exponential distribution. This condition requires that $(b_i\langle\mu\rangle S) \gg 1$. A large value for any one of these terms could limit the overall view of the gradient. Therefore, it is reasonable that the effective volume for phase *i* should be

$$V(ij\lambda\omega) = \frac{A_0(H_{0i} + H_{si})}{S\langle\mu\rangle \sin(\theta+\omega)} \quad \text{(Eq 21)}$$

That is, only the phase distributions at the surface are seen.

In the second case, if $(b_i\langle\mu\rangle S) \ll 1$, due to any one or any combination of these terms, the near-surface gradient is too small to be observable. Therefore, the effective volume is determined by the volume fraction in the substrate

$$V(ij\lambda\omega) = \frac{A_0 H_{0i}}{S\langle\mu\rangle \sin(\theta+\omega)} \quad \text{(Eq 22)}$$

In order to evaluate b_i, at least one measurement should be made in the range ($b_i\langle\mu\rangle S \approx 1$, and additional measurements are required to solve for H_{0i} and H_{si}. These are obtained at different values or with different μ values, because of a λ change.

The determination of the phase distributions for a polished PSZ dish after a wear test was conducted for both the worn track and an unworn region (Ref 11). The wear testing was conducted at an ambient temperature of 204 °C (400 °F), with an atmosphere of prepurified nitrogen. A 6.4 mm (0.25 in.) diameter pin was loaded to 12.5 N (1.27 kgf) against a disk

traveling at 0.3 m/s (1 ft/s) at the point of contact. The total time of testing was 61 h. XRD patterns from both the worn track and the back side of the disk were obtained with synchrotron radiation of wavelength λ= 0.24797 nm. Two paths were obtained using a typical symmetrical arrangement (ω = 0°) and an asymmetrical arrangement having the sample normal tilted toward the incident beam, giving a 6° angle with the diffracted beam. The XRD patterns include the (111) and ($11\bar{1}$) reflections of the monoclinic phase [M(111), M($11\bar{1}$)] and the overlapping (111) reflections of the cubic and tetragonal phases [C(111)] and [T(111)], respectively.

Figures 5 and 6 show the general features of the symmetrical and asymmetrical diffraction patterns. The peak separation was carried out using a Pearson VII least squares fitting procedure. Although wear testing introduces a detectable amount of the tetragonal phase, the combined intensity of C(111) and T(111) are used, along with M(111) and M($11\bar{1}$). These will be used later to determine the phase distributions of the combined cubic and tetragonal phases. The combined C(111) and T(111) reflections are denoted by CT(111).

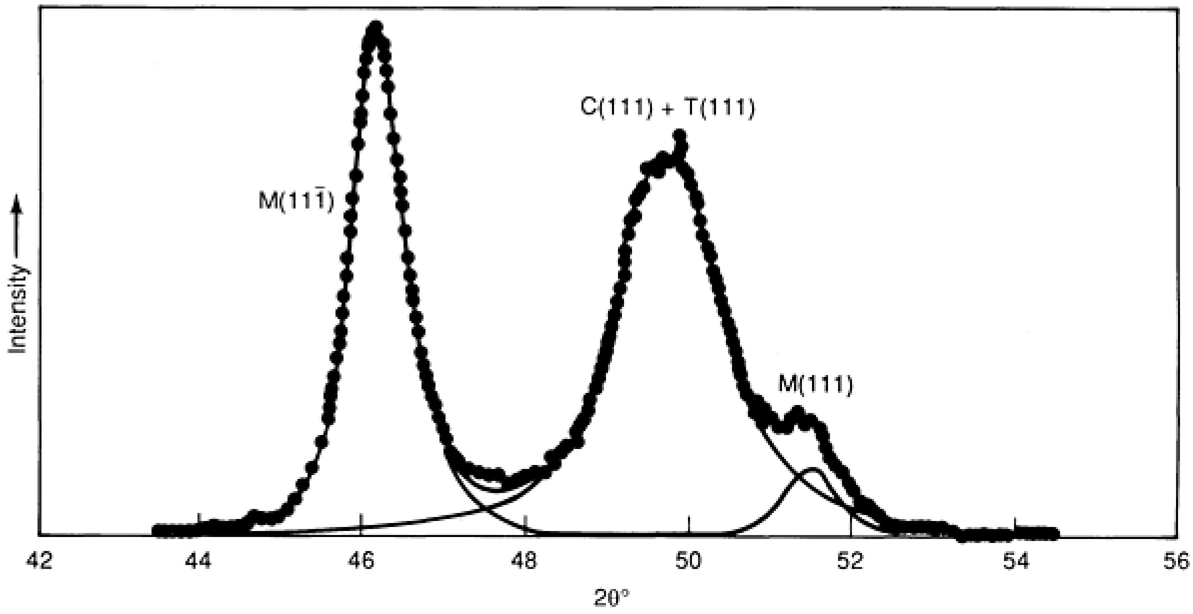

Fig. 5 X-ray diffraction data points for unworn side of a PSZ disk obtained using symmetrical optics and λ= 0.24797 nm. Individual profiles are shown as solid lines. Source: Ref 11

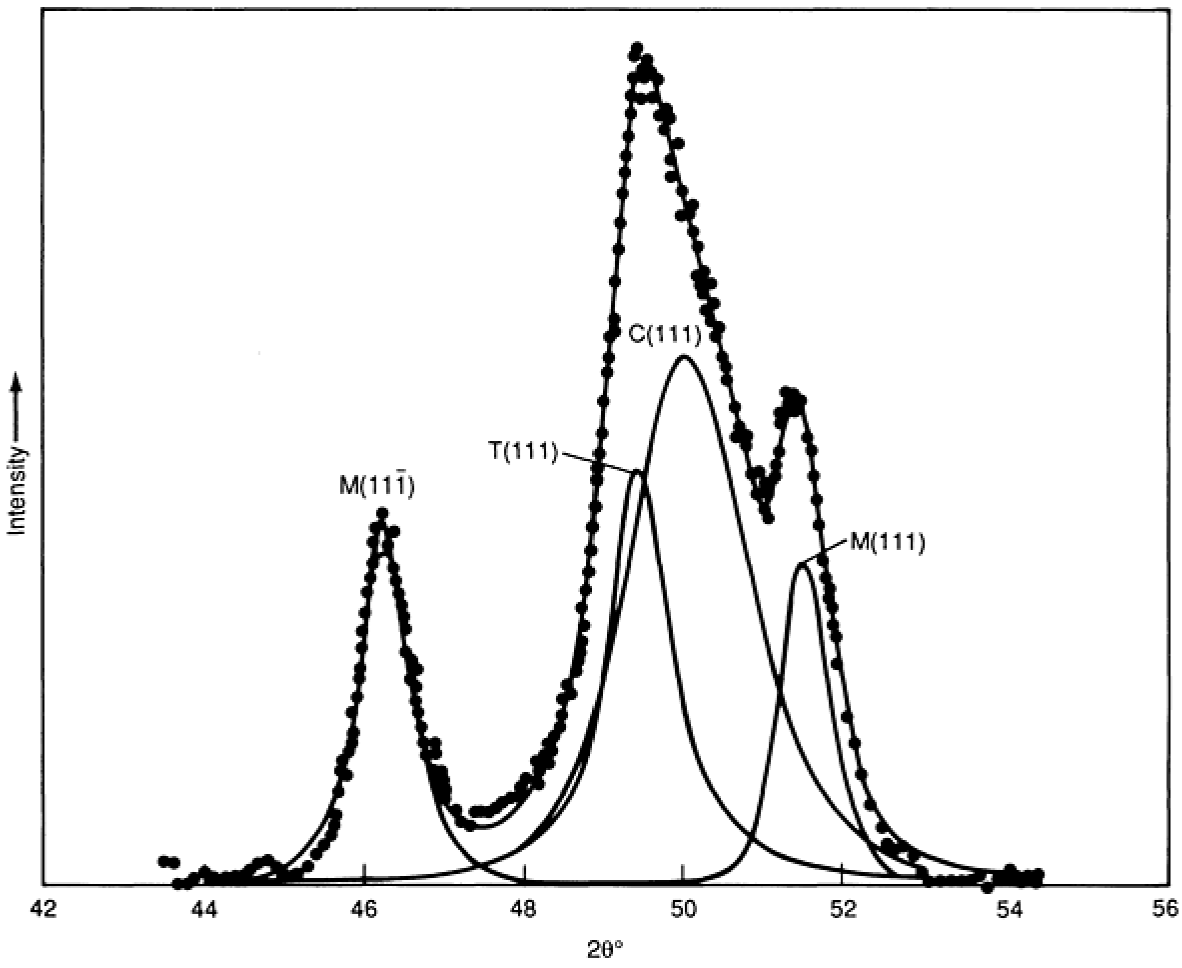

Fig. 6 X-ray diffraction data points for worn side of PSZ disk obtained with asymmetrical optics and λ= 0.24797 nm. Individual profiles are shown as solid lines. Source: Ref 11

A constant volume fraction of the undisturbed bulk region was obtained from the back side of the PSZ disk with CuK$\alpha 1$ radiation and symmetrical diffraction geometry. The linear absorption coefficient of PSZ for CuK$\alpha 1$ radiation is $\approx \frac{1}{4}$ of that for the λobtained with synchrotron radiation. This combination results in deeper penetration of the x-ray beam, which gives an XRD pattern that better represents the phase distribution in the bulk material. These intensities gave an upper limit of 0.445 for the volume fraction of cubic and tetragonal phases (H_{oct}). Profiles for both the worn track and the polished back side of the disk are shown in Fig. 7.

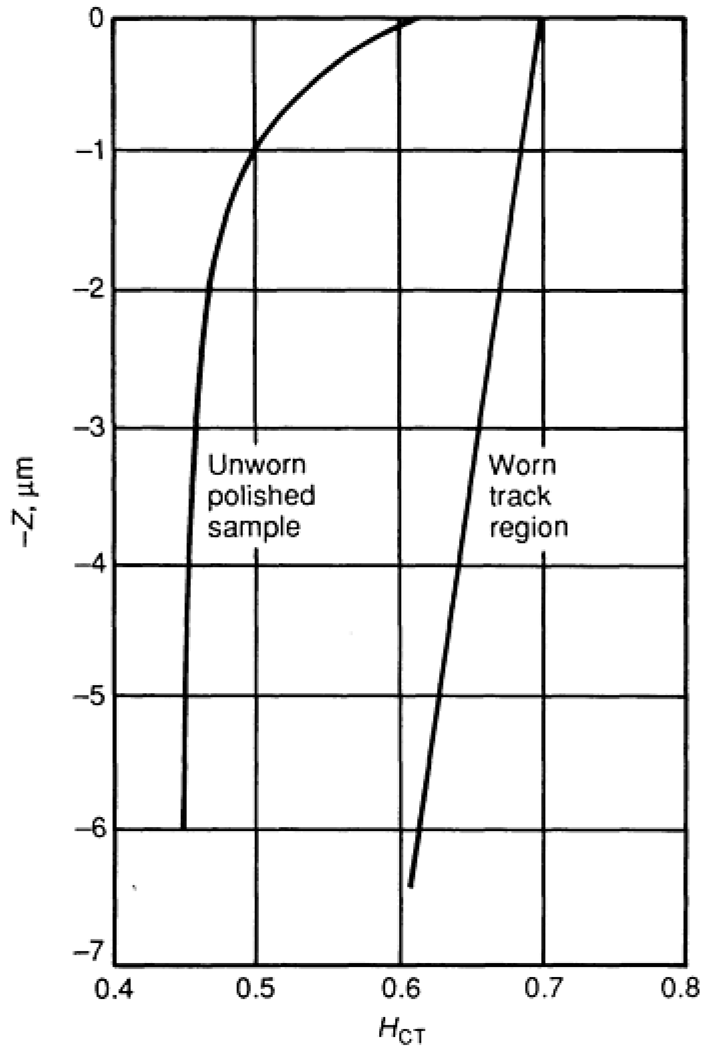

Fig. 7 Distribution of high-temperature cubic and tetragonal phases for unworn polished sample and worn track region. Source: Ref 11

Different probe lengths are obtained by adjusting $S<\mu>$. The ratio of the reduced intensity of one phase to another is directly related to the effective volume ratio

$$R_{ii'jj'\lambda\omega} = \frac{\sum_j I'_{ij\lambda\omega}}{\sum_{j'} I'_{i'j'\lambda\omega}} = \frac{\sum_j V_{ij\lambda\omega}}{\sum_{j'} V_{i'j'\lambda\omega}} \quad \textbf{(Eq 23)}$$

The notation is defined as follows: *i* and *i*' designate any two phases in a sample with *n* phases. The summations over *j* and *j*' indicate that more that one peak can be selected from each of the phases. Because *i* and *i*' can be any two of the *n* phases, Eq 23 represents a set containing up to (*n* - 1) independent intensity ratios for a fixed λ and ω. In the multiple-wavelength technique (Ref 12), one normally uses ω= 0° in Eq 23 to get 2 (*n* - 1) intensity ratios in terms of *n* effective volumes. With the integrated intensity ratios measured from the XRD patterns, the unknown parameters contained in the effective volumes can be determined because μ varies with λ. Similarly, with multiple-beam paths, one can use a fixed λ and several tilt angles, ω, to obtain the intensity ratios in terms of *n* effective volumes. The unknown parameters, located in the effective volumes, can be obtained from the measured integrated intensities and other data that are normally available.

Differential Gradient

Differential behavior is observed when the interplanar spacing, *d*, changes with depth below the free surface and intensity becomes redistributed along the 2θ axis. The *d*-spacing change can be relatable to composition changes resulting from small differences in atomic size or it can be due to residual strain from thermal and/or mechanical interactions at the free surface. Composition gradients have been most extensively studied using XRD (Ref 13, 14).

In the preceding example of integral behavior, a partially stabilized zirconia was used to show a phase gradient. For the present discussion, it is instructive to continue with zirconia, but to use one that is fully stabilized (FSZ) in the cubic form. Two samples were examined (Ref 15). One was polished to give σ= 0.027 μm, and a second was severely ground to give σ= 6.2 μm and a correlation distance (τ_c) of 81 μm. For the polished sample, the beam penetration distance was always much larger than σ, whereas for the ground sample, σ was always at least a factor of 3 larger.

The (111) peak profiles of the polished and the ground FSZ samples were obtained using Cuk$\alpha 1$ radiation and symmetrical diffraction optics. The optics. The CuK$\alpha 1$ component was obtained using a diffracted beam quartz monochromator and a fine-focus Cu tube. Results from the polished and ground samples are shown in Fig. 8. Profiles extend asymmetrically toward the low-angle side, because of a state of compression near the surface. The (111) profiles of the polished and the ground samples were also measured, using synchrotron radiation of 0.24794 nm with both symmetrical and asymmetrical optics, at the Oak Ridge National Laboratory beamline (National Synchrotron Light Source), before annealing. The polished and ground sample profiles measured with symmetric diffraction optics are shown in Fig. 8(a) through (d). Intensity bands are observed from ground and polished samples using two radiations. The longer synchrotron wavelength is less penetrating and better emphasizes the distribution near the surface zone.

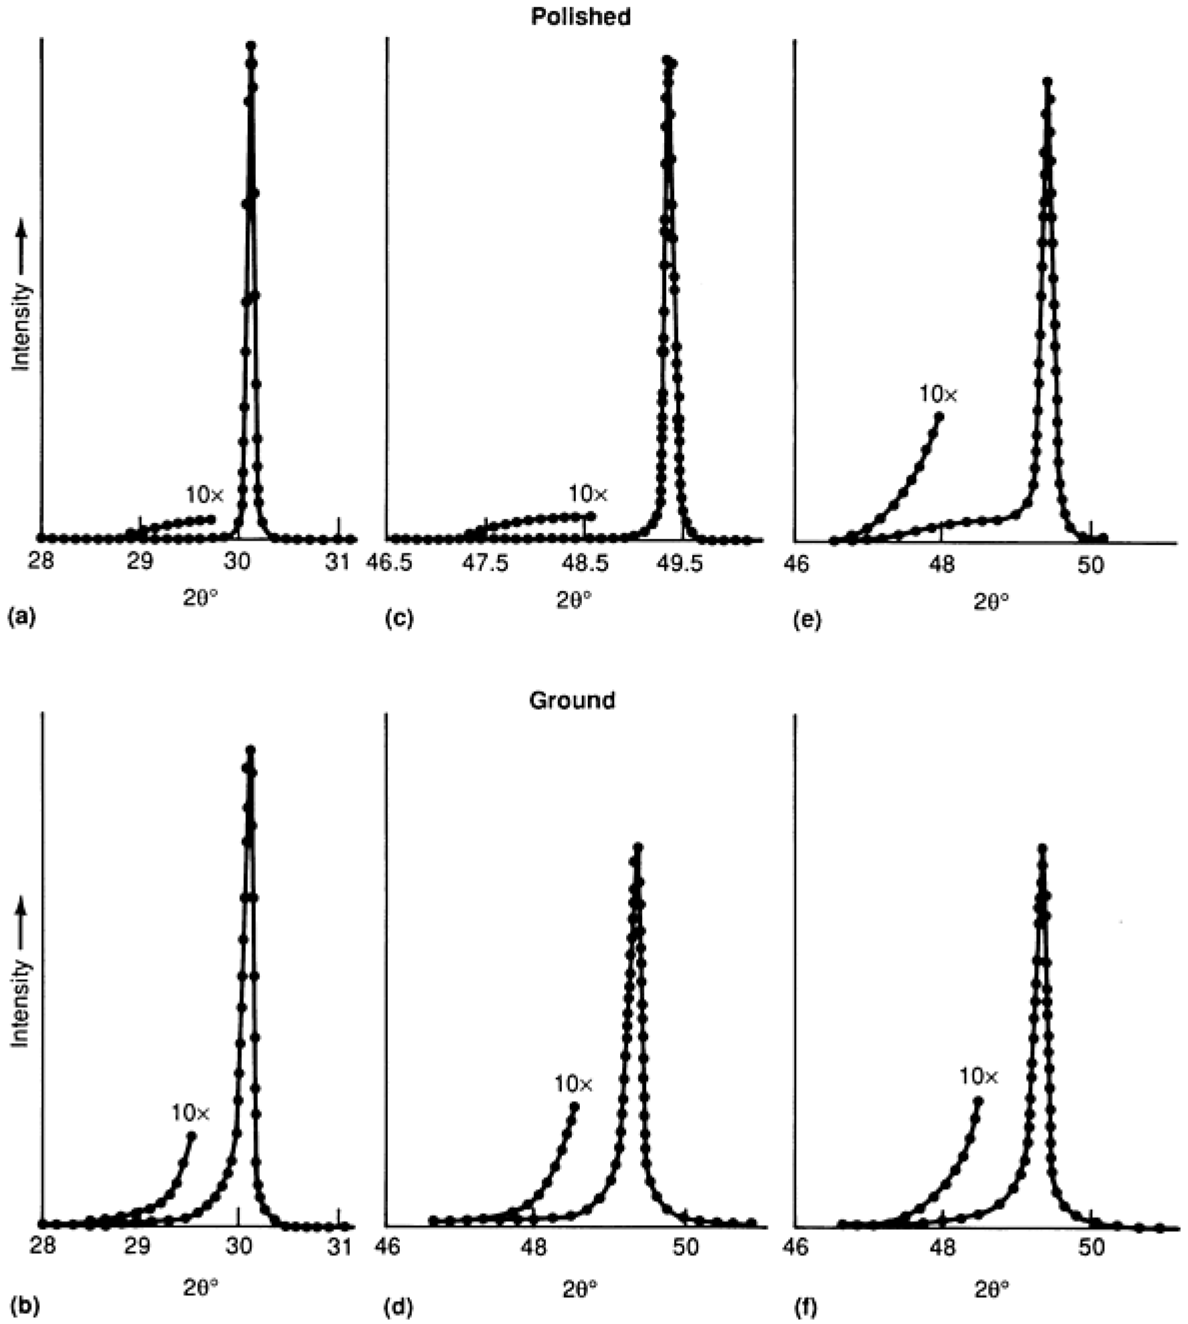

Fig. 8 (111) intensity bands from polished and ground samples of partially stabilized zirconia showing experimental data points and computer simulations (solid lines) for and symmetrical optics with CuKα radiation (λ - 0.15406 nm), (a) and (b); synchrotron radiation with λ= 0.24797 nm, (c) and (d); and 3° asymmetric optics with λ= 0.24797 nm, (e) and (f)

To further emphasize the near-surface regions, (111) profiles of both samples were measured with asymmetrical diffraction optics, as shown in Fig. 8(e) and 8(f). Asymmetric diffraction optics were obtained by tilting the sample normal toward the diffracted beam by an amount such that the incident angle is 3°. The small incident angle results in less penetration, and, as expected, influences the peak profile for the polished sample. The peak profile of the polished sample obtained with asymmetrical diffraction optics enhances the low-angle side of the pattern compared to that found with the symmetrical optics. For the ground sample, no change was observed between the profiles obtained with symmetrical and asymmetrical optics. This result will be discussed later.

After both samples were subsequently annealed at 1200 °C (2190 °F) for 1 h and furnace cooled, the profiles were indistinguishable. However, considerable sharpening was observed. To check these findings, the samples were repolished

using alumina powder. No peak shift was observed, but the profile was extended asymmetrically toward the low-angle side. This reconfirms the conclusion that the polishing process introduces a low-level intensity band, and the main peak remains unshifted. The peak shift between the profiles of the ground and polished samples before annealing is real, and is due to the extended range of the strain gradient in the severely ground sample.

With depth measured from a load surface asperity, the sample can be treated as a system of thin curved layers located at various depths. The *d*-spacing of each layer is treated as a constant, and the corresponding intensity is calculated using a theory that includes roughness. Figure 9 illustrates two strain profiles obtained from two radiations for the severely ground sample. The polished sample is essentially flat, with the layers parallel to the sample surface, whereas the ground sample is rough, and consists of layers of constant strain that follow the same fluctuation as the surface profile. The diffraction theory treats the intensity from each layer under both the symmetrical and asymmetrical diffraction conditions. The strain profiles for the polished sample are shown in Fig. 10. Because the *d*-spacing changes continuously from one layer to another, the intensities are spread over a 2θ range according to Bragg's law.

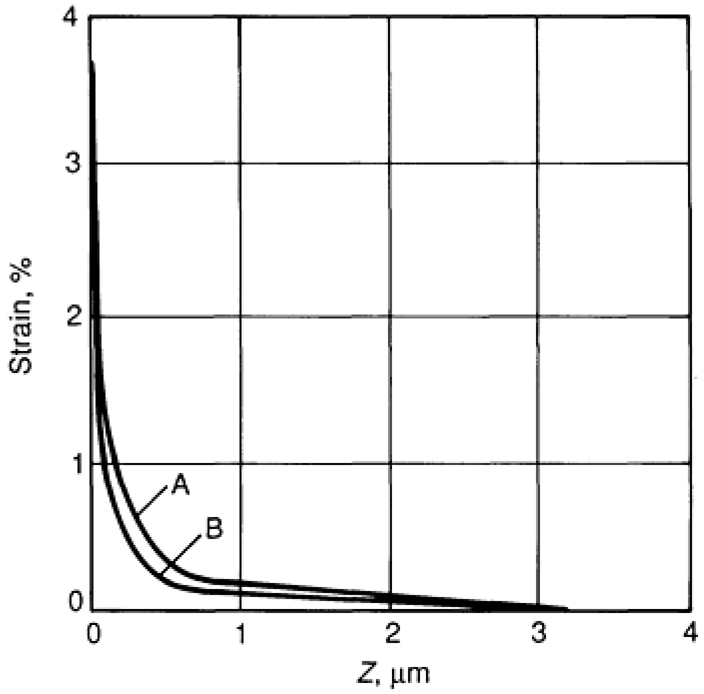

Fig. 9 Depth profiles of strain for ground sample obtained with symmetrical optics. A, CuKα radiation; B, λ = 0.24797 nm (synchrotron radiation). Source: Ref 15

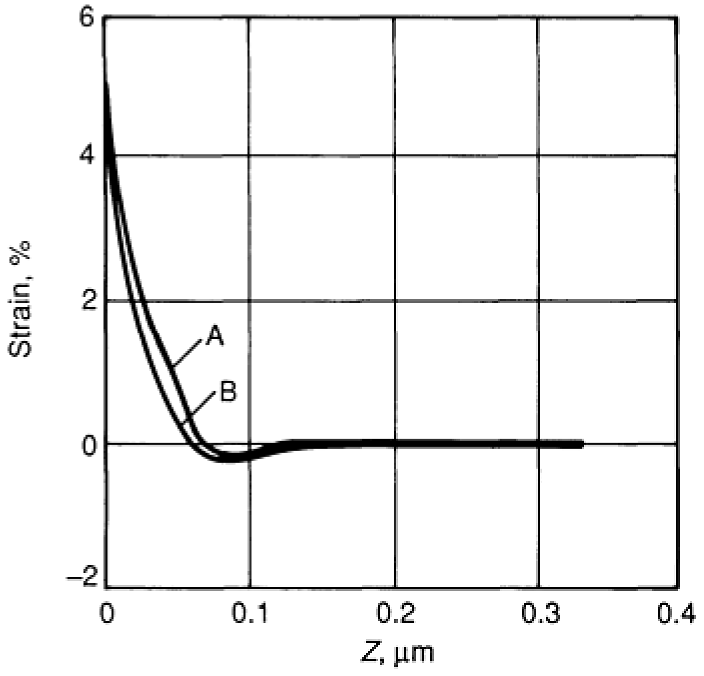

Fig. 10 Depth profiles of strain for polished sample obtained under the following conditions: A, symmetrical optics using CuK$\alpha 1$ (λ = 0.15406 nm and λ= 0.24797 nm) (synchrotron radiation); B, asymmetrical optics with λ= 0.24797 nm (synchrotron radiation). Source: Ref 15

Computer-simulated intensity bands are compared with the fitted experimental data in Fig. 8(a) through (f). Both the measured and simulated (solid lines) profiles are expanded vertically by 10 times at the low-angle side to better show the final fit. The redistribution of intensity, in this case, is weak and could be overlooked in routine XRD. It could be completely missed in complex powder patterns having many overlapping diffraction peaks.

A reexamination of Fig. 9 and 10 shows that the maximum compressive strain near the surface is large, giving $\sim$4% for the ground surface and $\sim$5% for the polished. Although polishing gives the highest strain, the overall zone thickness is about $\frac{1}{10}$ the size found after severe grinding.

Analysis of Debris Particles

At one instant of time during a wear test, a small fraction of the asperities of a surface become separated as debris particles. It would be very instructive to be able to focus only on the characteristics of these regions, that is, to determine the crystal phases, dislocation density, and a statistical description of their arrangement. However, these features are lost in an examination of the overall near-surface region because of their small volume fraction.

An alternative is to device efficient methods of collecting the debris particles that break away from these special asperities. An analysis of debris particles could be useful in establishing wear mechanisms. This collection need not require the dismantling of a machine, but rather, a concentrate of wear fragments could be collected at filter locations. Ideally, one would like to look back and relate the structural parameters of debris to the conditions present in the asperities prior to breakaway, and to correlate these findings with machine operational conditions. The previous discussion of substrate structure relates to wear conditioning processes. Both substrate and debris should be examined in a comparative approach.

For material that contain more than one crystal phase, or a material that can undergo further phase transformation, the first question one might ask is: What phases are present? By knowing the stability of these phases from either the equilibrium diagrams or the temperature range of metastable, phases, one can relate back to thermal and chemical conditions prior to the breakaway point. This is particularly true if the particles are small and have a high surface/volume ratio, allowing

rapid cooling from the local temperature at an asperity during separation. An example of a debris analysis is given later for zirconia.

X-ray diffraction profile analysis has been used to examine highly deformed metals since the 1950s. More recently, this has been described in Ref 6 and 7. The results provide a mean subgrain size and root mean square strain as a function of distance and crystal direction. Early investigations were carried out on "cold-work" filings. In other words, powder samples were obtained by filing a solid sample whose average temperature was close to room temperature. Any local heating associated with the breakaway process was overlooked in what was considered to be a cold-working process. The most reliable data of this type have been reexamined (Ref 15, 16). The process of producing filings can be treated as one form of wear process. A major concern of line-shape techniques is the need to examine the full profile as pairs of first- and second-order Bragg peaks. When profiles overlap for one reason or another, one must make procedural compromises.

Recent advances allow a least squares fitting procedure to be used on overlapping data sets (Ref 16). It gives the mean particle size and two strain parameters, $<\epsilon^2_{1U}>$, $<\epsilon^2_{1D}>$. The mean square strain varies according to

$$<\epsilon^2_{n}> = <\epsilon^2_{1U}> + <\epsilon^2_{1D}>/n \quad \textbf{(Eq 24)}$$

where n gives distance between two points in the crystal in units of the average d-spacing, d, for the first order of a set of reflections ($h_1k_1l_1$) and ($h_2k_2l_2$). Strain is determined along columns perpendicular to the reflecting planes. Knowing the two strain parameters given above allows $<\epsilon^2_{n}>$ to be evaluated. A pair of fitted profiles obtained from zirconia debris are shown in Fig. 11 (Ref 17).

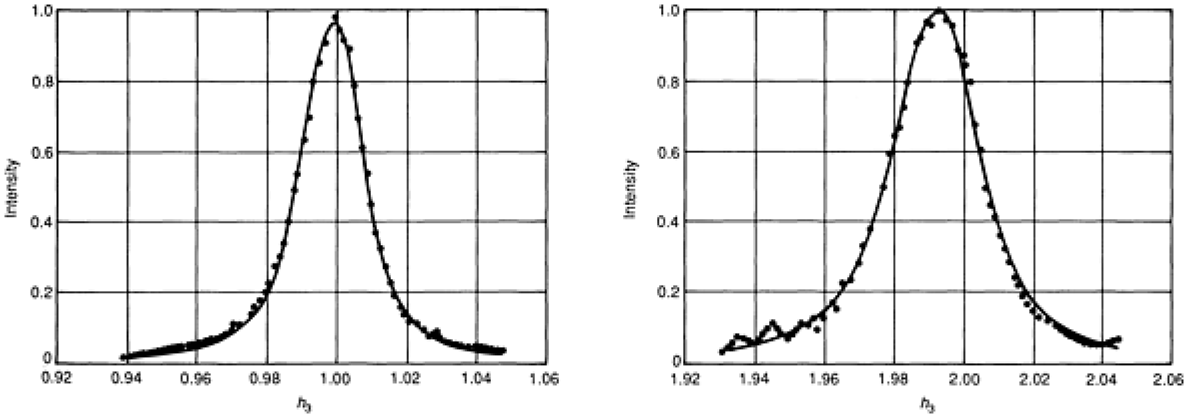

Fig. 11 Least squares fitting of (200) (left) and (400) (right) profiles using procedures described in Ref 18

Equation 24 presents the results in a purely statistical form, and does not provide a basic connection with dislocation theory. It has been shown that the two strain parameters noted above, as well as $<L>$, the average subgrain size, determine the dislocation density according to (Ref 18, 19):

$$n_d = 122\,\frac{d}{b^2}\,\frac{\langle \epsilon^2{}_{1D}\rangle}{L} \quad \textbf{(Eq 25)}$$

where b is the Burger's vector.

This varies directly with $<\epsilon^2_{1D}>$, and inversely with subgrain size, L. A second parameter, obtained from the more-recent line-shape analysis, contains the correlation distance, R_c, for unlike dislocation relative to L. This is given by (Ref 17, 18):

$$\frac{R_c}{L} = 1.10 \exp\left(\frac{0.62L\langle\epsilon^2{}_{1U}\rangle}{d\langle\epsilon^2{}_{1D}\rangle}\right) \quad \textbf{(Eq 26)}$$

Isotropic elasticity theory has been used to obtain these relationships for dislocation density and correlation parameters. In applying Eq 24, one need not assume that the material is isotropic.

Table 1 lists results for both face- and body-centered cubic materials. A common pattern is apparent. For cold-work filings, one finds that

$$1.33 \leq \frac{R_c}{\langle L\rangle} \leq 2.17 \quad \textbf{(Eq 27)}$$

For the most part, the dislocation density is high and in the $10^{11}/cm^2$ range. Dislocations are highly correlated, with R_c close to the average diameter of the subgrain for metallic filings and ZrO_2 debris.

Table 1 Results for body-centered cubic materials, face-centered cubic aluminum, and partially stabilized cubic zirconia

Material	<L>, nm	$n_d \times 10^{-11}/cm^2$	R_c/<L>	$\langle\epsilon^2_{1D}\rangle \times 10^4$	$\langle\epsilon^2_{1U}\rangle \times 10^6$
Cr	28.5	3.67	1.79	2.63	1.47
V	20.0	6.56	2.17	3.46	4.05
Mo	26.0	4.60	1.99	3.30	2.72
W	21.5	7.32	1.66	4.56	3.27
Nb	20.0	1.53	1.33	0.84	0.29

ZrO_2	8.6	12.70	1.42	4.84	4.90

Aluminum filings are prepared under liquid nitrogen.

Source: Ref 18

The results given in Table 1 for body- and face-centered cubic material allow a simple explanation to be given for the structure of cold-worked fragments. Filings show a high degree of correlation (small R_c/<L>) and high dislocation densities. This is related to sample conditions, such as the temperature and local conditions at which a high-density dislocation structure is produced. Fragments produced by filing or grinding at room temperature, or even at liquid nitrogen temperature, cannot be "cold." Instead, they are rapidly heated to a high temperature during fracture, and rapidly quenched, because of their high surface-to-volume ratio. Dislocations are mobile for short periods of time over short distances and can cluster.

Table 1 includes results from cubic debris particles obtained from a worn PSZ. The substrate contains three phases, as already discussed. It should be noted that the cubic phase is stable at high temperatures, making it reasonable that only the cubic form should be found in the debris. The dislocation density for zirconia is the highest entry, whereas the correlation distance is close to the mean diameter. One can present the same arguments for zirconia debris as for cold-worked metal filings. Prior to breakaway, material at the asperity has a very high dislocation density. A high separation temperature allows some dislocation movement to form subgrain clusters.

The question of how much debris one must collect for an ideal line-shape analysis needs to be considered. Typically, for quantitative work, one would like to be able to fill a cavity of at least 15 mm (0.6 in.) in diameter to a depth of 2 mm (0.08 in.). The sample thickness should be several times the penetration depths already discussed. Quantitative diffractometer studies require much more sample than what is required for an x-ray powder camera, but also offer the opportunity for more extensive data analysis.

Conclusions and Future Trends

Both the wear-modified phase distribution and the debris indicate that at least a fraction of the surface material has been subjected to high temperatures during wear testing. Zirconia debris has an even higher dislocation density than metal filings, indicating severe deformation before breakaway from the surface. High correlation between dislocations is likely to result from a time-restricted, thermally activated process taking place at an elevated temperature immediately after fracture. It was found that large residual compressive strains build up in the ground surface region of the zirconia substrate. A state of dynamic equilibrium is likely to be present between the production of regions of high defect density-residual strain and relaxations produced by annealing. The annealing processes within near-surface bulk substrate material is likely to offer a spectrum of possibilities.

Data from a ground PSZ sample revealed the formation of a place gradient extending over a distance of several microns. This represents another form of conditioning that could influence subsequent wear testing. Depths from a few tenths to the micron range are typical x-ray probe distances for many commercial materials.

Future research will require a careful selection of samples and radiation. Quantitative diffractometer data will give the greatest amount of information. A part from local surface asperities, the mean surface should be flat. Typically, it also should have surface dimensions ranging from 10 to 30 mm (0.4 to 1.2 in.) to fit into commercial systems. XRD data should be inter-related with XRF or other near-surface analyses revealing chemical changes. Variable penetration depths often allow the condition near a surface to be compared with deeper regions that are relatively unaffected by wear processes.

A detailed analysis of diffraction patterns from concentrated industrial wear debris under different conditions may establish trends that predict malfunctions. Similarities or differences between the wear from a given machine and testers, which are used to simulate machine conditions, could also be examined.

Thin-film attachments are available for most commercial diffractometers, allowing low glancing angles to be attained. This can greatly reduce the beam penetration. These attachments should be considered for examinations of worn surfaces, as well as for thin layers of debris.

Perhaps the most severe restriction in an x-ray analysis using conventional x-ray sources is the limited area of disturbed surface available for examination using routine pin-on-disk testing. One would rather examine square cross sections of at least 15 mm (0.6 in.). Although synchrotron radiation would allow one to examine a small fraction of this size, it is often not readily available. A smaller-sized sample used with conventional sources would force compromises in the data analysis and lessen the opportunity to obtain quantitative results. Any use of x-rays must begin with a consideration of sample size.

Basic Tribological Parameters

Horst Czichos, BAM (Germany)

Introduction

TRIBOLOGICAL PARAMETERS are characteristics of mechanical systems with "interacting surfaces in relative motion," including the initiation of motion. The tribological processes of interacting surfaces have a dual character. They are on one hand necessary for the functional performance of "tribosystems" or "tribocomponents" (see the "Glossary of Terms" in this Volume), but are on the other hand inevitably connected with friction and wear. In engineering applications, the functional purpose of trobosystems can be broadly classified into the following categories (Ref 1):

- The guidance, transmission, coupling, control, stop, and annihilation of motion, force, mechanical energy, and power (bearings, joints, gears, clutches, cams and tappets, bolts and nuts, fasteners, and brakes)
- The transportation and control of flow of matter (pipelines, wheel/rail, tire/road, valves, and seals)
- The forming, machining, and tearing of materials (drawing, pressing, cutting, shaping, quarrying, and dredging)
- The generation and transmission of information (printing heads and magnetic recording interfaces)

The diagnosis of friction and wear data of such tribosystems or corresponding laboratory test configurations and test specimens requires special attention because numerous characteristics, parameters, and factors must be taken into consideration. This is due to the fact that friction and wear are not intrinsic materials properties, but must be related to the entire system of interacting components, namely materials pairs and interfacial lubricants. This is obvious from a comparison between the test conditions to obtain strength data or friction and wear data (Fig. 1).

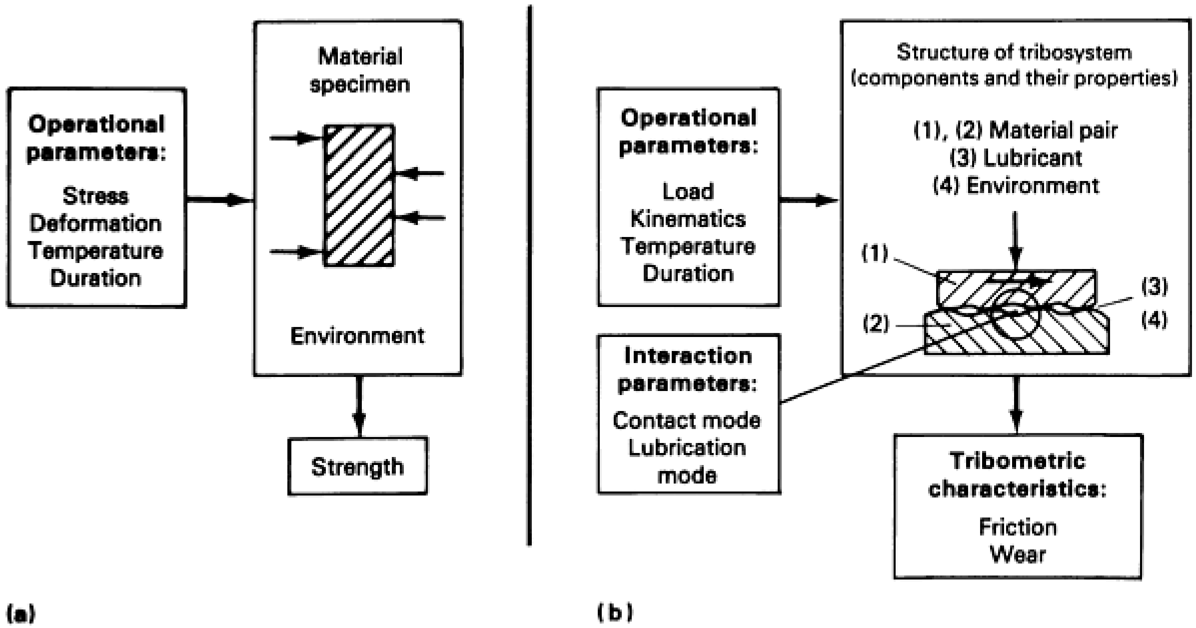

Fig. 1 Characteristics and parameters of (a) strength tests and (b) friction and wear tests

In strength tests (Fig. 1a), the deformation or fracture resistance of a material specimen in a given environment is determined under the action of a certain stress mode, such as tension, compression, shear, bending, or torsion. The

resulting strength data (in terms of force per cross section, or energy) are considered as intrinsic materials properties depending basically on the following groups of parameters:

- *Materials parameters,* such as composition, microstructure, and specimen geometry
- *Operational parameters,* such as stress type, load, deformation velocity, and temperature

In a friction or wear test (Fig. 1b), the resistance against motion (friction) or the resistance against surface damage (wear) of a material/material pair (dry system) or a material/lubricant/material combination (lubricated system) in a given environment is determined under the action of a certain type of motion, such as sliding or rolling. The resulting tribometric characteristics--in particular the friction or wear data--must understood as tribological systems characteristics associated with the following group of parameters:

- *Structural parameters,* which characterize the components (materials, lubricant, and environment) involved in the friction and wear process and their physical, chemical, and technological properties
- *Operational parameters,* that is, the loading, kinematic, and temperature conditions and their functional duration
- *Interaction parameters,* which characterize, in particular, the action of the operating parameters on the structural components of the tribological system and define its contact and lubrication modes

Structural Parameters

The analysis of structural parameters must identify first the components involved in a given friction and wear problem. Figure 2 shows typical examples of tribosystems subject to friction and wear together with corresponding simplified test configurations and their elementary structure. This figure illustrates that in any friction and wear situation, four tribocomponents are involved (Ref 2):

- Triboelement (1)
- Triboelement (2)
- Interfacial element (3), for example, lubricant or dust particles
- Environmental medium (4), for example, air or corrosive atmosphere

Table 1 lists examples of the tribocomponents that make up various tribosystems.

Table 1 Structural components of common tribosystems

Tribosystem	Triboelement (1)	Triboelement (2)	Interfacial element (3)	Environmental medium (4)	Type of systems structure
Gear box	Gear 1	Gear 2	Gear oil	Air	Closed
Wheel/rail	Wheel	Rail	Moisture	Air	Open
Sliding guide	Slider	Support	Grease	Air	Closed
Bearing	Bushing	Shaft	Lubricant	Oil mist	Closed
Dredge	Shovel	Soil	. . .	Dust	Open
Milling system	Milling wheel	Milling jaw	Minerals	Air	Open

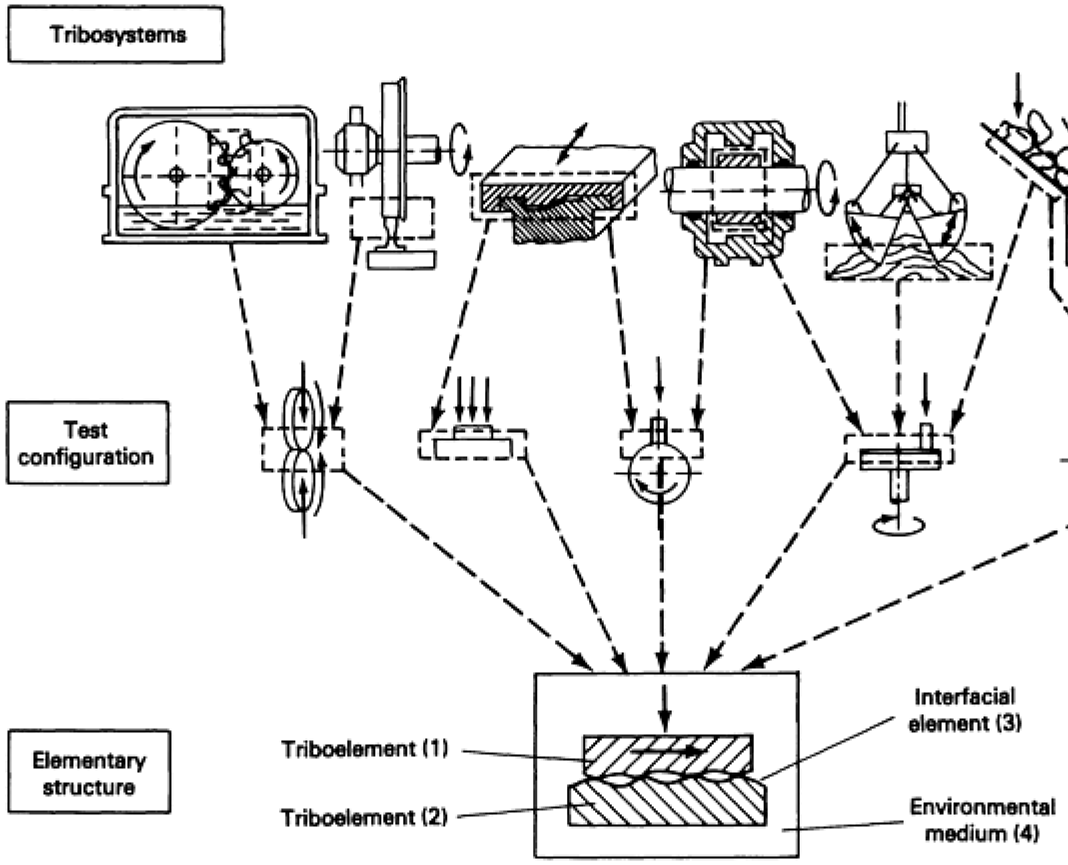

Fig. 2 Examples of engineering tribosystems, test configurations, and their elementary structure

In analyzing the structure of tribosystems, a distinction can be made between "closed systems," in which all components are continuously involved in the friction and wear process, and "open systems," in which a materials flow in and out of the system occurs.

The friction and wear data of tribosystems depend on various properties of their structural components (tribocomponents). Structural parameters of closed tribosystems can be classified in most cases into two groups.

Group A consists of triboelements (1) and (2) and involves:

- *Chemical parameters* such as volume composition and surface composition
- *Physical parameters* such as thermal conductivity
- *Mechanical parameters* such as elastic modulus, hardness, and fracture toughness
- *Geometric parameters* such as geometry dimensions, and surface topography
- *Microstructural parameters* such as grain size, dislocation density, and stacking fault energy

Group B consists of interfacial (fluid) element (3) and environmental (gaseous) medium (4) and involves:

- *Chemical parameters* such as composition, additive content, acidity, and humidity
- *Physical parameters* such as density, thermal conductivity, and flash and fire point
- *Mechanical parameters* such as viscosity, and viscosity-temperature and viscosity-pressure characteristics

For open systems, for example, manufacturing systems such as machining and molding, or quarrying and dredging systems, the structural parameters characterizing the materials flow in and out of the system are often difficult to specify.

In addition to the structural elements necessary to fulfill the functional purpose of the tribosystem, detrimental elements such as dirt, dust, and moisture may also be present and must be recognized in the analysis of structural parameters. To assist in the compilation of the various parameters relevant to a given friction and wear problem, a data sheet of basic tribological parameters is described later in this article (see the section entitled "Data Sheet of Basic Tribological Parameters").

Operational Parameters

Operational parameters characterize the functional conditions of a tribosystem. They can be considered (with the exception of friction-induced temperatures) as independent variables that can be varied during tribological testing to obtain friction and wear data experimentally. The basic operational parameters in tribology are:

- *Type of motion,* that is, the kinematics of triboelements (1) and (2), to be classified in terms of sliding, rolling, spin, and impact and their possible superpositions (Fig. 3). The kinematics can be continuous, intermittent, reverse, or oscillating
- *Load* (F_N), defined as the total force (including weight) that acts perpendicular to the contact area between triboelement (1) and (2), as shown in Fig. 3
- *Velocity* (v), to be specified with respect to the vector components and the absolute values of the individual motions of triboelements (1) ad (2). According to the Table 2, distinctions must be made among the relative velocity v_r (relevant to friction-induced temperature rises), the sum velocity v_s (relevant, in lubricated tribosystems, to the formation of an elastohydrodynamic film), and the slide-to-roll ratios
- *Temperature* (T) of the structural components at stated location and time, that is, the initial (steady-state) temperature and the friction-induced temperature rise (average temperature rise and flash temperatures) to be estimated on the basis of friction heating calculations (see the following article in this Section on "Design of Friction and Wear Experiments")
- *Time* dependence of the set of operational parameters (F_N, v, T, for example, load cycles and heating or cooling intervals
- *Duration* (t) of operation, performance, or test

In addition to these functional operational parameters, disturbances such as external vibrations or radiation might need to be taken into consideration as well.

Table 2 Type of motion and velocities of the components of a tribosystem for sliding and sliding and rolling

Type of motion		Velocities u, v and slip s				
		u_1	u_2	$v_r = \|u_1 - u_2\|$	$v_s = \|u_1 + u_2\|$	$s = 2\left[\frac{u_1 - u_2}{u_1 + u_2}\right]$
Sliding						
Simple sliding		$u_1 > 0$	$u_2 = 0$	$v_r = u_1$	$v_s = u_1$	$s = 2$
Sliding		$u_1 > 0$ $\|u_1\| > \|u_2\|$	$u_2 < 0$	$v_r > u_1$	$v_s < u_1$	$2 < s < \infty$
Pure sliding		$u_1 > 0$	$u_2 = -u_1$	$v_r = 2u_1$	$v_s = 0$	$s = \pm\infty$
Sliding		$u_1 > 0$ $\|u_1\| < \|u_2\|$	$u_2 < 0$	$v_r > \|u_2\|$	$v_s < \|u_2\|$	$-\infty < s < -2$
Simple sliding		$u_1 = 0$	$u_2 < 0$	$v_r = \|u_2\|$	$v_s = \|u_2\|$	$s = -2$
Sliding and rolling						
Simple sliding		$u_1 > 0$	$u_2 = 0$	$v_r = u_1$	$v_s = u_1$	$s = 2$
Rolling with slip		$u_1 > 0$ $u_1 > u_2$	$u_2 > 0$	$v_r < u_1$	$v_s > u_1$	$0 < s < 2$
Pure rolling		$u_1 > 0$	$u_2 = u_1$	$v_r = 0$	$v_s = 2u_1$	$s = 0$
Rolling with slip		$u_1 > 0$ $u_1 < u_2$	$u_2 > 0$	$v_r < u_2$	$v_s > u_2$	$-2 < s < 0$
Simple sliding		$u_1 = 0$	$u_2 > 0$	$v_r = u_2$	$v_s = u_2$	$s = -2$

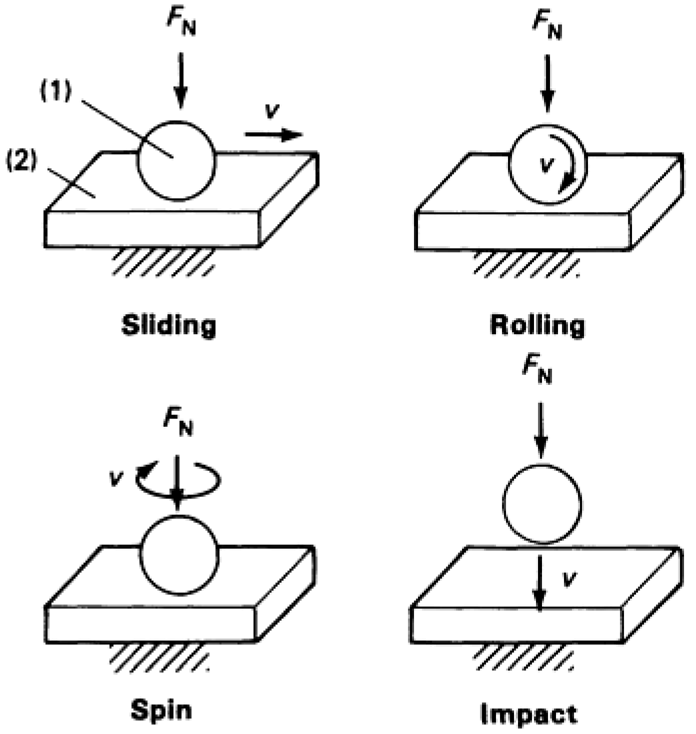

Fig. 3 Kinematics of tribosystems

Interaction Parameters

Interaction parameters characterize the action of the operational parameters on the structural components of tribosystems. These parameters define in particular the contact mode and the lubrication mode of a tribosystem with a given material/material or material/lubricant/material structure. The contact mode of two touching solid bodies is characterized microscopically by materials interactions, which are described by contact stresses and stress distributions. The materials and stress interactions cause a resistance against motion (friction) and may lead to surface damage (wear). Therefore, the materials and stress interactions in tribosystems are also called friction and wear mechanisms, or generally tribological processes, and specified in terms such as adhesion, abrasion, tribochemical reactions, surface fatigue, and so forth.

Interface Forces and Energies. Theoretically, the microscopic interaction forces between contacting solids include, at least in principle, all those types of atomic and molecular interaction that contribute to the cohesion of solids, such as metallic, covalent, and ionic, that is, primary chemical bonds (short-range forces), as well as secondary van der Waals bonds (long-range forces) (Ref 3, 4). These surface forces depend in a complicated manner on the physicochemical nature of the materials and the structure and composition of the outermost surface layers and contaminants. It should also be noted that the chemical composition, the electronic nature, and the microstructure of surfaces may be quite different from that of the subsurface (volume) of a material.

Experimentally, the only macroscopic way to characterize adhesive interactions between two solid bodies contacting under a normal load, F_N, is to destroy the bonding and to measure in the opposite direction to F_N the force, F_A, necessary for the separation of the surfaces. The ratio $a = F_A/F_N$ is termed the coefficient of adhesion. On the microscopic level, it is possible to determine with an atomic force microscope (noise level $\sim 2 \times 10^{-11}$ N) the interface forces (including friction forces) between single atoms of contacting surface tips (Ref 5).

In energetic terms, the formation of a solid/solid contact results in a net release of surface energy resulting from the replacement of two surfaces by one solid/solid interface of lower surface energy. The change in surface energy per unit area of contact, $\Delta\gamma$, can be written as:

$$\Delta\gamma = \gamma_1 + \gamma_2 - \gamma_{12} \quad \textbf{(Eq 1)}$$

where γ_1 is the surface energy of solid 1, γ_2 is the surface energy of solid 2, and γ_{12} is the surface energy of the interface.

Contact Deformation Modes. The surfaces of solid tribocomponents possess a certain roughness for which cross-sectional topography descriptors such as the centerline average (CLA), or the peak-to-valley roughness, as well as stochastic parameters such as the variances of the height and slope of asperities and the curvature are used for characterization (Ref 6). In addition, fractal geometry approaches may also be applied (Ref 7).

If two nominally flat and dry solid materials (1) and (2) are brought into static contact under the action of a normal load (Fig. 4), the touching asperities of this tribocontact deform elastically or plastically under the given load. The dominating contact deformation mode is governed by a deformation criterion (the so-called plasticity index), which depends on the deformation properties and the parameters of the surface topography of the contacting bodies (1) and (2) defined in Fig. 4 (Ref 6). The summation of individual contact spots gives the real area of contact, A_{or}, which usually is much smaller than the apparent geometrical area of contact. The real area of contact depends in the elastic case primarily on the ratio of F_N to the composite elastic modulus E' (see the discussion of "Contact Stresses" below) and in the plastic case on the ratio of F_N to the yield pressure, p_y, or the hardness, H, of the softer of the contacting bodies. If, in addition to the normal load, a friction force F_F is introduced, a junction growth of asperity contacts may occur, leading to a considerably larger area of contact. The basic parameters relevant to the contact mode of a materials/materials pair are summarized in Fig. 4. In engineering applications, the contact deformation mode may be additionally influenced by disturbances such as misalignments or vibrations.

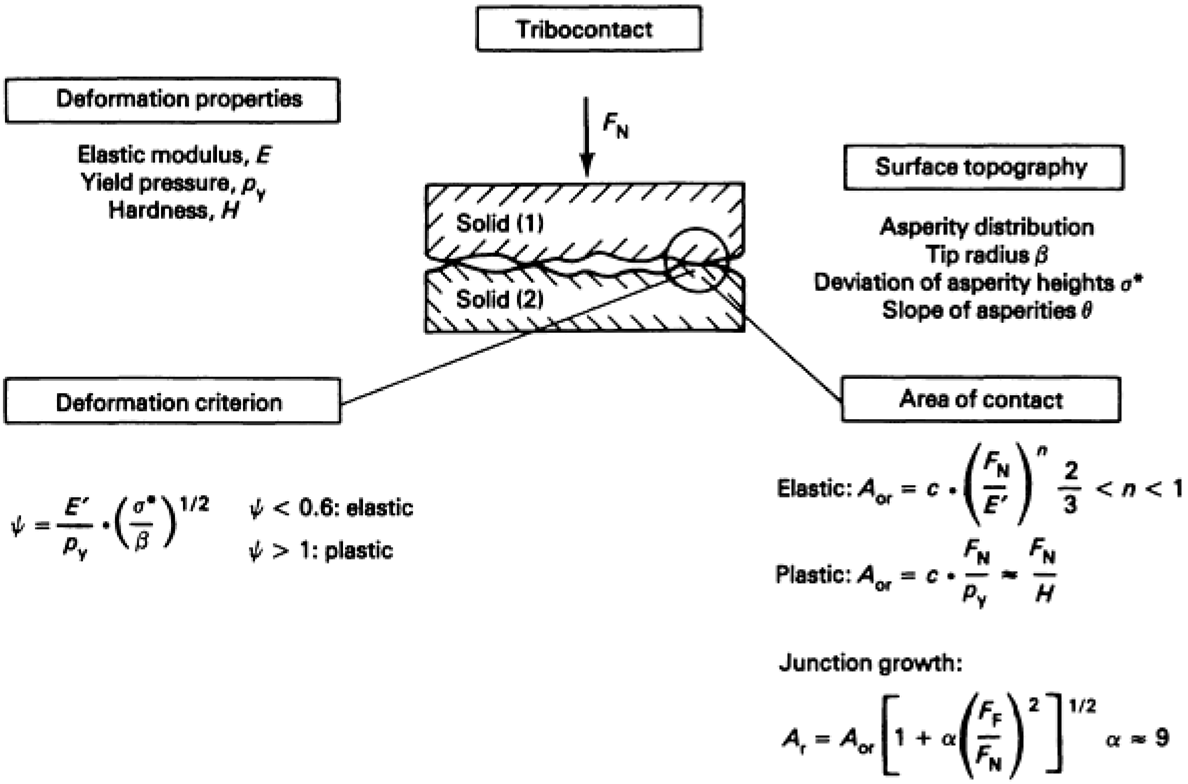

Fig. 4 Characteristics of a tribocontact between solid bodies

Contact stresses in a tribosystem depend on groups of parameters characterizing (1) the contact geometry, for example, conformal or contraformal contact configurations, (2) the elasticity, viscoelasticity, plasticity, or hardness of the materials, and (3) the external static or dynamic load.

For curved bodies, the macroscopic elastostatic contact situation is described by the Hertzian equations (Ref 8). To illustrate the basic parameters, consider the fundamental idealized case of the pure elastic contact of two spherical bodies (1) and (2) of radii r_1 and r_2, elastic moduli E_1 and E_2, and Poisson's ratios v_1 and v_2 under a normal load, F_N, as shown in Fig. 5(a). The contact pressure, p, at a location 1 within the contact area and the radius of contact a_H are given by:

$$p = \frac{3\,F_N}{2\pi a_H^2}\left[1 - \left(\frac{1}{a_H}\right)^2\right]^{1/2} \quad (0 \leq 1 \leq \alpha_H) \qquad \textbf{(Eq 2)}$$

$$a_H = \left[\frac{3r}{2E}\right]^{1/3} F_N{}^{1/3} \qquad \textbf{(Eq 3)}$$

where

$$r = \left[\frac{1}{r_1} + \frac{1}{r_2}\right]^{-1} \qquad \textbf{(Eq 4)}$$

is the equivalent radius of curvature, and

$$E = \left[\frac{1 - \nu_1^2}{2E_1} + \frac{1 - \nu_2^2}{2E_2}\right]^{-1} \qquad \textbf{(Eq 5)}$$

is the composite elastic modulus.

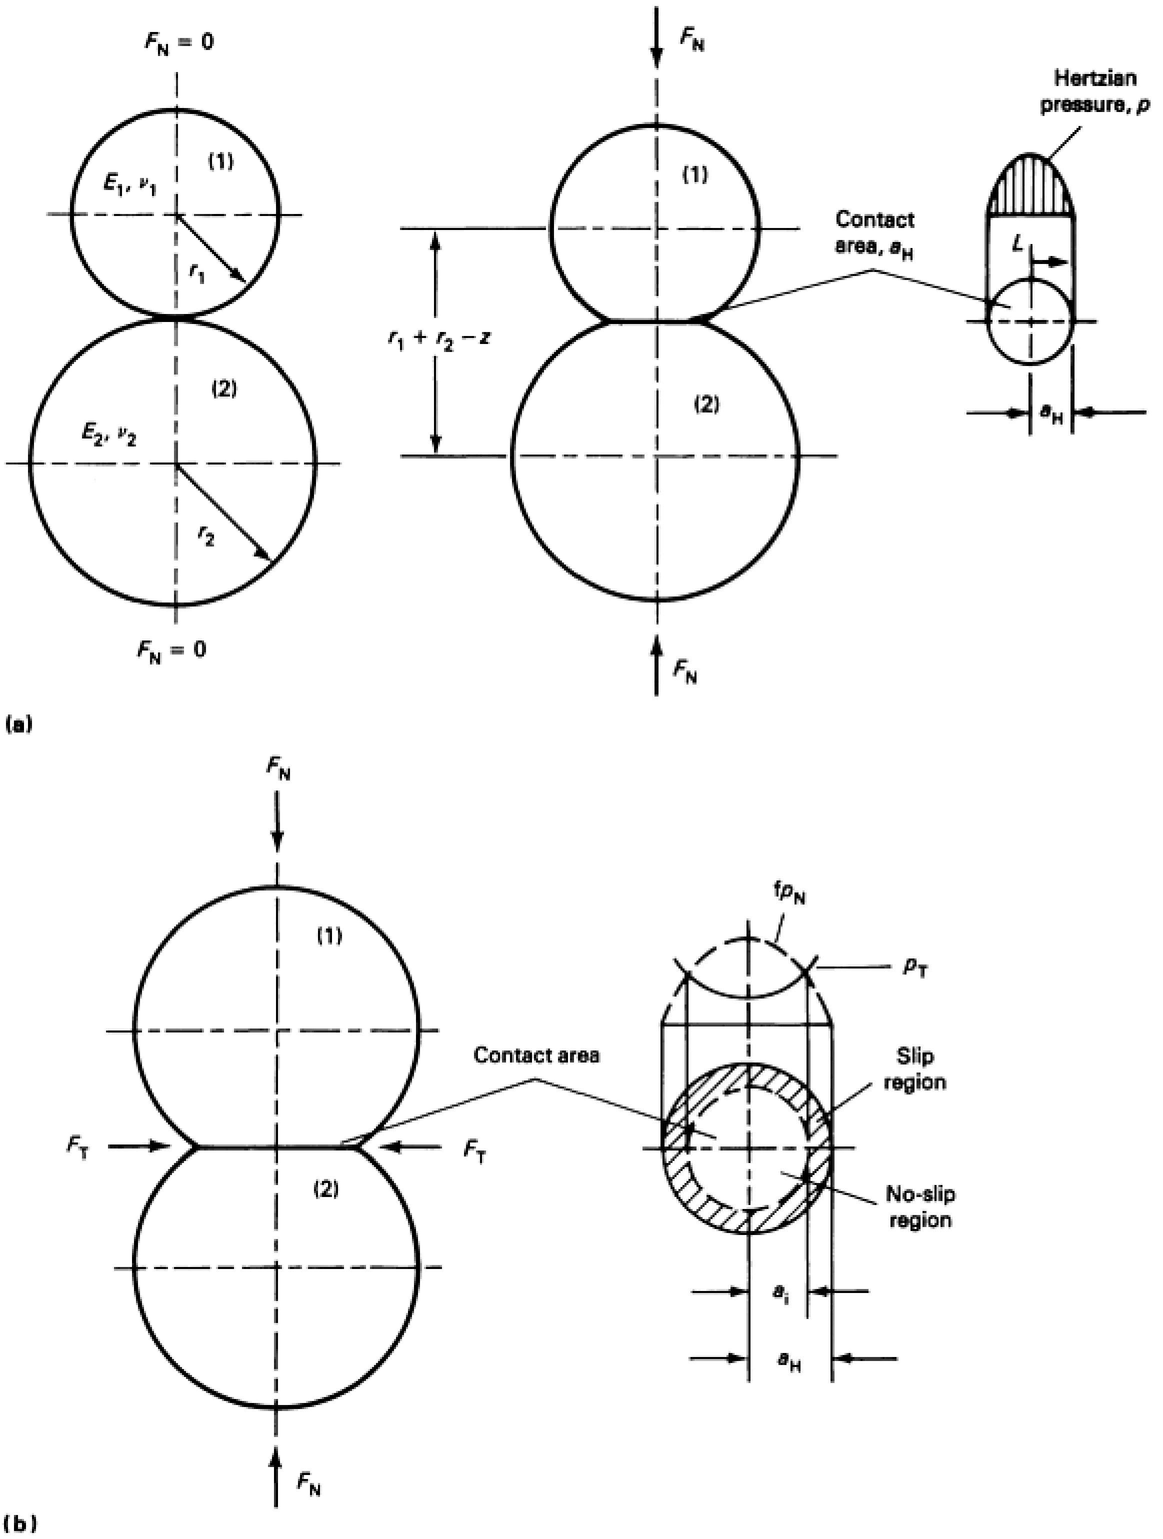

Fig. 5 Hertzian contact between spherical bodies under (a) normal forces and (b) combined normal and tangential forces

If a tangential force $F_T < F_N \cdot f_0$ (where f_0 is the static coefficient of friction) is additionally applied to a static Hertzian contact, slip and no-slip regions within the Hertzian contact area result before a macroscopic horizontal relative motion between body (1) and body (2) occurs. If a_H denotes the radius of the Hertzian contact circle, it follows, according to Mindlin (Ref 9), that no slip occurs within a circle of radius:

$$a_i = a_H \left[1 - \frac{F_N^2}{F_T^2}\right]^{1/3} \quad \textbf{(Eq 6)}$$

whereas in the part of the Hertzian contact zone in which the radius is between a_i and a_H, slip occurs (Fig. 5b).

In the case of macroscopic relative motion, the superposition of normal forces, F_N, and frictional forces $F_F > F_N \cdot f_0$ (perpendicular to F_N) in a tribocontact leads to complex stress distributions in the contacting bodies. The multiaxis stress condition may be converted into a uniaxial tensile stress in such a way that the uniaxial tensile load affects the material to the same extent as the multiaxial stress state. The basic stress hypotheses described below are suggested for tribocontacts such as rolling-element bearings or gears (Ref 10).

Distortion Energy Hypothesis (DEH). The equivalent stress, $\sigma_{E, DEH}$, is obtained by equating the distortion energies for uniaxial and multiaxial loading (Mises criterion):

$$\sigma_{E, DEH} = \frac{1}{2}^{1/2} [(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2]^{1/2} \quad \textbf{(Eq 7)}$$

where $\sigma_1 > \sigma_2 > \sigma_3$ are the principal normal stresses.

The distortion energy hypothesis takes into account how all three differences between the principal stresses influence the initiation of plastic deformation of the material.

Shear Stress Hypothesis (SH). The extent to which the material is stressed is represented by the maximum effective principal shear stresses, T_{max} (Tresca criterion). Using the Mohr notation, the equivalent stresses are given by

$$\sigma_{E, SH} = |\sigma_1 - \sigma_3| = |2\, T_{max}| \quad \textbf{(Eq 8)}$$

where σ_1 and σ_2 are the principal normal stresses.

According to this hypothesis, fatigue occurs due to flow processes in the plane of the maximum principal shear stresses T_{max}, which is located at 45° to the principal stress system.

In addition to the contact pressure distribution of spherical bodies with a circular contact area illustrated in Fig. 5, Fig. 6 shows the contact pressure distribution in an elliptical Hertzian contact of two bodies with curvature in two planes. The resulting principal normal stresses σ_1, σ_2, σ_3 along the *z*-axis (directed into the material) for an axis ratio A/B = 6 are plotted on the left side. The equivalent stresses formed in accordance with the DEH and SH stress hypotheses are shown on the right.

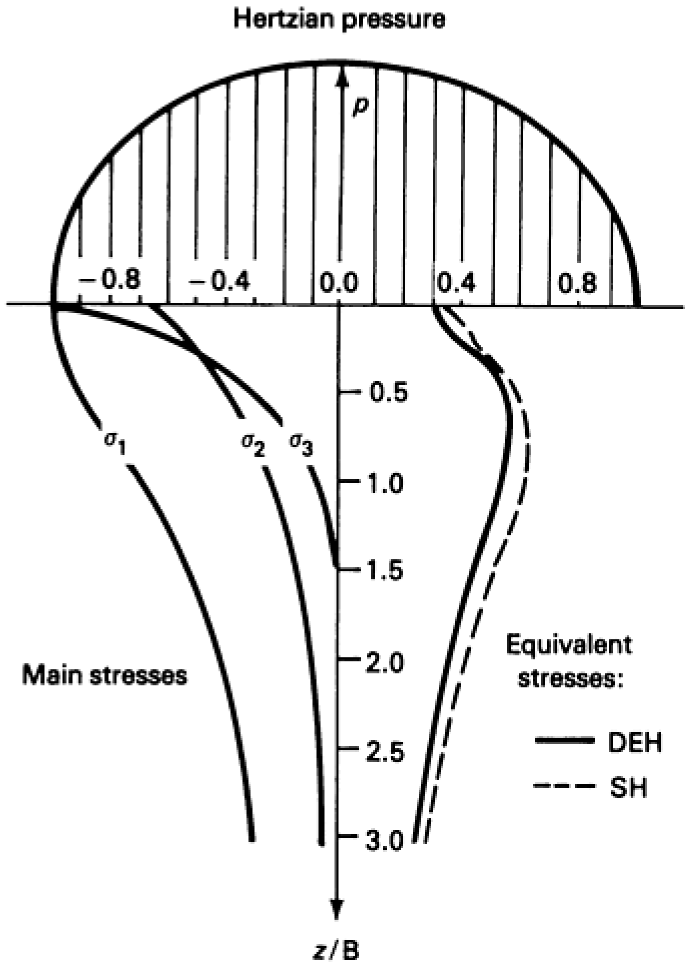

Fig. 6 Material stress for curved surfaces and elliptical contact (A/B = 6)

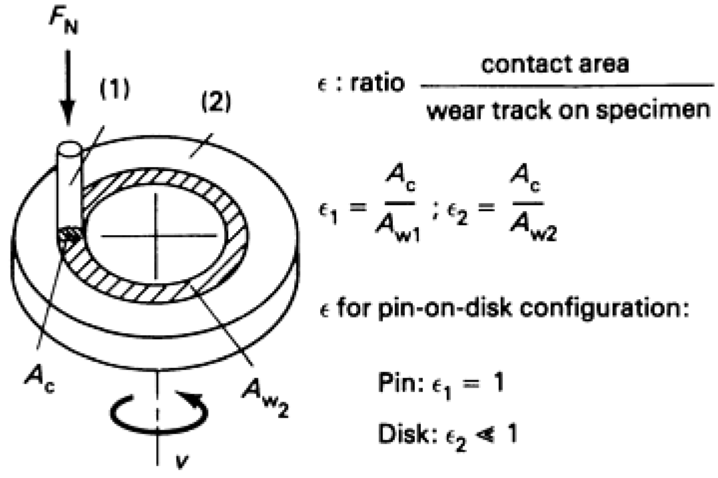
Contact Area/Wear-Track Ratio. The formation of a contact is a necessary condition for all friction and wear processes that occur, by definition, in the momentary contact area A_c. The kinematics and time-dependent variation of the contact area leads to wear tracks (A_{w1}, A_{w2}), which may be different for the tribocomponents (1) and (2) of a given tribosystem. As illustrated in Fig. 7 for the example of a pin-on-disk testing system, a tribocontact parameter, ϵ, can be defined. This tribocontact parameter is also called the contact area/wear-track ratio (Ref 11).



Characteristics of tribocomponents for which $\epsilon = 1$	Characteristics of tribocomponents for which $\epsilon < 1$
Permanent contact	Intermittent contact
No macroscopic cyclic stressing	Cyclic stressing
Permanent friction heating	Intermittent friction heating
Reduced material-atmosphere interactions	Direct material-atmosphere interactions on A_w - A_c

Fig. 7 The tribocontact parameter, ϵ, for a pin-on-disk configuration

If for a given tribosystem, the tribocontact parameters of tribocomponent (1) and tribocomponent (2) are unequal (that is, $\epsilon_1 \neq \epsilon_2$), then the two tribocomponents are subject to different tribological actions with respect to the kinematics, stresses, friction-induced heating, and material-atmosphere interactions as summarized in Fig. 7. It follows that in investigations of tribosystems, the response of both tribocomponents to the interfacial tribological processes must be carefully analyzed. Therefore, the tribocontact parameter plays an important role in the appropriate design of friction and wear test configurations to be used for simulative testing of the components of real triboengineering systems. For example, a material for a certain triboengineering component should only be tested in a test configuration where the materials specimens have the same tribocontact parameter as in the real triboengineering system.

The lubrication modes of tribosystems, consisting of triboelement (1), triboelement (2), and lubricant (3), are determined by structural parameters (for example, elastic moduli, E_1, and E_2, radii of curvature r_1 and r_2, surface roughness R_{a1} and R_{a2}, lubricant viscosity, μ, and the viscosity-pressure coefficient, α) and operational parameters (for example, load, F_N, velocity, v, and bulk oil temperature, T). Three main lubrication regimes can be distinguished by Stribeck curves (Ref 12). Figure 8 shows how lubrication regimes and variations of friction and wear coefficients are functions of the parameter combination $\mu \cdot v \cdot F_N^{-1}$, or the film thickness-to-roughness ratio λ.

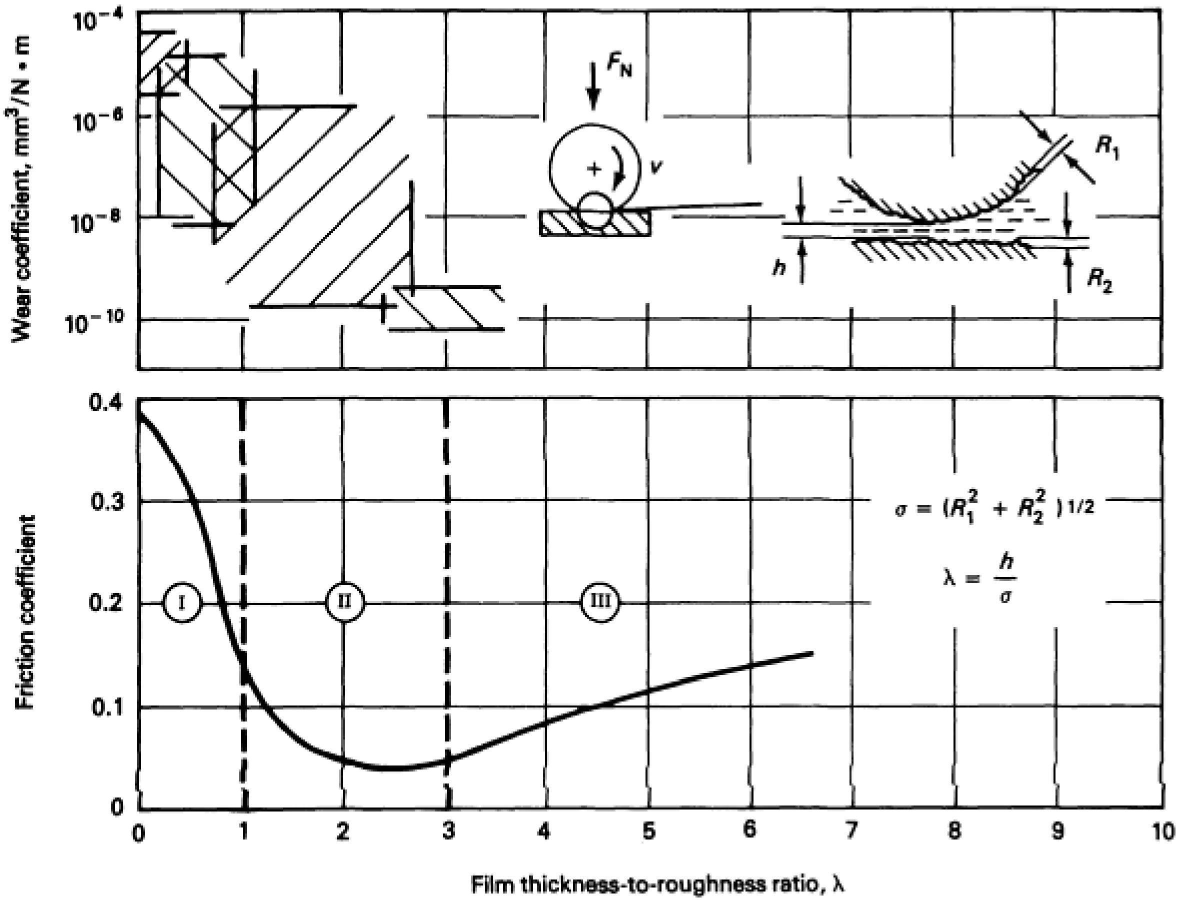


Fig. 8 Lubrication regimes and variations of friction and wear coefficients as functions of the ratio of film thickness to roughness

Regime I: boundary lubrication ($\lambda < 1$). In this regime, the tribological behavior is governed by solid/solid friction and wear processes, influenced by interface physics and chemistry.

Regime II: mixed lubrication or partial elastohydrodynamic (EHD) lubrication ($1 < \lambda < 3$). This regime consists of a dynamic, stochastically distributed coexistence between partial solid/solid asperity contacts and partial lubricant film separations.

Regime III: fluid film lubrication (hydrodynamic or EHD lubrication) ($\lambda > 3$). In this regime, the tribological behavior is determined by the rheology of the lubricant and can be calculated by the methods of fluid mechanics, for example, the Reynolds equation.

The different lubrication regimes are connected with different ranges of friction coefficient and wear coefficient values as illustrated schematically in Fig. 8. Additional information can be found in the article "Lubrication Regimes" in this Volume.

Tribometric Characteristics

Tribometric characteristics are measures of the results of interfacial interactions, that is, tribological processes in tribosystems. Friction and wear can be described phenomenologically by force-related or energy-related parameters with respect to friction, and by geometry-related or matter-related parameters with respect to wear (Ref 13). In addition to the numeric friction and wear parameters defined below, other tribometric characteristics, such as friction-induced noise or vibrations, may also be of interest. Further, the tribological processes as well as changes in the composition and microstructure of the triboelements and the resulting shape and composition of wear surfaces and wear particles must be characterized (see the Sections of this Handbook that deal with laboratory characterization techniques). It is important to

recognize, however, that friction and wear parameters are system-dependent characteristics that must be related to the pertinent tribosystem as described in the article "Presentation of Friction and Wear Data" in this Section.

Friction Parameters. Friction, usually classified as static or dynamic friction, is the resistance to initiate or sustain relative motion of contacting bodies (Fig. 1b). The diagnosis of the relevant parameters shows that depending on the kinematics (Fig. 3), friction can be measured as frictional force, F_F, in sliding and frictional torques, T_{FR} or T_{FSP}, in rolling or spinning, respectively (Ref 14). The static or dynamic sliding friction coefficient, f, is defined as the quotient between the friction force, F_F, to initiate or sustain relative motion tangential to the normal load, F_N, that is, $f = F_F/F_N$. It follows that a rolling friction coefficient and a spin friction coefficient can be defined as the quotient of the friction torque and the normal load times a characteristic radius related to the contact geometry. The frictional work or energy, E_F, with respect to the kinematics (Fig. 3) for sliding, rolling, and spinning, respectively, is given by:

$$E_{FS} = \int_{S_F} F_F \cdot ds_F \qquad \textbf{(Eq 9)}$$

where S_F is the sliding distance,

$$E_{FR} = \int_{\Psi_F} T_{FR} \cdot d\psi_F \qquad \textbf{(Eq 10)}$$

where ψ is the rolling angle, and

$$E_{FSP} = \int_{\Psi_{SP}} T_{FSP} \cdot d\psi_{SP} \qquad \textbf{(Eq 11)}$$

where ψ_{SP} is the spin angle.

In these equations the time dependence of the operational parameters has to be recognized (see the earlier section of this article on "Operational Parameters"). The average frictional power is defined as frictional work or energy divided by the operating duration, t (that is, $P_F = E_F/t$). For sliding friction, $P_F = F_F \cdot v = f \cdot F_N \cdot v$.

Wear Parameters. Wear is the progressive loss of substance from the operating surfaces of the mechanically interacting elements of tribo-systems. As illustrated in a simplified manner in Fig. 9, wear may be measured in terms of:

- *Length,* that is, one-dimensional changes in the geometry of interacting triboelements perpendicular to their common contact area
- *Area,* that is, two-dimensional changes of cross sections of interacting triboelements perpendicular to their common contact area
- *Volume,* that is, three-dimensional changes of geometric regions of interacting triboelements adjacent to their common contact area. Wear volumes are connected via density or specific gravity with wear masses or wear weights

In addition to these quantities, a wear-time ratio may be defined as wear velocity (Ref 15). Other common wear parameters are the wear rate, which is the wear volume per unit of sliding distance, and the wear coefficient, k, which is defined as:

$$k = \frac{W}{F_N \cdot s} \qquad \textbf{(Eq 12)}$$

where W is the wear volume (in mm^3), F_N is the applied load (in Newtons), and s is the sliding distance (in meters).

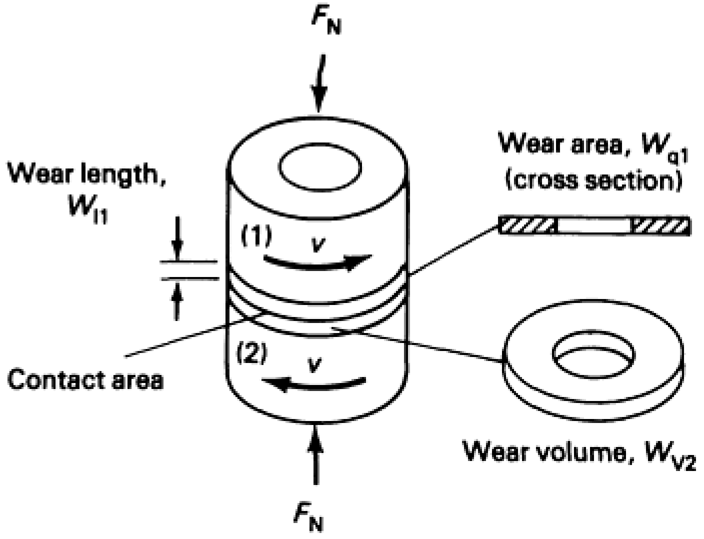

Fig. 9 Wear quantities illustrated for a tribosystem consisting of two sliding cylinders

It should be emphasized that wear quantities must be determined for both components involved in a wear process, that is, triboelement (1) and triboelement (2) of a given (closed) tribosystem.

Data Sheet of Basic Tribological Parameters

The foregoing analysis has shown that the diagnosis of the relevant parameters of tribosystems must recognize

- Structural parameters
- Operational parameters
- Interaction parameters
- Friction and wear parameters

A data sheet containing the main items of these parameter groups is given in Fig. 10. The data sheet, designed primarily for the characterization of closed tribosystems, can serve as a general guide for the compilation of the parameters to be specified individually for a given tribosystem. If necessary, the data sheet can be shortened or extended, but in any case at least the structural tribocomponents (1) to (4) must be identified and characterized and the set of the operational variables (F_N, v, T, t) determined.

Designation of tribo-system:

Fig. 10 Data sheet for determining basic tribological parameters

In summary, the data sheet can support the following tasks:

- Systematic analysis of tribosystems and compilation of relevant parameters
- Guide for the planning and performance of tests or failure analyses
- Documentation of test results
- Input document for tribological databases

Design of Friction and Wear Experiments

Horst Czichos, BAM (Germany)

Introduction

FRICTION AND WEAR EXPERIMENTS must be carefully designed in order to meet the objectives of the tribotesting to be performed. During the design process, the wide variety of (1) tribological phenomena in industrial applications, (2) mechanical engineering equipment, and (3) laboratory studies available for tribotesting must all be considered. Generally speaking, the scope of tribotesting can be classified into the following primary areas:

- Evaluation of the function, performance, maintainability, reliability, life, or efficiency of engineering tribosystems or tribocomponents
- Quality control of tribocomponents
- Characterization of the tribological behavior of materials and lubricants
- Investigation of basic tribological processes and friction-induced energy losses or wear-induced

materials losses

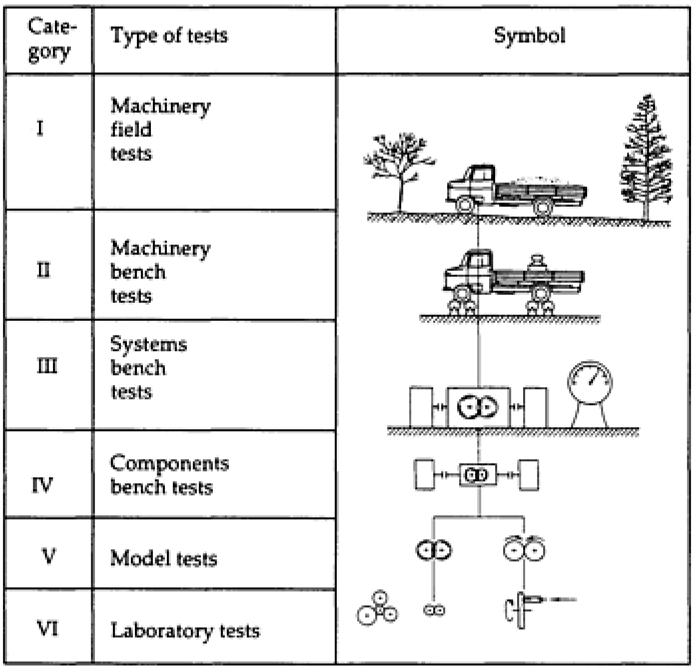
The tribotesting equipment to be used, the test conditions to be specified, and the friction and wear data to be measured must be selected with respect to the aims of tribotesting.

Categories and Conditions of Tribotests

Depending on the structure and function of the tribomachinery, tribosystem, tribocomponent, or specimen to be studied, tribotests can be grouped into six categories (Ref 1). These categories, which are listed in Fig. 1, consist of:

- *Category I: Machinery Field Tests.* Testing of actual tribomachinery under practical operating conditions
- *Category II: Machinery Bench Tests.* Testing of actual tribomachinery under practice-oriented (simplified, simulated, or accelerated) operating conditions
- *Category III: Systems Bench Tests.* Testing of specific tribosystems under practice-oriented operating conditions
- *Category IV: Components Bench Tests.* Testing of specific tribocomponents under practice-oriented operating conditions
- *Category V: Model Tests.* Testing of model test specimens under practice-oriented operating conditions
- *Category VI: Laboratory Tests.* Testing of arbitrary test specimens under laboratory operating conditions

Each tribotesting category has a different scope, and results obtained in one category cannot be simply transferred to another. This is obvious in considering the specific characteristics of the tribotesting categories listed in Fig. 1.



Category	Type of tests	Symbol
I	Machinery field tests	
II	Machinery bench tests	
III	Systems bench tests	
IV	Components bench tests	
V	Model tests	
VI	Laboratory tests	

Fig. 1 Categories of tribotesting

Tests of category I are performed with actual tribomachinery under practical conditions. Clearly, these tests represent the real performance of the object under study. However, full-scale field tests are usually very expensive. The broad

spectrum of the practical operating conditions often cannot be adequately characterized, and considerable efforts are necessary to confirm test results in a statistical manner in repeated tests.

In tests of category II to IV, in which actual tribomachinery, tribosystems, or tribocomponents are studied in well-defined bench tests, test results can be related to the actual triboengineering structures. An important consideration of these tests is the appropriate choice of operating conditions, which may be simplified, simulated, or accelerated as compared with the often unknown broad spectrum of the practical full-scale operating conditions. Sometimes attempts are made to determine the actual operating conditions of the full-scale filed performance with sensors and to simulate these conditions in less expensive bench tests. Because tribotests of categories I to IV differ in scope and testing conditions, the techniques and procedures to be applied for the determination of fraction and wear quantities must be related to the individual tests and cannot be generalized.

In tests of category V, model test specimens are used rather than actual tribocomponents. If an attempt is made to simulate actual triboengineering conditions with these tests, a sufficient similarity in the basic tribological parameters must be realized. These parameters, which were described in the previous article in this Section, include:

- The determination of the physicochemical nature of the model test specimens and the triboengineering system to be simulated (use of the same materials/lubricant/environment combination and connected materials properties)
- Similarity of the contact and lubrication mode (characterized, for example, by the tribocontact) parameter, ϵ, and the film thickness-to-roughness ratio, λ) to be obtained through an appropriate similarity in the kinematics, and the suitable choice of load, F_N, velocity, *v,* temperature, *T,* and test duration, *t,* as described in the article "Basic Tribological Parameters"

To support the appropriate selection of the structural and operational parameters of simulative testing, the characteristics of the actual tribosystem to be simulated should be compiled in a data sheet (see Fig. 10 in the article "Basic Tribologicial Parameters" in this Section), and the test conditions for simulative tests of category V should be selected accordingly.

Tests of category VI are used primarily in fundamental studies of friction and wear processes. The conditions of these tests are often selected to study specific tribological phenomena rather than to simulate real triboengineering behavior.

Laboratory Friction and Wear Tests and Simulative Tribotesting

The basic characteristics and relevant parameters of laboratory and simulative tests are shown in Fig. 2. The design of laboratory friction and wear tests should be carried out in the following steps:

- Choose a suitable test configuration for the test specimens of triboelement (1) and triboelement (2) and specify the geometry of the test configuration, materials characteristics and properties, and surface characteristics (clean surfaces before test)
- Characterize the interfacial element (3) (for example, the lubricant) and the environmental medium or atmosphere (4) in terms of their chemical nature, composition, and chemical and physical properties
- Choose a suitable set of the operational parameters, including type of motion, load (F_N), velocity (v), temperature (T), and test duration (t)
- Perform the tests as functions of varied structural parameters of the triboelements (for example, hardness or roughness) and operational parameters (for example, load cycles or velocity variations). The conditions of the tests, such as the time dependence of operational parameters, should be controlled by appropriate detectors or sensors and supported by on-line computer techniques
- Measure interesting tribometric characteristics, such as friction quantities, wear quantities, tribo-induced acoustic quantities (for example, noise or vibrations), and tribo-induced thermal quantities (for example, friction-induced temperature rise)
- Characterize the worn surfaces of triboelement (1) and triboelement (2) with respect to surface roughness and surface composition and structure

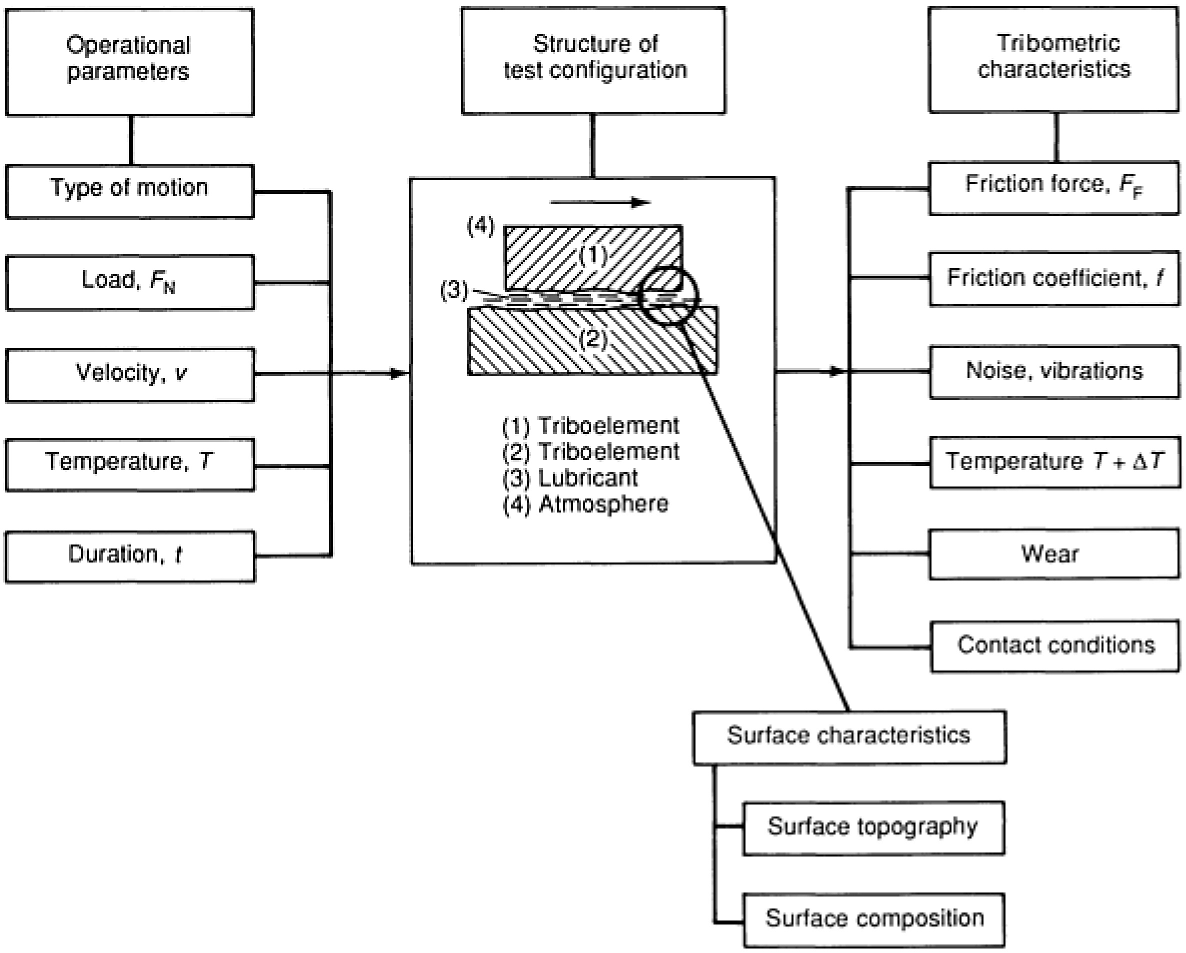


Fig. 2 Basic characteristics and parameters relevant to laboratory tribotesting

The results of laboratory tribotests, that is, the measured friction and wear quantities, can be symbolically represented by:

friction, wear = *f* (structural and operational parameters)

If an attempt is made to simulate the tribological behavior of a practical engineering tribosystem (TS) with a laboratory test configuration (TC), a sufficient similarity between the structural, operational, and interaction parameters of TC and TS must be reached. Figures 3(a), 3(b), 3(c), 3(d), and 3(e) show a series of tribotest flow charts used to support simulative tribotesting in the following steps:

- Selection of test configuration and structural parameters of test specimens (Fig. 3(a))
- Specification of operational parameters and specimen properties (Fig. 3(b))
- Tribotesting under unlubricated conditions (Fig. 3(c))
- Tribotesting under fluid-film lubrication (Fig. 3(d))
- Tribotesting under mixed or boundary lubrication (Fig. 3(e))

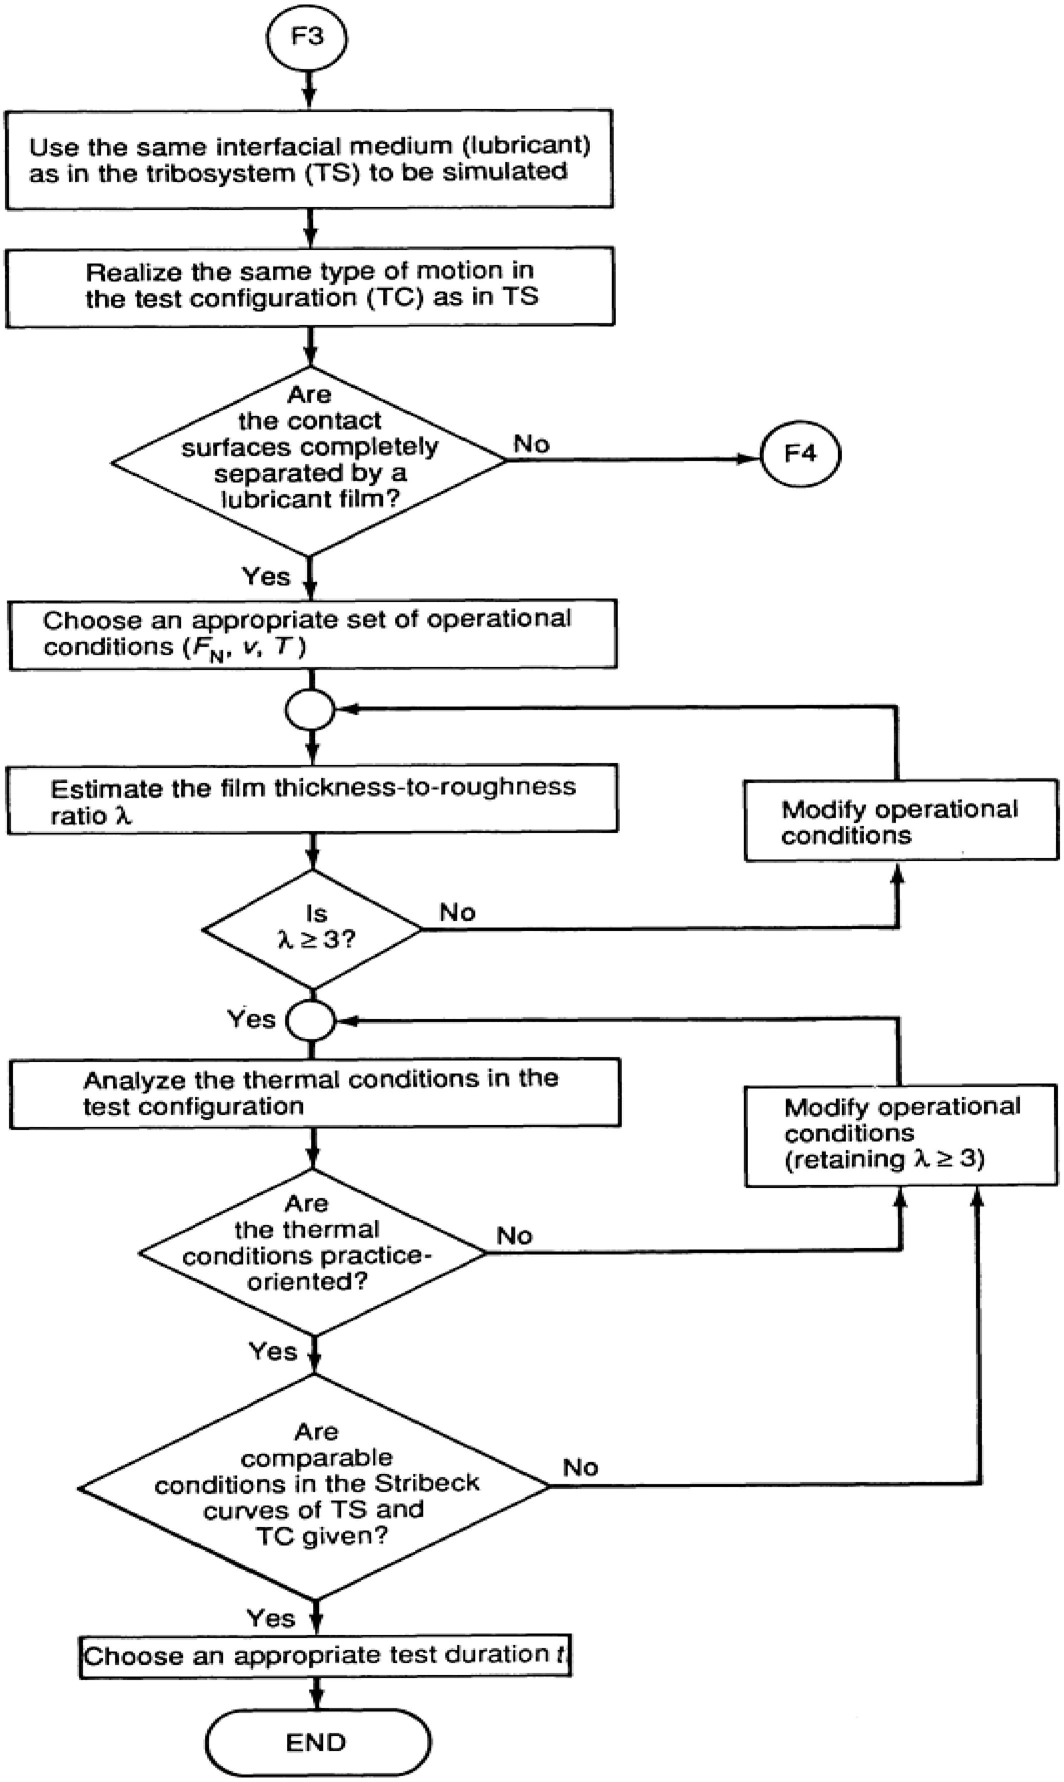

Fig. 3(d) Tribotest flow chart for testing under fluid-film lubrication

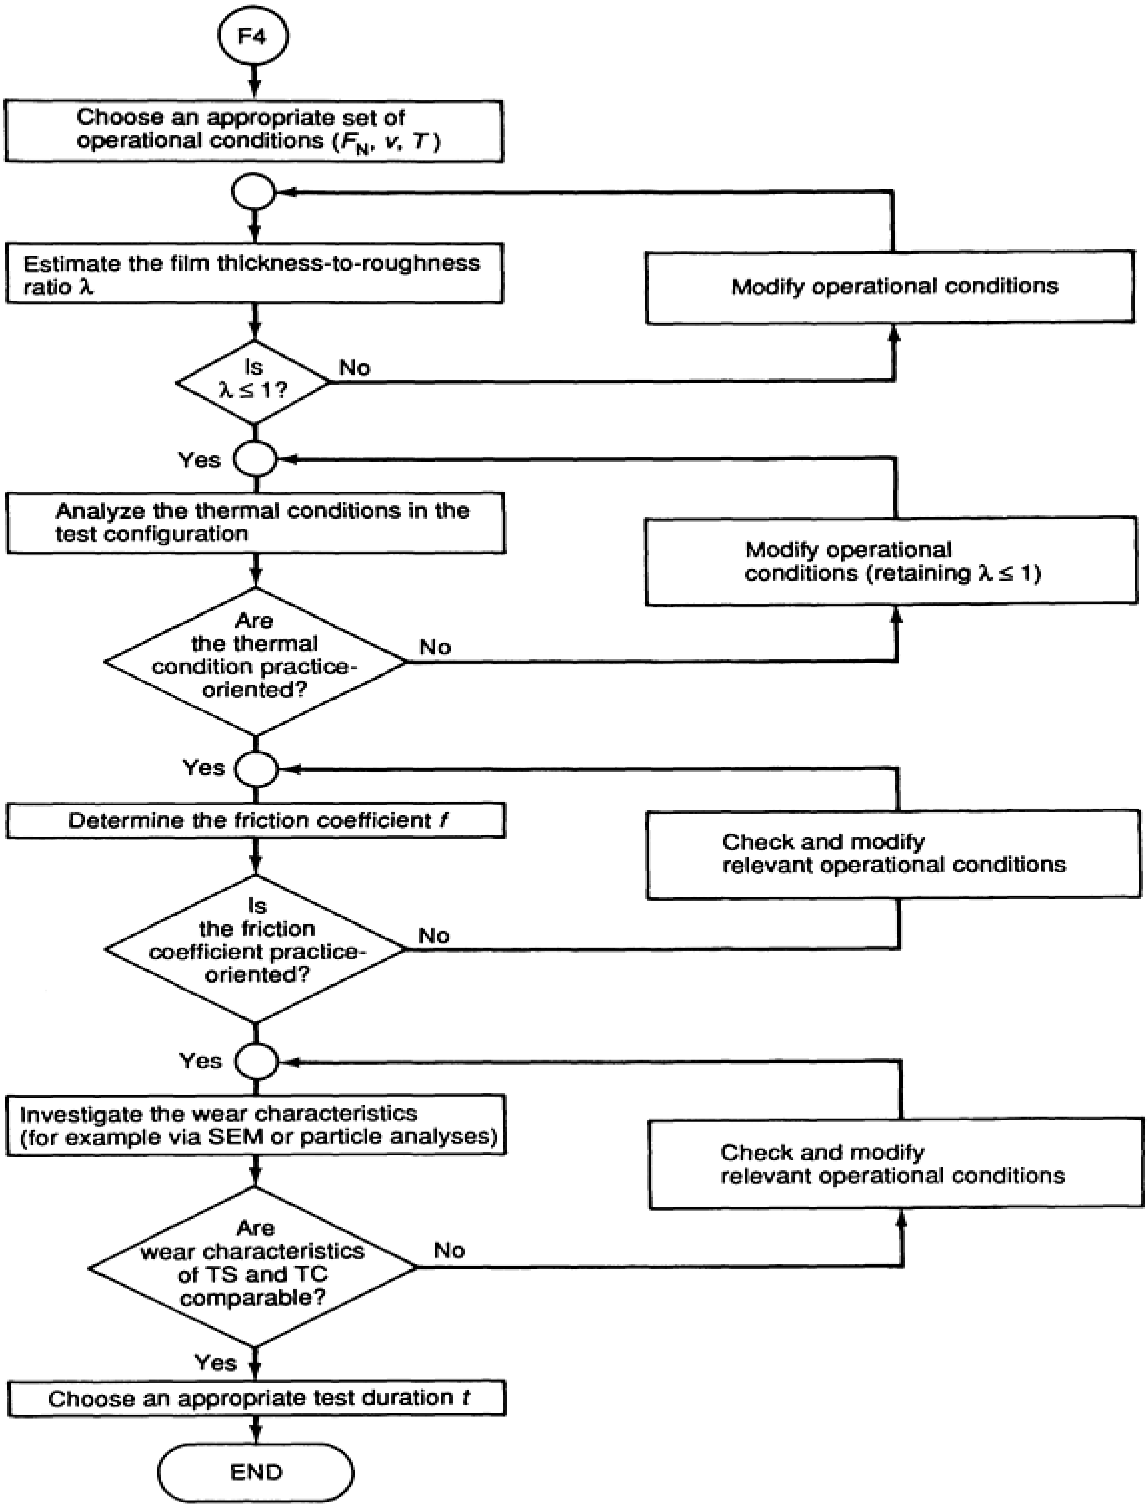

Fig. 3(e) Tribotest flow chart for testing under mixed or boundary lubrication

Evaluation of Tribotests

One of the primary problems in the evaluation of friction and wear data is coping with variability. Variability is inherent in every tribological process because of the great number of influencing parameters, their potential fluctuations, and time dependencies. Generally speaking, there are systematic deviations (bias) and random deviations to be considered in the evaluation of experimentally measured data. The two statistics most commonly used to characterize measured friction and wear data are the mean and the standard deviation (Ref 2). If y_1, y_2,. . ., y_n, are denoted the n individual observations of a random sample from a tribotest, the mean ($\bar{y}$) and standard deviation (s) are defined as follows:

$$\bar{y} = \sum_{i=1}^{n} y_i/n \qquad \textbf{(Eq 1)}$$

$$s = \sqrt{\frac{\sum_{i=1}^{n} (y_i - \bar{y})^2}{n-1}} = \sqrt{\frac{\sum y_i^2 - \left(\sum y_i\right)^2/n}{n-1}} \qquad \textbf{(Eq 2)}$$

While the mean characterizes the location of the observed values on a corresponding scale, the standard deviation gives a measure of how the *n* observations vary or spread about the average. The square of the standard deviation is called variance.

Recall that $\bar{y}$ and *s* can be computed for a sample of *n* observations. Therefore, call $\bar{y}$ and *s* sample parameters the sample mean and sample standard deviation. It is important to note that these parameters can be understood as estimates of "ideal" parameters which are characteristics of an assumed population of observations or, in other words, a random variable, *n*, realizations of which form the sample of observations under consideration. Call the corresponding parameters population parameters, or more precisely, population mean and population standard deviation, and, denote them μ and σ, respectively. It is then well known that a sample parameter approximates the corresponding population parameter if *n* increases.

Let *y* be a sample mean and *s* a sample standard deviation obtained from *n* measurements of a tribological quantity. Assume that the distribution of the corresponding population is approximately normal. One can then specify a confidence interval for the population parameter μ, that is, an interval that contains μ with a given confidence level 1 - α, and a certain probability, *p* (for example, $\alpha = 0.05$ and $1 - \alpha = p = 0.95$) by:

$$\bar{y} - \frac{t \cdot s}{\sqrt{n}} \leq \mu \leq \bar{y} + \frac{t \cdot s}{\sqrt{n}} \qquad \textbf{(Eq 3)}$$

The values of *t* (depending on the number of measurements *n* and the confidence level 1 - α) can be taken from Table 1. It follows that the evaluation of tribotests may lead to the following results:

$$\text{Measurand} = \bar{y} \pm \frac{t \cdot s}{\sqrt{n}} \qquad \textbf{(Eq 4)}$$

where $\bar{y}$ and *s* are the sample parameters of a sample of *n* individual measurements of a friction or wear quantity.

Table 1 Chart of *t* values (*n* number of individual observations, 1 - α confidence level)

n	$\alpha = 0.10$ $t_{0.10}$	$\alpha = 0.05$ $t_{0.05}$	$\alpha = 0.01$ $t_{0.01}$
3	2.920	4.303	9.925
5	2.132	2.776	4.604
7	1.943	2.447	3.707
10	1.833	2.262	3.250
15	1.761	2.145	2.977

20	1.729	2.093	2.861
25	1.711	2.064	2.797
30	1.699	2.045	2.756
40	1.695	2.021	2.704
60	1.672	2.000	2.660
120	1.658	1.980	2.617
∞	1.645	1.960	2.576

In a similar manner, a confidence interval can be obtained for the population standard deviation σ:

$$s \cdot \sqrt{n-1} / \sqrt{\chi^2_{1-\alpha/2}} < \sigma < s \cdot \sqrt{n-1} / \sqrt{\chi^2_{\alpha/2}} \quad \textbf{(Eq 5)}$$

where the values of χ^2 (depending on *n* - 1 and α) can be taken from the χ^2 distribution (Table 2).

Table 2 Chart of x^2 values (*n* number of individual observations, 1 - αconfidence level)

n	α= 0.10		α= 0.05		α= 0.01	
	$\chi^2_{1-\alpha/2}$	$\chi^2_{\alpha/2}$	$\chi^2_{1-\alpha/2}$	$\chi^2_{\alpha/2}$	$\chi^2_{1-\alpha/2}$	$\chi^2_{\alpha/2}$
3	5.991	0.103	7.378	0.051	10.597	0.010

40	54.572	25.695	58.120	23.654	65.476	19.996
60	77.931	42.339	82.117	39.662	90.715	34.770

Design of Experiments

Mathematical models, computer simulations, and statistical techniques are of fundamental importance for the appropriate design of experiments. Because detailed information on the tools used to design experiments is beyond the scope of this article, only a minimum of approaches will be outlined. For a more extensive treatment of the design and analysis of experiments, the reader is referred to Ref 3 and 4.

One-at-a-Time Approach. In the conventional approach to model or laboratory tribotesting, one quantity (*y*), for example, a friction quantity or a wear quantity, is measured as a function of only one independent variable (x_1) to be selected out of the following three categories: (1) test duration, *t*, (2) an operational variable (for example, load), or (3) a structural variable (for example, material hardness), where all other parameters and conditions are kept constant. In varying the values of the independent variable (x_1), a relationship of the form $y = f(x_1)$ is obtained. In a second test, the dependence of the measured quantity (*y*) on another independent variable (x_2) may be determined. The results of both tests can be jointly represented as a three-dimensional $y = f(x_1,x_2)$ graph.

An advantage of such one-at-a-time experiments is that the influence of single independent variables on the measured quantity can be clearly understood. However, a large number of experiments are necessary to determine the simultaneous influence of more than one variable on the measured quantity. For example, 24 experiments were needed to show the influence of the basic set of operating variables (pressure *p*, velocity *v*, temperature *T*) on the friction coefficient of a dry sliding polytetrafluoroethylene (PTFE)/materials pair, as shown in Fig. 4 (Ref 5).

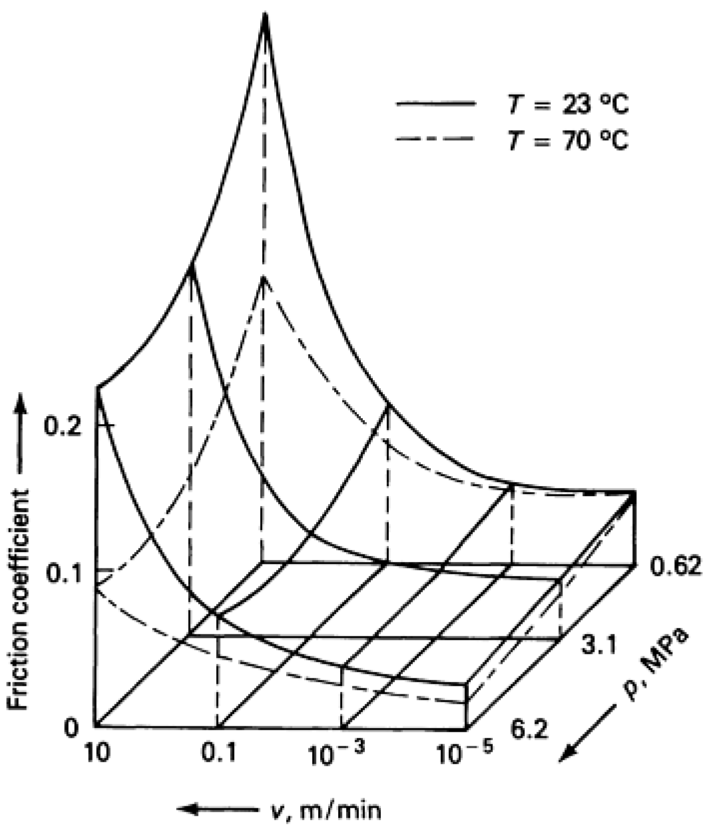

Fig. 4 Friction coefficient of PTFE/steel (AISI 52100, 800 HV, R_a = 0.02 μm) as a function of pressure (*p*), sliding velocity, (*v*), and temperature (*T*)

Simple Complete Factorials Approach. A complete factorial is a design of experiments in which a measured quantity is determined under the full set of combinations of the levels of all factors, that is, the variables included (Ref 4). It allows an assessment of the main effects of the single factors and the interaction effects of all factors. Although this method is based on the assumption of a linear dependence between the measured quantity and each of the independent variables, it may also serve as an approximative technique for nonlinear conditions as in tribology (Ref 6). The approach of the complete factorial design of experiments will be explained below by using data obtained in the example of tribotesting shown in Fig. 4.

The aim is to assess the main effects and the interaction effects of the three operational variables (pressure *p*, velocity *v*, and temperature *T*), each at two levels (denoted as high, h and low 1), on the measured friction coefficient *f*. The design is called a 2^3 factorial, and the eight operating variable combinations can be displayed graphically as a cube (Fig. 5). The values of the friction coefficient measured in the eight tests are listed in Table 3. The average value of the friction coefficient is:

$$\bar{f} = (0.05 + 0.03 + 0.36 + 0.22 + 0.05 + 0.02 + 0.18 + 0.09)/8 = 0.125 \quad \textbf{(Eq 6)}$$

Table 3 Test conditions and measured friction data

No. of test	Level of (*pvT*)	Pressure (*p*), MPa	Velocity (*v*), m/min	Temperature (*T*), °C	Friction coefficient (*f*)
1	(lll)	0.62	10^{-5}	23	0.05
2	(hll)	6.2	10^{-5}	23	0.03
3	(lhl)	0.62	10	23	0.36
4	(hhl)	6.2	10	23	0.22
5	(llh)	0.62	10^{-5}	70	0.05

6	(hlh)	6.2	10^{-5}	70	0.02
7	(lhh)	0.62	10	70	0.18
8	(hhh)	6.2	10	70	0.09

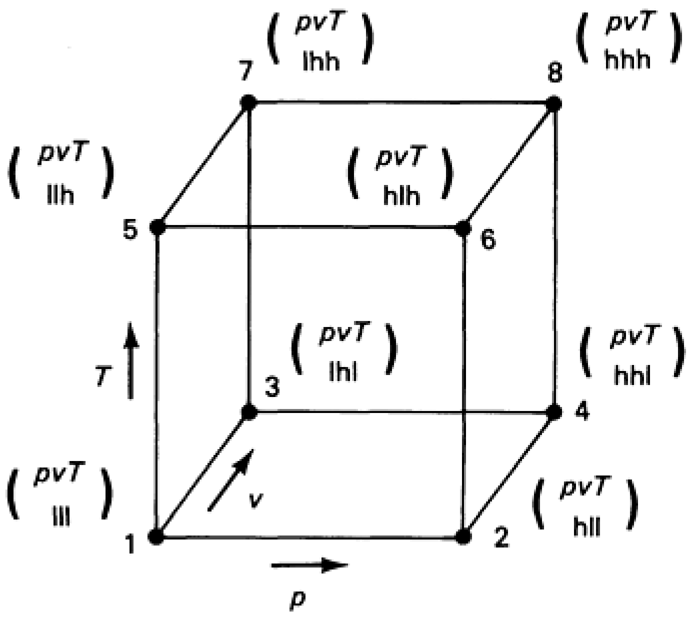

Fig. 5 Geometrical representation of the operating conditions of a 2^3 factorial design

By using the eight treatment combinations, the corresponding measured values of *f,* and the main effects of pressure, velocity, and temperature *T,* the two-factor interactions *pv, pT, vT* and the three-factor interaction *pvT* can be estimated using the data in Table 3.

Effect of Pressure. The effect of *p* when *v* and *T* are at low levels is (2 - 1) as shown in Fig. 5. Similarly, the effect of *p* when *v* is at the high level and *T* is at the low level is (4 - 3).

The effect of *p* when *T* is at the high level and *v* is at the low level is (6 - 5). Finally, the effect of *p* when both *v* and *T* are at the high level is (8 - 7).

Thus, the average effect of *p* is the average of these four combinations, or:

$$\Delta f(p) = (2 - 1 + 4 - 3 + 6 - 5 + 8 - 7)/4 \quad \textbf{(Eq 7)}$$

Equation 7 can be developed as a contrast between the four treatment combinations in the right face of the cube of Fig. 5 (where *p* is at the high level) and the four in the left face (where *p* is at the low level). Combining these gives:

$$\Delta f(p) = (2 + 4 + 6 + 8 - 1 - 3 - 5 - 7)/4$$
$$\Delta f(p) = -0.070 \quad \textbf{(Eq 8)}$$

which means that an increase of the contact pressure in this example lowers the average friction coefficient.

The effect of velocity v is a contrast between the four treatment combinations in the front face of the cube in Fig. 5 and the four in the back. This yields:

$$\Delta f(v) = (3 + 4 + 7 + 8 - 1 - 2 - 5 - 6)/4$$
$$\Delta f(v) = +0.175 \quad \textbf{(Eq 9)}$$

which means that an increase of the velocity increases the average friction coefficient considerably.

The effect of temperature T is a contrast between the four treatment combinations in the top face of the cube in Fig. 5 and the four in the bottom, that is:

$$\Delta f(T) = (5 + 6 + 7 + 8 - 1 - 2 - 3 - 4)/4$$
$$\Delta f(T) = -0.08 \qquad \textbf{(Eq 10)}$$

which means that an increase in the temperature lowers the average friction coefficient (similar to an increase of *p*).

Interaction Effects of Pressure, Velocity, and Temperature. When *T* is at the low level, the effect of the *pv* interaction is the average difference in the *p* effect at the two levels of *v*, that is, [(4 - 3) - (2 - 1)]/2. When *T* is at the high level, the *pv* interaction is [(8 - 7) - (6 - 5)]/2. The average *pv* effect is the average of these two combinations, or:

$$\Delta f(p,v) = (4 - 3 - 2 + 1 + 8 - 7 - 6 + 5)/4$$
$$\Delta f(p,v) = -0.045 \qquad \textbf{(Eq 11)}$$

which shows that the additional influence of *v* weakens the effect of *p* as discussed above in the description of effect of pressure.

The average effects of *pT* and *vT* are:

$$\Delta f(p,T) = (1 - 2 + 3 - 4 - 5 + 6 - 7 + 8)/4$$
$$\Delta f(p,T) = +0.01$$
$$\Delta f(v,T) = (1 + 2 - 3 - 4 - 5 - 6 + 7 + 8)/4$$
$$\Delta f(v,T) = -0.075 \qquad \textbf{(Eq 12)}$$

Equation 12 indicates that the combined effects of *p* and *T* in this example are almost negligible, whereas the effect of *T* at the two levels of *v* leads to a considerable decrease of the friction coefficient.

The *pvT* effect is defined as the average difference between the *pv* interaction for the two different levels of *T*. Thus:

$$\Delta f(p,v,T) = (8 - 7 - 6 + 5 - 4 + 3 + 2 - 1)/4$$
$$\Delta f(p,v,T) = +0.015 \qquad \textbf{(Eq 13)}$$

This combined effect can be neglected.

Summarizing the steps illustrated in the above discussion, a 2^3 factorial design, with 8 experiments to be performed, can be used to determine the effect of three independent variables (x_1, x_2, x_3), each at two levels, on a measured quantity *y* in tribotesting. Table 4 summarizes the results of the example discussed above, allowing an assessment of the main effects $\Delta f(p)$, $\Delta f(v)$, $\Delta f(T)$, and of the interaction effects $\Delta f(p,v)$, $\Delta f(p,T)$, $\Delta f(v,T)$, $\Delta f(p,v,T)$ on the coefficient of friction. Extended tables for more than three independent variables, or variation of these variables at more than two levels, can be designed accordingly (Ref 7, 8).

Round-Robin Tests

Terminology. The following qualitative terms (Ref 9) are of key relevance for the planning and evaluation of round-robin tests. More detailed information on the quantitative aspects of round-robin tests can be found in Ref 10, 11, 12.

Precision is a general term for the closeness of agreement between randomly selected individual measurements or test results. The standard deviation of the error of measurement may be used as a measure of "imprecision."

Repeatability is the closeness of agreement between mutually independent replicate test results obtained with the same test method on identical test materials, under the same conditions (that is, the same operator, laboratory, apparatus, and time).

Reproducibility is the closeness of agreement between replicate test results obtained with the same test method on identical test materials but under different conditions (that is, different operator, laboratory, apparatus, or time).

General Rules for Round-Robin Tests. A standard practice for conducting an interlaboratory study to determine the precision of a test method is given in ASTM E 691 (Ref 11). The general rules for the planning of round-robin tests are described in Ref 10. According to these standards, the aspects listed below are of key importance for the performance of round-robin tests.

Scope of the Tests. The goals to be reached during the round-robin tests should be determined from the outset.

Planning and Organization of the Tests. All participating partners should be informed of the scope of the test. Personnel for the test should include a coordinator of the entire test, a statistician for the planning and evaluation, and operators for the performance of the tests.

Guiding the Performance of the Tests. A clear description of the test method to be applied, the characterization of test materials, the test conditions, the variables to be varied, the quantities to be measured, and the number of repeated tests to be performed must be given. In addition, the format of compiling and describing the obtained results is to be specified.

Analyzing the Test Results. The specimens should be carefully selected, prepared, and characterized for the tests. The quantities to be measured and the format of reporting the measured data must be specified. For the analysis and evaluation of the test results as part of the standard round-robin test procedure, well-defined statistical techniques must be applied.

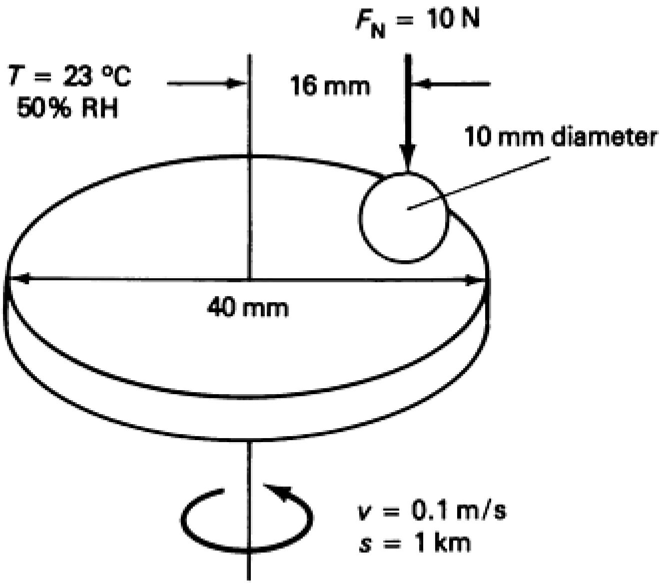
Case Study: International Round-Robin Sliding Wear Tests. An international round-robin comparison on the comparability, repeatability, and reproducibility of friction and wear tests has been performed within the framework of the Versailles Project on Advanced Materials and Standards (VAMAS) (Ref 13). Under the guidance of an international

committee on wear test methods, round-robin studies with α-Al_2O_3 ceramic and steel specimens were performed with 31 participating institutions from seven countries.

For the sake of simplicity, a ball-on-disk specimen configuration was selected as the test system. The test specimens were uniformly manufactured with respect to their geometry, dimensions, and surface finish. The conditions outlined below were specified on the basis of a thorough systems analysis of the main relevant characteristics of the tribotesters.

Test System. Conditions for the test system, which featured the ball-on-disk configuration shown in Fig. 6, were as follows:

- Stationary ball (10 mm, or 0.4 in., in diameter) against rotating disk (40 mm, or 1.6 in., in outer diameter and 32 mm, or 1.3 in., in track diameter)
- Rotation in the horizontal plane
- Direction of rotation of disk to be indicated by each laboratory
- Ball, disk, and debris to be collected and protectively stored in plastic containers
- Holders for disk and ball are left to the discretion of each laboratory
- Participants were asked to report (if possible) vibrations (for example, vibration amplitudes and frequency distribution) of the test rig at the stated location
- Participants were asked to report (if available) the stiffness data of the test rig



Material pairings			Measurements
Disk \ Ball	Steel	Alumina	• Friction force
Steel	Kit 1	Kit 2	• Wear (system, ball, disk)
Alumina	Kit 3	Kit 4	• Wear surfaces (SEM, profilometry)

Fig. 6 Conditions of VAMAS round-robin sliding wear tests. F_N, normal load; *v*, sliding velocity; *s*, sliding distance; *T*, ambient temperature; RH, relative humidity of the atmosphere

Materials used during the tests included an α-Al_2O_3 ceramic and AISI 52100 steel. The composition, roughness, hardness, and microstructure data were provided to each test participant.

Atmosphere. Laboratory air with a relative humidity (RH) of 50 ± 10% and a temperature of 23 ± 1 °C (73 ± 2 °F) was to be used.

Lubricant. No lubricant was to be used in the round-robin tests.

Operating variables included:

- Motion, continuous unidirectional sliding
- Normal load, F_N = 10 N (2.25 lbf)
- Sliding velocity, v = 0.1 m/s (0.33 ft/s)
- Temperature, T = 23 ± 1 °C (73 ± 2 °F)
- Sliding distance, s = 1 km (0.62 mile)
- Number of tests, 3 to 5

Preparation of Surfaces. Specimens were to be used in the as-received condition, that is, no mechanical surface finishing by the participants was necessary because specimens were centrally prepared in a uniform manner prior to distribution

Surfaces were cleaned immediately prior to each test. Washing in freon ($Cl_2FC\text{-}CF_2Cl$) was preferred to washing in ethyl alcohol since the water content in the alcohol could corrode the metallic surfaces. Following washing, the specimens were dried in warm air, rinsed with hexane, and re-dried in a drying oven at 110 °C (230 °F) for 30 min.

In addition, only chemicals of pure quality were to be used and samples had to be stored and transported in desiccators.

Wear and Friction Measurements. For wear measurements, each participant was asked to indicate whether wear of ball, wear of disk, or total wear of both ball and disk were measured. Participants were also required to continuously measure and record linear wear, to weigh specimens before and after each test, to measure the wear scar diameter on the ball with an optical microscope, and to provide profilogram results of both surfaces before and after the test.

Similarly for friction measurements, each participant was asked to indicate whether the frictional force or the friction torque were measured. They were also required to submit a simplified graph giving the fluctuations at the beginning and the end of the test, as well as minimum and maximum deviations during the test.

For both wear and friction measurements, all debris was collected.

Examination. Surfaces and debris were to be examined by optical color photography and scanning electron microscopy techniques. All photomicrographs had to be supplied at the standard magnifications of 50×, 100×, 200×, 500×, and 1000×.

A detailed instruction sheet containing the above points and specimen pairings ready to be tested were sent from a central source to all participants.

Data Evaluation. For the evaluation of numeric friction and wear data, the results of the participating laboratories were treated in the following manner to obtain statistically sound data.

Only the results of laboratories that performed more than one test run per specimen kit were considered. If laboratories reported only average values (as estimated by themselves from repeated test runs) these values were treated as if obtained from three measurements.

From the results obtained from the participating laboratories, the following four types of numeric data were determined:

- The friction coefficient was determined after a sliding distance of 1000 m (3300 ft)
- The wear rate of the system was measured under steady-state conditions, that is, the displacement of the test specimens perpendicular to the sliding interface between 300 and 1000 m (1000 and 3300 ft) sliding distance divided by the sliding distance. It should be noted that this is a geometry-dependent quantity

that cannot be compared directly with the wear rates of other test systems

- The ball wear scar diameter
- The disk wear-track width. From the numeric data of the four quantities (friction coefficient, wear rate, ball wear scar diameter, and disk wear-track width), the mean values and the standard deviations for the different material pairings were calculated (Table 5)

Table 5 Results of the VAMAS round-robin sliding wear tests.

See Fig. 6 for test conditions.

	Kit 1 Steel-steel	Kit 2 Ceramic-steel	Kit 3 Steel-ceramic	Kit 4 Ceramic-ceramic

Number of laboratories	. . .	19	. . .	. . .

(a) At 1000 m sliding distance.

(b) Determined from the wear curve (steady-state range between 300 and 1000 m sliding distance).

(c) Material transfer from disk to ball.

(d) Material transfer from ball to disk.

A comparison of the reported data showed that all the laboratories were able to perform the tests under the specified operating conditions of load, velocity, and ambient temperature. However, the values of the relative humidity of the ambient atmosphere varied between 13% and 78% and less than half of the participating laboratories were able to keep the operating conditions within the specified range of 50 ± 10% RH.

The results of the VAMAS round-robin comparison show that good reproducibility for the numeric friction and wear data was obtained. These data can be summarized in terms of the relative standard deviations (s_r and s_R according to ASTM Standard E 691 divided by the mean value) as follows (Ref 13):

- Reproducibility of friction data: within laboratories ±9% to ±13%; interlaboratory, ±18% to ±20%
- Reproducibility of specimen wear data: within laboratories, ±5% to ±7%; interlaboratory, ±15% to ±20%
- Reproducibility of systems wear data: within laboratories, ±14%; interlaboratory, ±29% to ±38%

These results indicate that the reproducibility of friction and wear measurements is comparable with that of other engineering quantities, provided that the tests are performed under well-controlled conditions, applying standard round-robin test procedures.

Appendix: Calculations of Elastic Contact Dimensions and Stresses (Ref 14)

Peter J. Blau, Oak Ridge National Laboratory

General parameters used to calculate the elastic contact dimension and the stress of nonconforming surfaces are given in Table 6. The relation of these variables to specific contact geometries (Fig. 7) is given in Table 7.

Table 6 Elastic contact and stress nomenclature

Symbol	Definition
P	Normal force (load)
p	Normal force (load) per unit contact length
E_1	Modulus of elasticity (Young's modulus) for body 1
E_2	Modulus of elasticity (Young's modulus) for body 2
v_1	Poisson's ratio for body 1
v_2	Poisson's ratio for body 2
D	Diameter when only one body in the contact is curved
D_1	Diameter of body 1 (in the case of two curved bodies, by convention $D_1 > D_2$)
S_c	Maximum compressive stress (Hertzian stress)
a	Radius of the elastic, circular contact
b	Width of the contact (used for cylinders)
c	Semimajor axis of an elliptical contact area (used for crossed-cylinders)
d	Semiminor axis of an elliptical contact area (used for crossed-cylinders)
α	Geometric factor used in crossed-cylinders calculations
β	Geometric factor used in crossed-cylinders calculations

Table 7 Formulas for calculating elastic contact dimensions and stresses of contact geometries shown in Fig. 7

Geometry of the contact	Elastic contact dimension[(a)]	Maximum compressive stress
Sphere-on-flat	$a = 0.721\ ^3\sqrt{PDC_0}$	$S_c = 0.918\ ^3\sqrt{P/(D^2C_0^2)}$
Cylinder-on-flat	$b = 1.6\ \sqrt{pDC_0}$	$S_c = 0.798\ \sqrt{p/(DC_0)}$
Cylinder-on-cylinder (parallel axes)	$b = 1.6\ \sqrt{pC_0/\mathrm{A}}$	$S_c = 0.798\ \sqrt{(pA)/C_0}$
Ball-in-spherical socket	$a = 0.721^3\ \sqrt{(PC_0)/B}$	$S_c = 0.918\ ^3\sqrt{P(B/C_0)^2}$
Cylinder-in-a-circular groove	$b = 1.6\ \sqrt{(pC_0)/B}$	$S_c = 0.798\ \sqrt{(pB)/\mathrm{C}_0)}$
Crossed-cylinders[(b)] (axes perpendicular)	$c = \alpha^3\sqrt{(PC_0)/A}$ $d = \beta_c$	$S_c = 0.4775\ (P/cd)$

(a) $C_0 = [(1 - v_1^2)/E_1] + [(1 - v_2^2)/E_2)$; $A = [(D_1 + D_2)/D_1D_2]$; $B = [(D_1 - D_2)/D_1D_2]$.

(b) To determine the values of α and β, first divide the larger diameter by the smaller to obtain a diameter ratio, then use Fig. 8 to determine the appropriate values for the two constants.

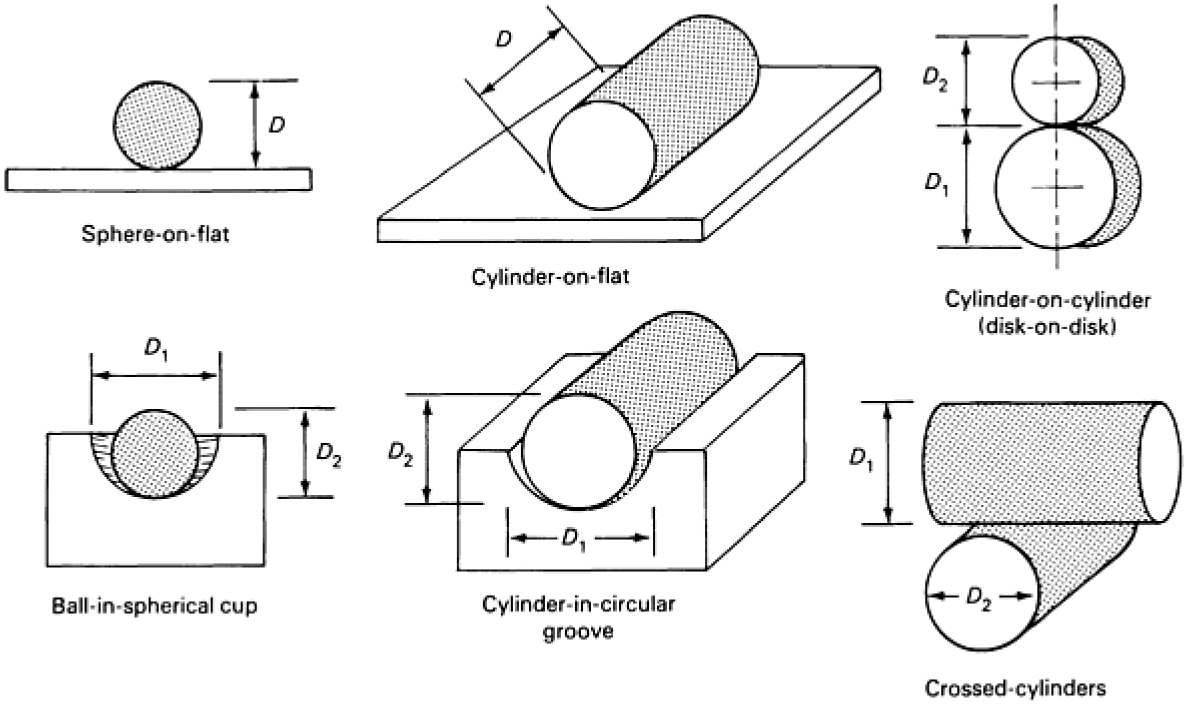

Fig. 7 Typical contact geometry models showing relation of *D, D_1*, and *D_2* in elastic contact and stress analysis (see Table 7)

To calculate the maximum stress level of crossed-cylinder geometry designs, an additional step is required. Two elastic contact dimension constants, α and β, must be obtained from Fig. 8 to calculate *c* and *d,* which are then substituted into the required formula for maximum compressive stress.

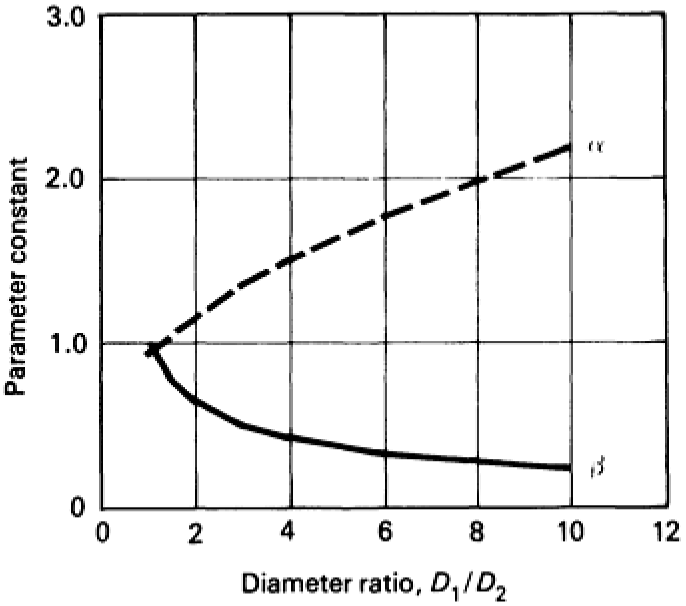

Fig. 8 Value of parameter constants, α and β, as a function of the ratio of diameters (*D_1/D_2*, where *D_1* > *D_2*) for crossed-cylinder contact geometries

Presentation of Friction and Wear Data

Horst Czichos, BAM (Germany)

Introduction

THE RESULTS OF TRIBOTESTS lead to friction and wear data, generally referred to as tribodata, which are system-dependent characteristics presented in the form of tribographs, transition diagrams, or tribomaps.

Tribographs are graphical presentations of a measured friction or wear quantity as function of:

- Operational parameters, for example, load (F_N), velocity (v), temperature (T), or test duration (t)
- Structural parameters, for example, materials pairings, hardness, roughness, or microstructure
- Interaction parameters, for example, contact stresses, film thickness-to-roughness ratio, or lubrication modes

Transition diagrams characterize critical conditions of operational parameters that separate regimes of efficient performance for a given tribosystem from regimes of inefficient performance (failure).

The third form of data presentation is the tribomap, which characterizes operational conditions that separate different wear mechanism regimes or different ranges of wear data.

Tribographs

The presentation of friction and wear data as a function of operational and structural parameters will be illustrated by some simplified examples of typical tribographs in this section. Emphasis is placed on the dependence of tribodata on time, operational parameters, structural parameters, and interaction parameters.

Dependence of Tribodata on Time

The simplest type of tribotest involves subjecting a given tribosystem to a defined constant set of structural and operational parameters and measuring friction or wear as functions of time only. The resulting observed friction or wear master curves in dry sliding are discussed in a simplified generalizing manner in the following paragraphs.

Friction-Time Master Curves. The typical friction-time curve during dry sliding consists of a simplified presentation of four stages of friction coefficient (Ref 1, 2). A typical example for a metal/metal system is shown in Fig. 1.

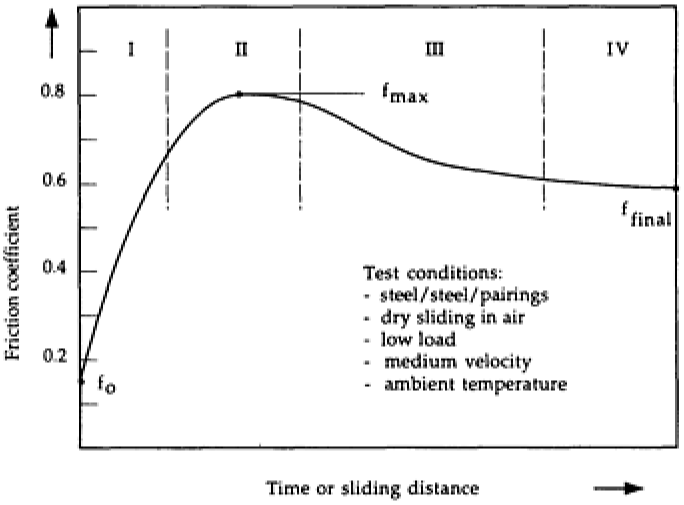

Fig. 1 A friction-time master curve

The initial value of the friction coefficient value of stage I, which is usually about f_0 ~0.1, is dependent on low loads, F_N, and on the shear resistance of surface contaminants, but is largely independent of material combinations. Surface layer removal and an increase in adhesion due to the increase in clean interfacial areas as well as increased asperity interactions and possible wear particle entrapment lead to a gradual increase in the friction coefficient.

Stage II, which produces the maximum value of the friction coefficient (f_{max} ~0.3 to 1.0 for most metal pairs), is reached when maximum interfacial adhesion, asperity deformation, and wear particle entrapment occur.

In stage III, a decrease in the friction coefficient may occur due to the possible formation of protective tribochemical surface layers and a decrease in plowing and asperity deformation processes.

Stage IV is characterized by steady-state interfacial tribological conditions leading eventually to almost constant friction coefficient values.

It should be noted that Fig. 1 shows a simplified smoothed friction graph, which in practice may be overlapped by short-term fluctuations, friction peaks, or stick-slip effects. It follows then that friction behavior should be characterized by the following (average) data in addition to the friction graph:

- Initial friction coefficient, f_0
- Maximum friction coefficient, f_{max}
- Friction coefficient at the end of test, f_{final}

Wear-Time Master Curve. The typical wear-time curve of dry sliding metal/metal systems consists of three wear stages (Ref 3). A typical example is shown in Fig. 2.

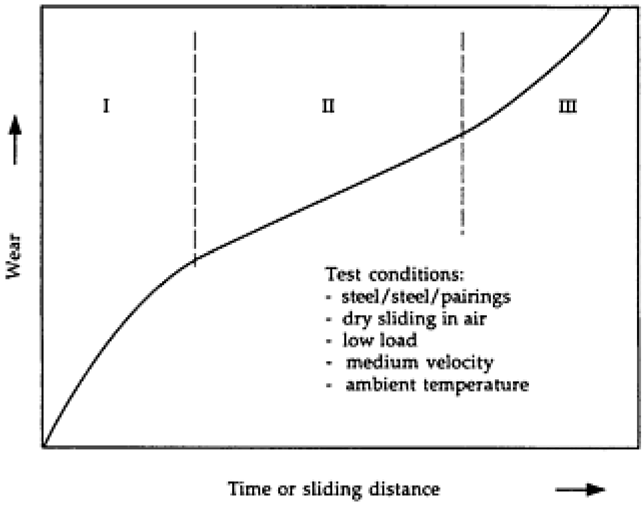

Fig. 2 A wear-time master curve

Stage I, which may have been preceded by a non-wear incubation period, is called the running-in period. During stage I, the probability of the occurrence of elementary wear events may decrease if, through changes in surface topography, the interaction rate of surface asperity collisions decreases. In the simplest case of this "self-accommodation" of the tribosystem, the amount of wear volume *W* may be given by a square-root function of time:

$$\frac{dW}{dt} \sim \frac{1}{W} \rightarrow W(t) = \text{const } t^{1/2} \quad \textbf{(Eq 1)}$$

In stage II, the tribosystem may exhibit relatively stable behavior under the action of the tribological processes. In this case the probability of wear events remains constant. This steady-state situation is characterized by a constancy of the wear-loss output per unit of time without change in the tribological processes. For engineering applications, tolerable wear coefficient values should be in the range of $k < 10^{-6}$ $mm^3/N \cdot m$. It follows that:

$$\frac{dW}{dt} = \text{const} \rightarrow W(t) = \text{const} \cdot t \quad \textbf{(Eq 2)}$$

In stage III an acceleration of wear may occur through an accumulation of elementary wear processes. During stage III, changes in the state of the system are of a directed nature and the increments in the wear processes in this regime are mutually dependent. Large increments in one interval of time cause even larger increments in the next time interval. It follows that:

$$\frac{dW}{dt} \sim W \rightarrow W(t) \sim e^{\text{const} \cdot t} \quad \textbf{(Eq 3)}$$

In this case a self-acceleration of the wear process may occur that can lead to catastrophic damage, that is, failure of the entire system.

Dependence of Tribodata on Operational Parameters

In addition to the dependence on time and motion, tribodata also depend on the set of operational parameters, which include:

- Load, F_N
- Velocity, *v*, in sliding, rolling, and so forth
- Temperature, *T*, at stated location and time

Therefore, in the presentation of tribodata, the primary influencing operational parameters must be carefully identified as will be illustrated in the following examples of tribographs for steels, ceramics, and polymers.

Dependence of Wear on Load and Velocity. A well-known characteristic example of the dependence of wear on load, F_N, and sliding velocity, *v*, is shown in Fig. 3 (Ref 4). Gradual or sharp transitions between mild or severe wear are caused by a change in the structure of oxides (α-Fe_2O_3, Fe_3O_4, or FeO) on the sliding surfaces or by the breaking away of protective oxide films (Ref 5, 6). Above these transitions, wear increases about linearly (on a logarithmic scale) with increasing load up to a second transition, which is recognized by a sharp drop in wear. This is due to the formation of a new protective oxide film that forms at high-contact temperature (Ref 7).

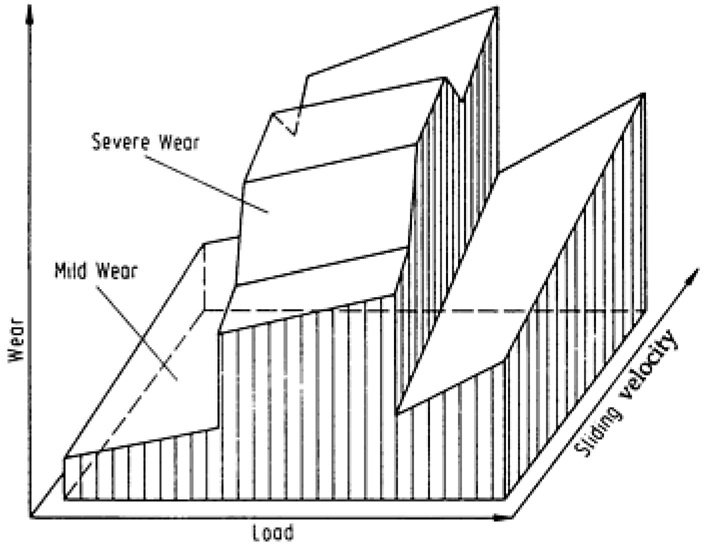

Fig. 3 Wear intensity of steels in dry sliding as a function of load and sliding velocity (logarithmic scales)

Dependence of Wear on Velocity and Temperature. The dependence of the wear coefficient on sliding velocity, *v*, and bulk specimen temperature, *T*, is illustrated for dry-sliding ceramic pairs (partially stabilized zirconia, MgO-PSZ) in Fig. 4, which shows a gradual changeover from low wear to high wear (Ref 8). As functions of the increase of *v* and *T*, the initial monoclinic and tetragonal ZrO_2 phases change under the high hot-spot temperatures and microasperity pressures to cubic ZrO_2, with a volume reduction of up to 9 vol%. This leads to increased wear due to surface tension and then to intergranular microcracking.

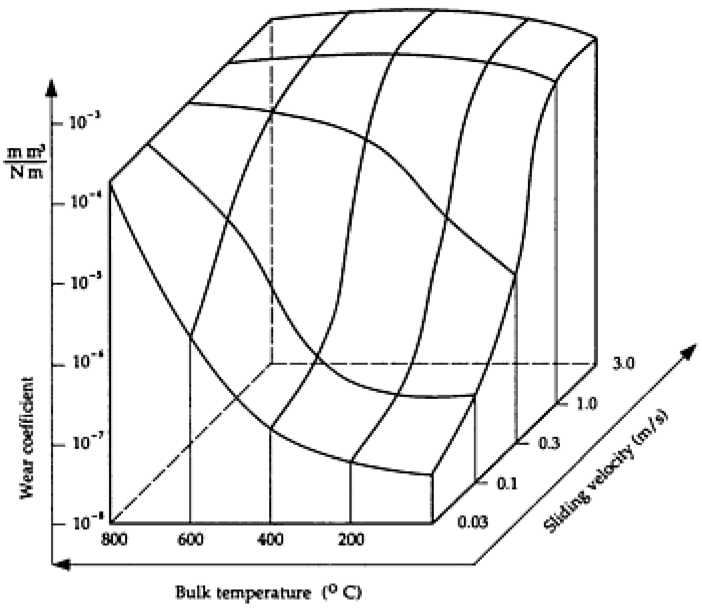

Fig. 4 Wear coefficient of zirconia ceramics in dry sliding as a function of sliding velocity and temperature

Dependence of Friction on Load, Velocity, and Temperature. The dependence of the friction coefficient on the set of operational parameters (F_N,v,T) for a polymer/steel sliding system was described in the previous article in this Section on "Design of Friction and Wear Experiments." Figure 4 for the same article shows the relationship of the friction coefficient with F_N, v, and T.

Dependence of Tribodata on Structural Parameters

Tribodata are also closely related to the structural components of tribosystems. Key structural parameters include:

- Composition
- Roughness
- Modulus
- Hardness
- Toughness
- Microstructure

The dependence of tribodata on structural parameters, which was described in detail in the article "Basic Tribological Parameters" in this Section, will be illustrated in this article by considering only the example of the abrasive wear resistance of material (Fig. 5). For metals, the increment in abrasion resistance with increasing hardness is substantially larger in pure metals than in heat-treated steels. At the same bulk hardness, steels with higher carbon content show higher abrasion resistance. Ceramics show lower abrasion resistance than pure metal or annealed steels of comparable hardness when hard abrasives are used. Polymers exhibit low abrasion resistance due to their low hardness. For thermoplastics, the abrasive wear resistance depends also on another important structural parameter, namely the rupture strength (Ref 9), as can be seen from Fig. 6.

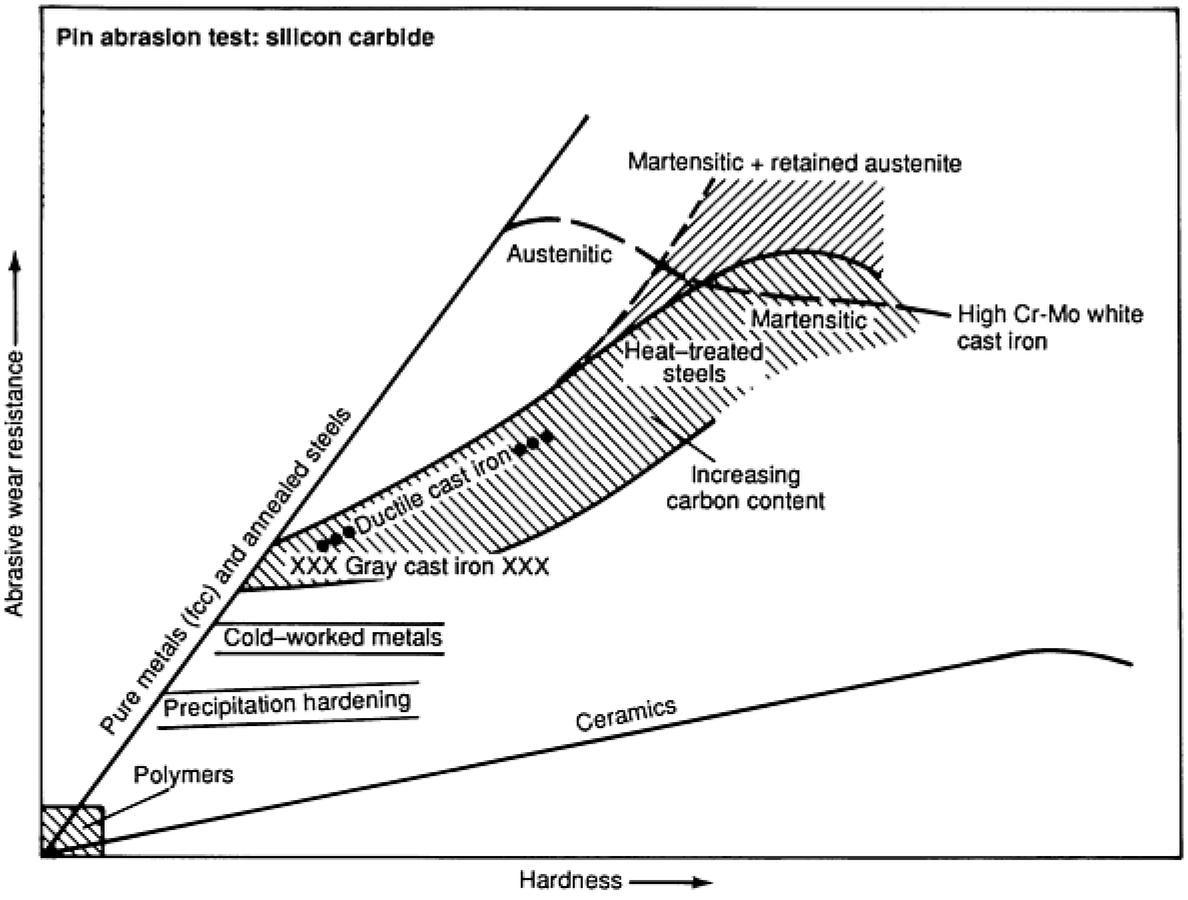

Fig. 5 Abrasive wear resistance of different materials as a function of bulk hardness

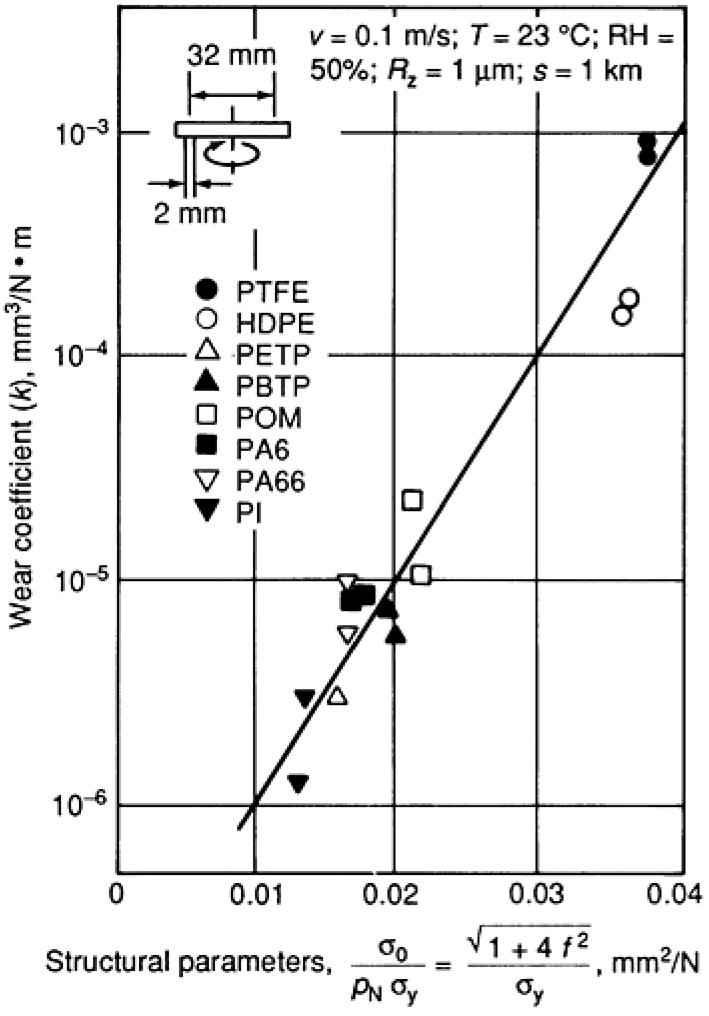

Fig. 6 Abrasive wear coefficient of polymer/steel (AISI 52100 steel, 800 HV, roughness R_z = 1 μm) sliding pairs as a function of stress and strength parameters. p_N, contact pressure; σ_0, interfacial stress; σ_y, polymer rupture strength; *f*, friction coefficient. Source: Ref 9

Finally, it should also be emphasized that for an unambiguous presentation of wear data, a distinction must be made between system wear and component wear. As can be seen from Fig. 7, for a Si_3N_4 ceramic, different values for component wear (ball or disk specimen) and the system wear of both partners of a ball-on-disk configuration result.

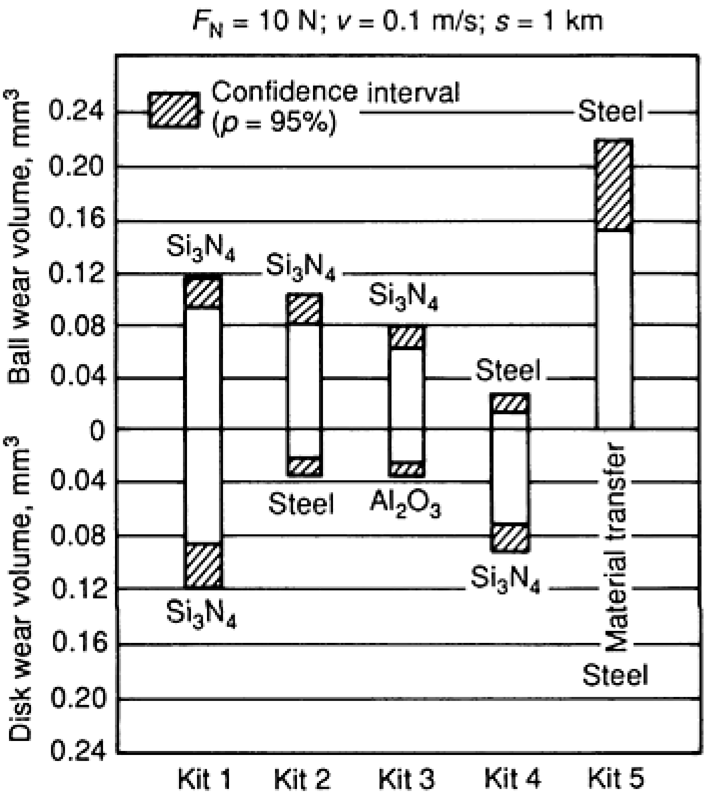

Fig. 7 Presentation of wear data for the components of a laboratory tribotesting system (ball-on-disk configuration, VAMAS reference conditions as described in the article "Design of Friction and Wear Experiments")

Dependence of Tribodata on Interaction Parameters

The dependence of tribodata on interaction parameters is the key feature of friction and wear data as compared with other materials-related quantities, such as strength data. Interaction parameters are in existence only during the operation of the tribosystem under consideration. They determine the dynamic state of the tribosystem and are not intrinsically derivable from the static individual tribocomponents. As discussed in the article "Basic Tribological Parameters" in this Section, fundamental interaction parameters that influence friction and wear data include:

- Interface forces and energies (connected with interface physics and chemistry)
- Contact deformation modes
- Contact stresses
- Contact area/wear-track ratio
- Lubrication modes

Furthermore, interaction parameters must characterize possible interfacial "third-body processes" (Ref 10), which involve the compositional, microgeometrical, and microstructural changes of interfaces and the generation, formation, and detachment of wear particles.

Transition Diagrams

Regimes of efficient and inefficient performance of tribosystems may be distinguished by transition diagrams. For lubricated sliding Hertzian (steel) contacts, a methodology for the determination of transition diagrams has been developed by the International Research Group on Wear of Engineering Materials (IRG-OECD) (Ref 11, 12). The primary features of this methodology are summarized below.

Step 1. Tribological tests should be run with a defined lubricated Hertzian contact system (for example, a ball-on-ring or ball-on-flat specimen configuration) under constant operating conditions of sliding velocity, *v*, bulk oil temperature, *T*, sliding distance, *s*, and test duration, *t*, with a stepwise increased load, F_N. The tests may be run either with new specimens for each load step (that is, a "no run-in procedure" where $t < 10$ s), or with only one specimens set (that is, a "run-in procedure"). The friction coefficient, *f*, and wear volume *W* are then measured and the wear coefficient, $k = W/(F_N \cdot s)$, is calculated.

Step 2. For a constant set of (*v*,*T*,*t*,*s*), the critical load F_{Ncrit} for the transition from regime I (partial elastohydrodynamic, EHD, lubrication) to regime II (incipient scuffing), as shown in Fig. 8, is characterized by:

$$f < 0.1 \rightarrow f > 0.3$$
$$k < 10^{-6}\ \text{mm}^3/\text{N} \cdot \text{m} \rightarrow k > 5 \times 10^{-6}\ \text{mm}^3/\text{N} \cdot \text{m} \qquad \textbf{(Eq 4)}$$

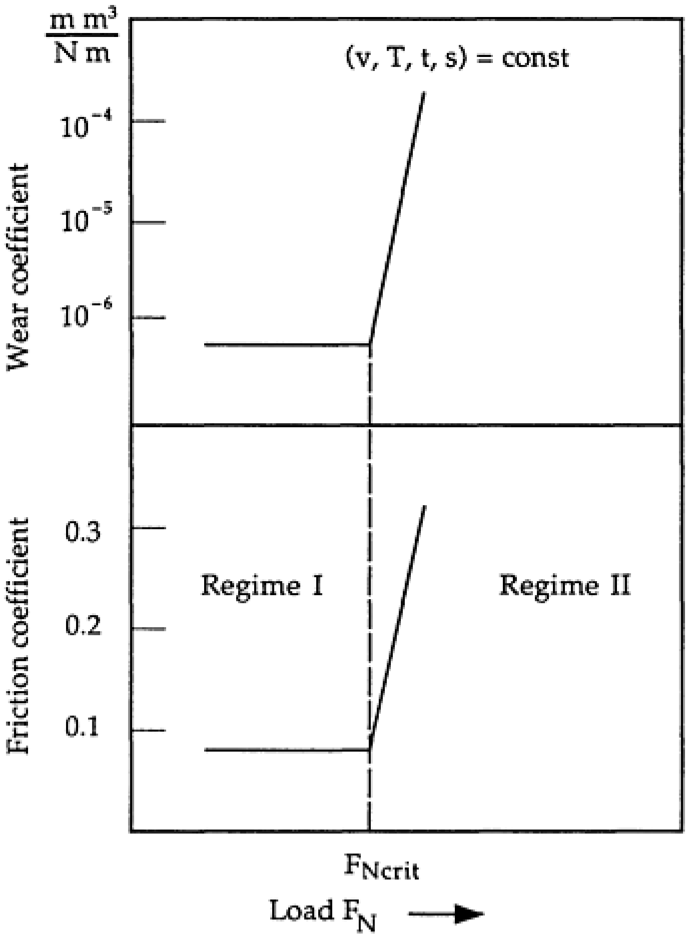

Fig. 8 Determination of critical failure loads, F_{Ncrit}, for sliding lubricated concentrated contacts

During step 3, the critical load, F_{Ncrit} for a variation of sliding velocity, *v* (the other parameters *T*, *t*, and *s* being held constant), is determined. The graph of F_{Ncrit} versus the corresponding values of *v* is called the IRG transition diagram (Fig. 9). Note that in addition to the I/II transition, there is a II/III transition that characterizes the change from incipient scuffing to complete seizure.

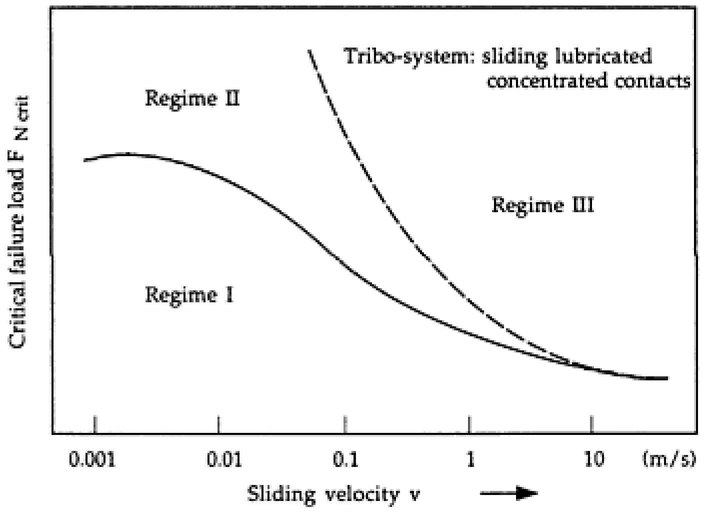

Fig. 9 IRG transition diagram for sliding lubricated concentrated contacts (critical failure load as a function of sliding velocity)

A F_{Ncrit}/T transition diagram characterizing the critical failure load as a function of the bulk oil temperature, *T*, (for constant *v*,*t*,*s*) may also be determined. In combining these two diagrams, a three-dimensional failure surface results (Ref 13), which characterizes the load-carrying capacity of lubricated concentrated contacts as a function of sliding velocity, *v*, and bulk oil temperature, *T* (Fig. 10).

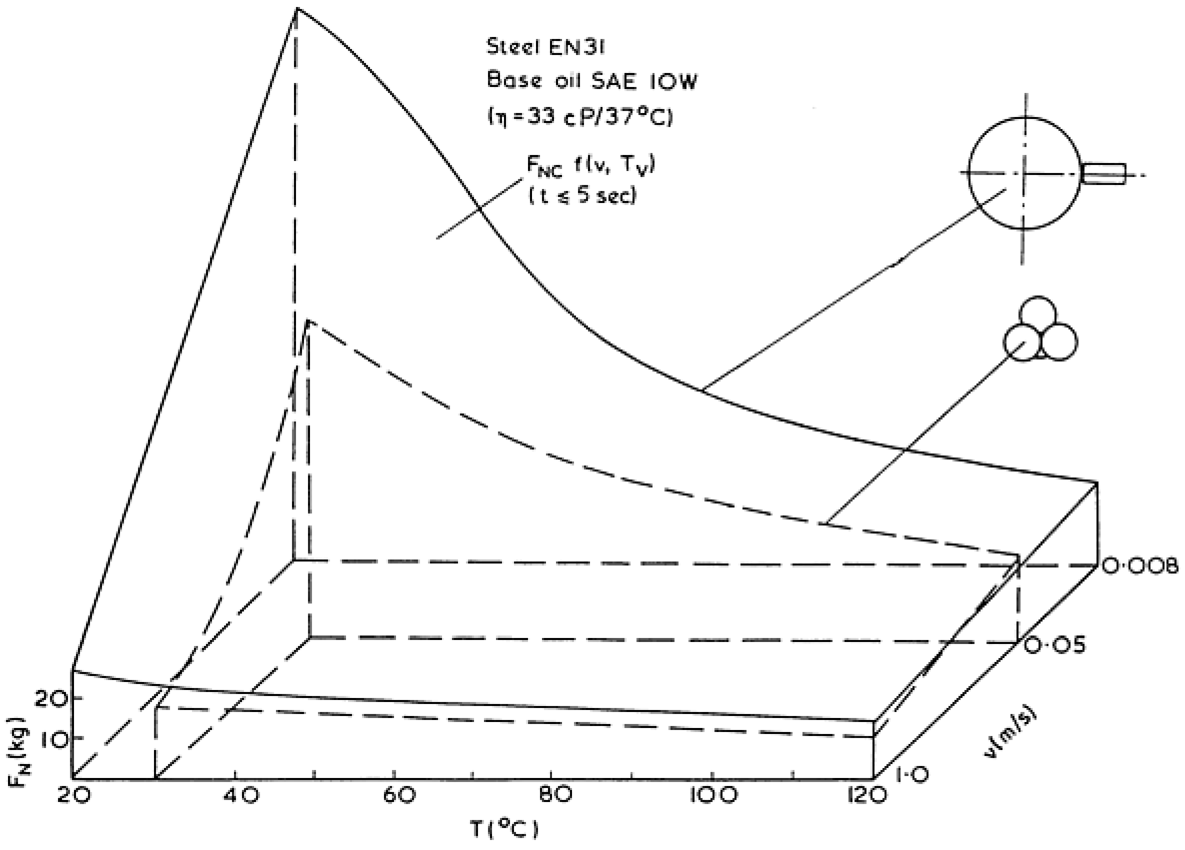

Fig. 10 Critical failure load , F_{Ncrit}, of sliding lubricated concentrated contacts as a function of sliding velocity, *v*, and bulk oil temperature, *T*. Oil viscosity (given in cP) is indicated by η.

With the use of IRG transition diagrams, the influences of materials properties, lubricant characteristics (for example, viscosity or chemical additives), or environmental conditions (for example, inert gas or humidity) on the functional limits of the operational variables of sliding lubricated contacts can be characterized (Ref 11, 12, 13).

Tribomaps

Tribomaps characterize regimes of different tribological processes (or different ranges of friction and wear data) by giving boundaries of operational parameters for these regimes. For the design of empirical wear mechanism maps, Ashby and co-workers (Ref 14, 15) have used normalized values for wear rate, load, and sliding velocity defined by:

$$\tilde{W} = W/A_n$$
$$\tilde{F}_N = F_N/A_n \cdot H_0 \qquad \textbf{(Eq 5)}$$
$$\tilde{v} = v \cdot r_0/a$$

where A_n is the nominal (apparent) contact area of the wearing surface, H_0 is the room-temperature hardness, a is the thermal diffusivity, r_0 is the radius of the circular nominal contact area, $\tilde{W}$ is the volume lost per unit area of surface, per unit distance slid; $\tilde{F}_N$ is the nominal pressure divided by the surface hardness, and $\tilde{v}$ is the sliding velocity divided by the velocity of heat flow.

In analyzing the results of wear tests published in the literature, the different dominating wear mechanisms were classified into the following categories:

- Seizure
- Melt-dominated wear
- Oxidation-dominated wear (mild and severe oxidational wear)
- Plasticity-dominated wear (including delamination wear)

For each wear regime, the boundaries of the operational parameters F_N and v were estimated; the resulting wear map is shown in Fig. 11. Additional information on wear maps can be found in the article "Friction and Wear of Cutting Tools and Cutting Tool Materials" in this Volume.

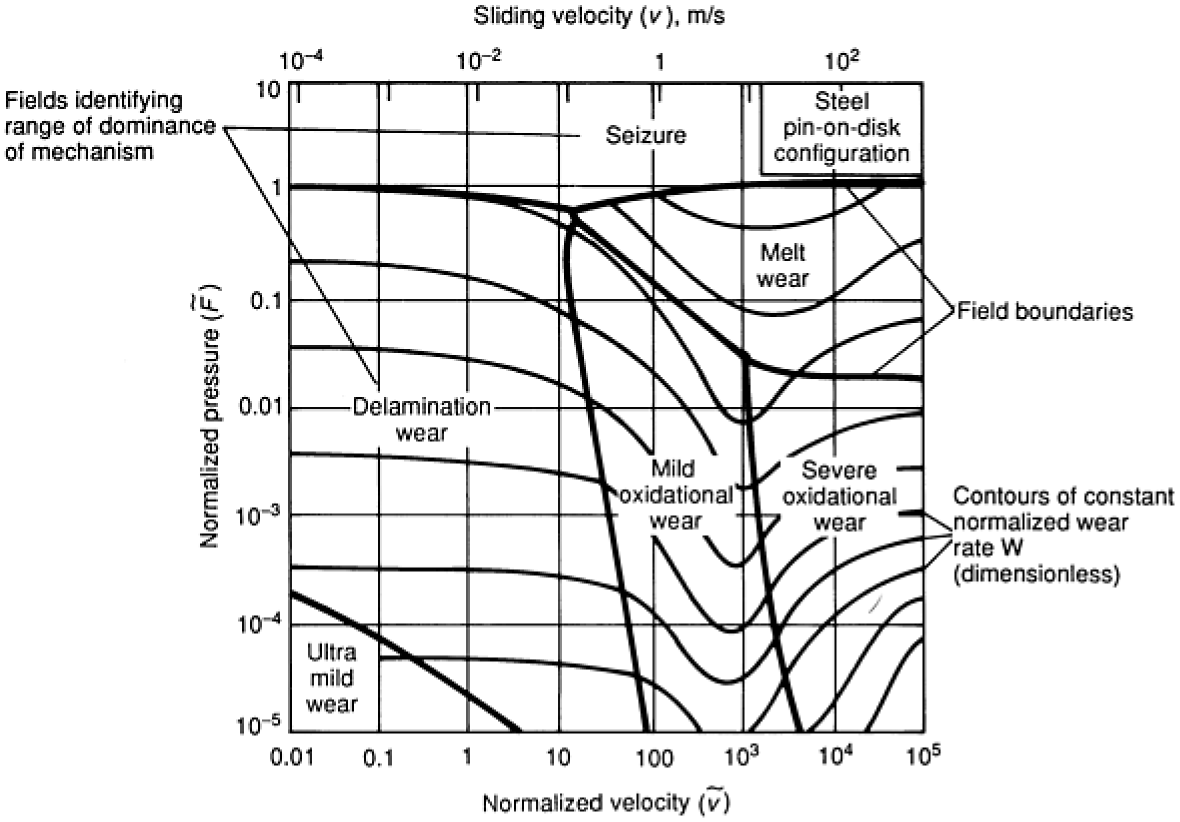

Fig. 11 Empirical wear mechanism map for steel (pin-on-disk configuration)

Concepts of Reliability and Wear: Failure Modes

Horst Czichos, BAM (Germany)

Introduction

METHODS TO CHARACTERIZE THE RELIABILITY of mechanical equipment on the basis of measurements or estimations of wear are often tried in mechanical engineering applications (Ref 1). In this article, statistical techniques and probability concepts for the evaluation and presentation of wear and reliability data are briefly outlined. More detailed information on reliability analysis can be found in the references provided as well as Vol 17 of *ASM Handbook* (formerly 9th Edition *Metals Handbook*).

Acknowledgements

The author would like to thank his tribology colleagues at BAM, and in particular Karl-Heinz Habig and Erich Santner for their help in the preparation of this Section. Special thanks are also due to BAM mathematicians. Wolfgang Gerisch and Thomas Fritz for their review and valuable contributions.

Characteristics of Reliability

Reliability is defined as "the probability of a device performing its purpose adequately for the period of time intended under the operating conditions encountered." (This is the classic definition of reliability given by the Radio Electronics and Television Manufacturers Association in 1955.) In a quantitative way, the reliability of systems, devices, or products may be characterized by the probability concepts outlined in Table 1.

Table 1 Reliability probability concepts

Equation	Concept
$F(t)$	Probability distribution function of the lifetime random variable
$f(t) = \frac{dF(t)}{dt}$	Density function
$\lambda(t) = \frac{f(t)}{1 - F(t)}$	Failure rate
$R(t) = 1 - F(t) = \exp\left(-\int_0^t \lambda(\tau)d\tau\right)$	Reliability function: probability that the system or device will not fail during the time period $(0, t)$
$\text{MTTF} = \int_0^\infty t f(t)dt$	Mean time to failure

Relationship Between Wear and Reliability

Consider as a starting point for the reliability considerations of tribosystems that wear behavior is a function of time (Ref 2). In the previous article on "Presentation of Friction and Wear Data," it was explained that for time-dependent wear of a tribosystem, three different wear stages can be distinguished:

- Self-accommodation or running-in wear
- Steady-state wear
- Self-acceleration (catastrophic damage) of wear

These wear mode changes in the system behavior may follow each other with time, as indicated in Fig. 1. In this figure, W_{lim} denotes a maximum admissible level of wear losses. At this level the system structure has changed in such a way that the functional input-output relations of the system are disturbed severely. Repeated measurements show random variations in the data, as indicated by the dashed lines in Fig. 1.

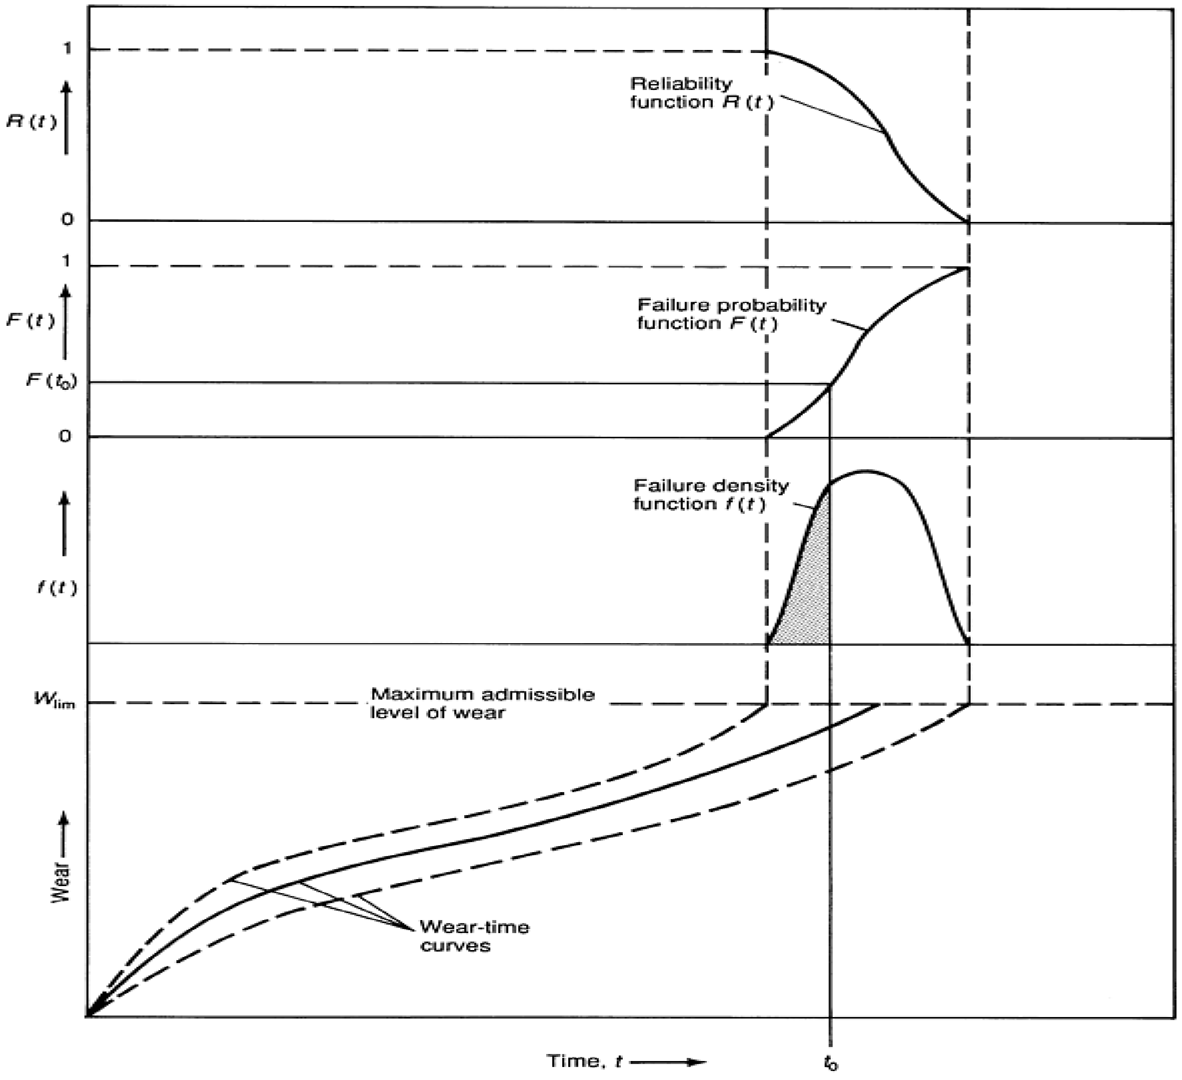

Fig. 1 Simple curves of wear and failure and reliability functions

From sample curves of wear, a probability density function, $f(t)$, of the time for reaching the maximum admissible level of wear (W_{lim} = constant) is obtained. For a given time, t_0, the shaded area under the curve $f(t)$, that is, the value of $F(t_0)$, is a measure of the probability that the system fails within the time $t < t_0$.

Statistical Distributions of Wear and Reliability

For the modeling of the distribution of measured wear data and the estimation of reliability data, statistical distributions may be used. In the following paragraphs, some of the statistical distributions that have been applied for these purposes are briefly reviewed in a highly simplified manner in order to illustrate the given probability concepts. With respect to the estimation of the occurring parameters, the calculation of confidence intervals, and related subjects, the reader is referred to Ref 3, 4, 5, 6.

For exponential distribution:

$$\begin{aligned} \lambda(t) &= \lambda = \text{const} \\ f(t) &= \lambda \cdot \exp(-\lambda t) \\ R(t) &= \exp(-\lambda t) \\ \text{MTTF} &= 1/\lambda \end{aligned} \qquad \textbf{(Eq 1)}$$

In this case, the failure rate is constant, which means that failure occurs accidentally without an accumulation of fatiguelike effects during service time. Components in a machine fail in this mode, for example, when the failure is brittle fracture. In Fig. 2 the density function of the failure of a diesel engine control unit is plotted showing an exponential distribution (Ref 7).

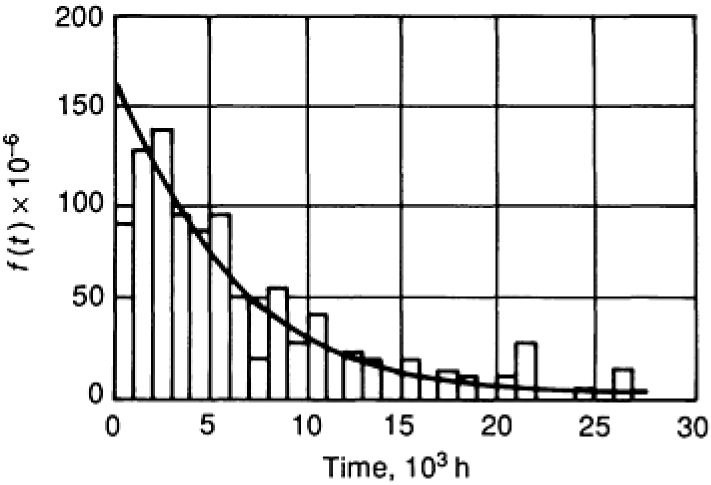

Fig. 2 Failure density function of diesel engine control units

For normal distribution:

$$f(t) = \left(1/\sigma\sqrt{2\pi}\right)\exp\left\{-\frac{1}{2}\left(\frac{t-\mu}{\sigma}\right)^2\right\}$$

$$\lambda(t) = \frac{f(t)}{1-\phi((t-\mu)/\sigma)} \qquad \textbf{(Eq 2a)}$$

where ϕ is the standard normal distribution function, and

$$\begin{aligned} R(t) &= 1 - \phi((t-\mu)/\sigma) \\ \text{MTTF} &= \mu \end{aligned} \qquad \textbf{(Eq 2b)}$$

Many machine components obey this distribution, especially if the failure occurs due to wear processes.

For lognormal distribution:

$$f(t) = \left(1/t\sigma\sqrt{2\pi}\right)\exp\left\{-\frac{1}{2}\left(\frac{\ln(t)-\mu}{\sigma}\right)^2\right\}$$

$$R(t) = 1 - \phi\left(\frac{\ln(t)-\mu}{\sigma}\right) \quad \text{(Eq 3)}$$

$$\lambda(t) = \frac{f(t)}{1-\phi((\ln(t)-\mu)/\sigma}$$

$$\text{MTTF} = \exp\,(\mu + \sigma^2/2)$$

This distribution is concentrated on the positive t-axis. Its failure rate increases to a maximum and then decreases to zero. Therefore, it can be used for modeling survival times after extreme stress.

For the Weibull distribution:

$$\lambda(t) = \frac{C}{t_0}t^{c-1}$$

$$f(t) = \frac{C}{t_0}t^{c-1}\exp\,(-t^c/t_0) \quad \text{(Eq 4)}$$

$$R(t) = \exp(-t^c/t_0)$$

$$\text{MTTF} = t_0^{1/c}\,\Gamma((C+1)/C)$$

In its simplest form, this is a distribution with two key parameters: t_0, the nominal life, and the constant C. This distribution is found to represent failure of many kinds of mechanical systems, such as fatigue in ball bearings. As an example, Fig. 3 shows the probability distribution function of the time to failure, $F(t)$, as determined by testing 500 grease-lubricated ball bearings at 1000 rpm (Ref 8).

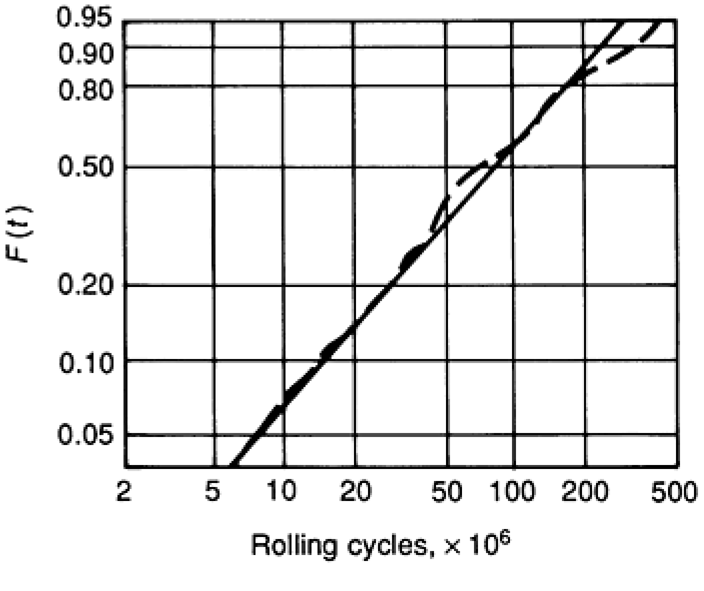

Fig. 3 Failure distribution function of ball bearings

For the Gamma distribution:

$$f(t) = C \frac{(Ct)^{x-1}}{\Gamma(x)} \exp(-Ct)$$

$$\lambda(t) = C\, t^{x-1} \exp(-Ct)/[\Gamma(x) - \Gamma(x, Ct)]$$

(Eq 5a)

where $\Gamma(a,z)$ is the standard incomplete gamma function, and

$$R(t) = (\Gamma(x) - \Gamma(x,Ct))/\Gamma(x)$$
$$\text{MTTF} = x/\text{C}$$

(Eq 5b)

where $\Gamma(x)$ is a Gamma function. This is also a distribution with two parameters. Theoretically, the importance of this distribution is attributed to the fact that the equation is an *x*-fold convolution of the exponential function. It means physically that a component fails at *x*th shock which occurs as a Poisson statistical process with parameter C. In Fig. 4, the density function of the failure of a piston in a diesel engine is plotted showing a Gamma distribution with *x* = 2 (Ref 7).

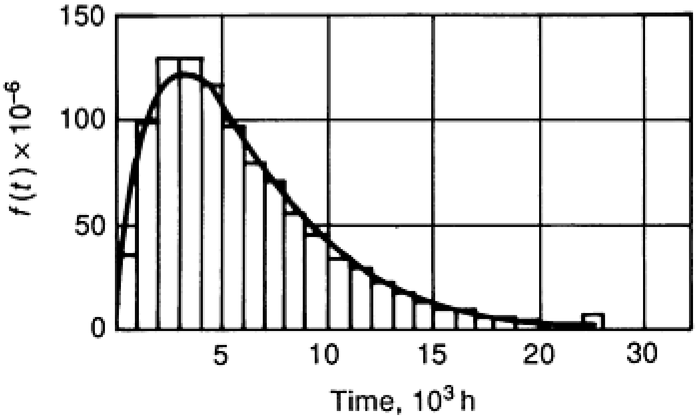

Fig. 4 Failure density function of diesel engine pistons

Wear and Failure Modes

The aforementioned examples of statistical distributions indicate that different failure modes and different elementary failure processes are associated with different types of failure distribution functions. It follows that from the experimental determination of failure distribution curves, conclusions may be drawn as to the type of failure mechanism. For most tribosystems failing as a consequence of wear processes, the failure behavior is characterized by the normal distribution or the Weibull distribution. If for a given type of tribosystem the failure mode and the type of failure distribution are known, this knowledge can be used to improve the reliability of the system (Ref 9). For instance, this approach can be used to select the type of a ball or roller bearing system to operate under a given set of operating conditions with high operational safety (Ref 10). More general treatments concerning correlations between life data, statistical lifetime distribution, and failure models can be found in Ref 3, 4, 5, 6, 11 and 12.

Dependence of Failure Rate on Operating Duration

To conclude the brief discussion on the failure and reliability of tribosystems, and dependence of the failure rate on the operating duration of a system should be considered. If the failure rate is plotted as a function of time, a curve known as the "bathtub curve" is generated (Fig. 5).

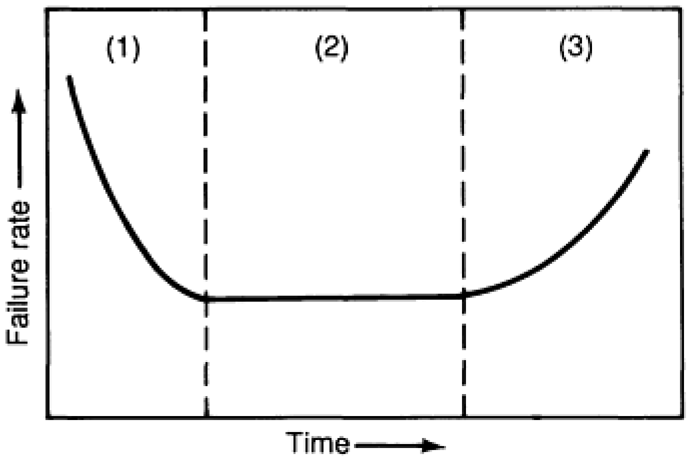

Fig. 5 "Bathtub" failure rate curve

In this curve, three regimes can be distinguished: (1) early failures, (2) random failures, and (3) wear-out failures. None of the distribution curves discussed above have this bathtub-shaped failure curve, but an approximation can be obtained by selecting an appropriate probability density function for each of the three regimes. Regime (1) describes the region of the "infant death" of the system. This regime is characterized by a decrease of the failure rate with time during running-in wear. Regime (2), which exhibits a constant failure rate, is the region of normal running. Here failure occurs as a consequence of statistically independent factors. Regime (3) is characterized by an increase of the failure rate with time. Here failure may be due to aging effects. As described above, for a great deal of tribo-induced failures, the failure rate increases with time. Thus region (3) of the bathtub curve of Fig. 5 appears to be relevant for the normal mode of wear-induced failure of mechanical systems.

Friction and Wear of Rolling-Element Bearings

Tedric A. Harris, Pennsylvania State University

Introduction

ROLLING-ELEMENT BEARINGS, also called rolling bearings and antifriction bearings, are among the most common machine elements. The basic design of the current ball bearings was devised by Leonardo da Vinci in the 15th century. (See Ref 1 for a history of lubrication and bearings.) The term *rolling element* refers to the ball or roller components that are used to separate the inner and outer rings. The term *antifriction* is used because the bearings tend to have very low friction characteristics compared to fluid film bearings or simple sliding bearings. In addition to the components cited above (that is, balls or rollers, inner rings, and outer rings), most rolling bearing have a *cage* (also called a *separator* or *retainer*) that spaces the rolling elements during operation. The cage also serves to retain the rolling elements in the bearing prior to assembly and also in the subsequent application. Figure 1 illustrates the components in a typical ball bearing. Note that the rolling elements run on an inner ring track called the inner raceway; similarly, the outer ring track is called the outer raceway.

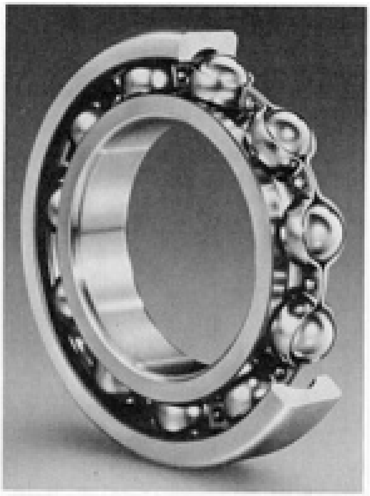

Fig. 1 Cutaway view of radial ball bearing showing inner ring, outer ring, balls, and cage assembly

Rolling bearings have much less friction torque than conventional hydrodynamic bearing types, and starting friction torque is only marginally greater than operating friction torque. In addition, rolling-element bearing deflection is not as sensitive to load fluctuation as is deflection in a hydrodynamic bearing. In most applications, only a small quantity of lubricant is required for satisfactory operation, eliminating the need for expensive and space-consuming lubricating systems. Moreover, rolling-element bearings require less space than corresponding hydrodynamic bearings, and they can be selected or designed in compact units to support combination loads (for example, radial, thrust, and moment loads). The load and speed ranges to which a given rolling-element bearing may be subjected and function efficiently under each condition are significantly wide. In general, if a rolling-element bearing can satisfy the operating conditions for a given application, it represents the economical choice.

Types of Rolling-Element Bearing

There are two basic rolling-element types: balls and rollers. Ball bearings enjoy the most universal usage. However, for applications in which very heavy loads must be supported, roller bearings find extensive usage. In addition to categorizing

rolling bearings according to rolling-element type, such bearings are also identified according to the predominant loading they are designed to support (for example, radial load or thrust load [also called axial load]). Within each subcategory type (for example, radial ball bearings, thrust ball bearings, radial roller bearings, and thrust roller bearings), there are several different basic variations, the usage of each depending on the load and speed conditions to be accommodated.

Ball Bearings

Ball bearings can be further classified as either radial ball bearings, angular-contact ball bearings, or thrust ball bearings.

Radial Ball Bearings. The most common ball bearing type is the nonseparable Conrad assembly (Fig. 2). The nominal contact angle between a ball and a raceway is 0° (the contact angle is defined as the angle the ball-raceway load vector makes with the bearing radial plane). The bearing is designed to carry moderate radial road. The bearing can, however, support some thrust (axial) and moment load in addition to the radial load. In this case, the contact angles between balls and raceways increase beyond 0° with the application of thrust. In most cases, the bearings can operate at high speeds of rotation ($\leq 5 \times 10^5\ n \cdot d_m$, where n is the speed of rotation in rev/min and d_m is the pitch diameter, above which special cooling is often required to keep operating temperatures at <170 °C, or 338 °F). Because the bearing balls and rings form an inseparable unit when assembled, cages are either two-piece riveted assemblies or one-piece snap-on plastic (generally fiberglass-filled polyamide [nylon]) units. When using bearings with plastic cages, care must be exercised to ensure the compatibility of the cage material with the bearing lubricant and operating temperatures. The latter must not be >120 °C (>248 °F).

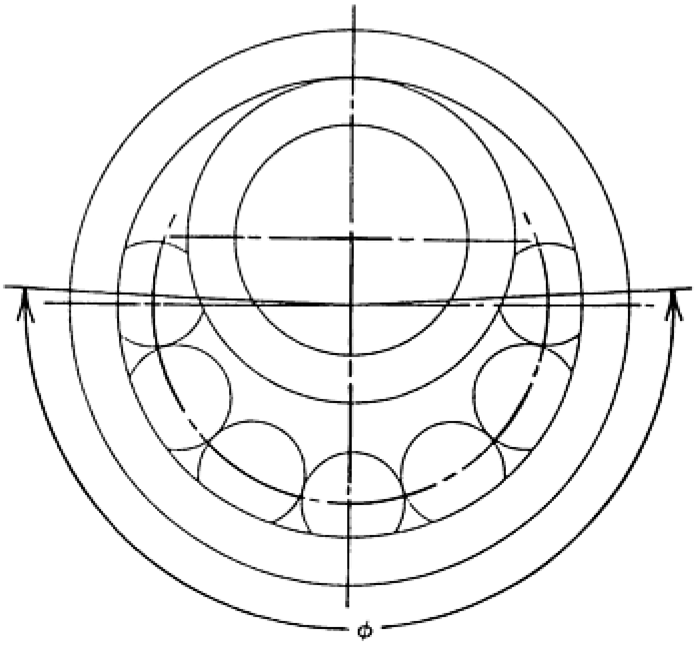

Fig. 2 Schematic showing assembly process for a nonseparable Conrad-type ball bearing. ϕ, assembly angle

Self-aligning ball bearings are principally double-row radial bearings that can accommodate radial load simultaneously with substantial misalignment (for example, from 1.5 to 3° depending on internal design), without detriment to bearing endurance. In conjunction with the principal radial load, they can also support some axial loading. Because the outer raceway is a portion of a sphere (Fig. 3), the conformity of the outer raceway to the ball is not close. Accordingly, the outer raceway has less load-carrying capacity than does the inner raceway. The reverse is true for almost all other basic types of radial rolling-element bearings.

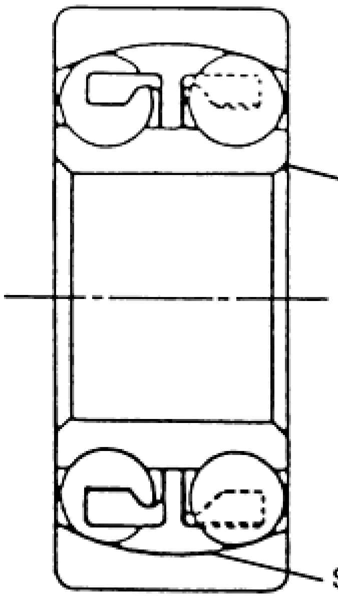

Fig. 3 Typical construction of a self-aligning ball bearing incorporating a spherically shaped outer raceway

Angular-contact ball bearings are radial bearings designed to support substantial amounts of axial load in addition to radial load. Basic catalog bearing designs have nominal contact angles from 15 to 40° (Fig. 4); the bearings having the higher contact angles can carry the greater amount of axial loading. For the 40° contact angle bearing, applied thrust load must be at least equal to radial load for satisfactory operation. The bearings can also support simple axial loading. The bearings are always mounted in pairs to accommodate thrust loading induced by applied radial loading; they may be mounted in back-to-back or face-to-face duplex arrangements (Fig. 5). The former provides substantial resistance to moment loading (that is, high stiffness), whereas the latter provides greater ability to accommodate misalignment. In addition, angular-contact bearings can be mounted in tandem for increased axial load-carrying capacity (Fig. 6). Duplex angular-contact ball bearings can be axially preloaded to achieve increased stiffness (that is, reduced deflection under applied loading).

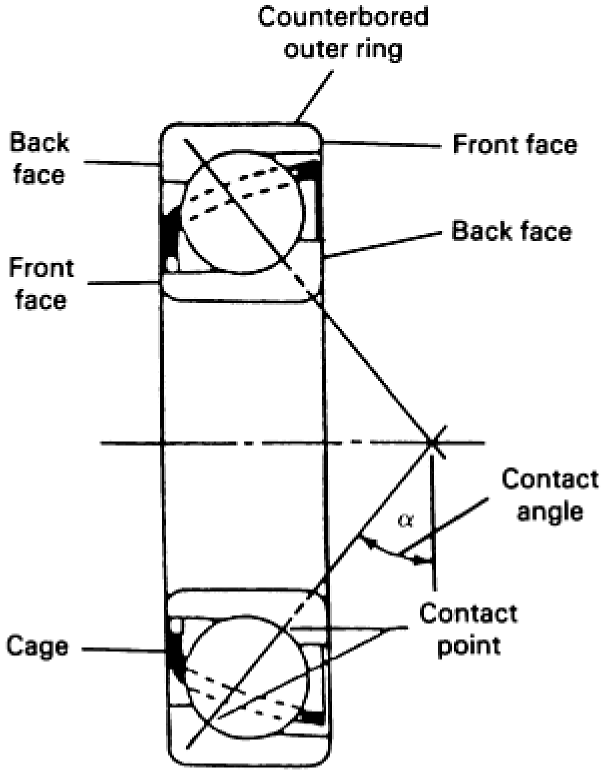

Fig. 4 Key components of an angular-contact ball bearing

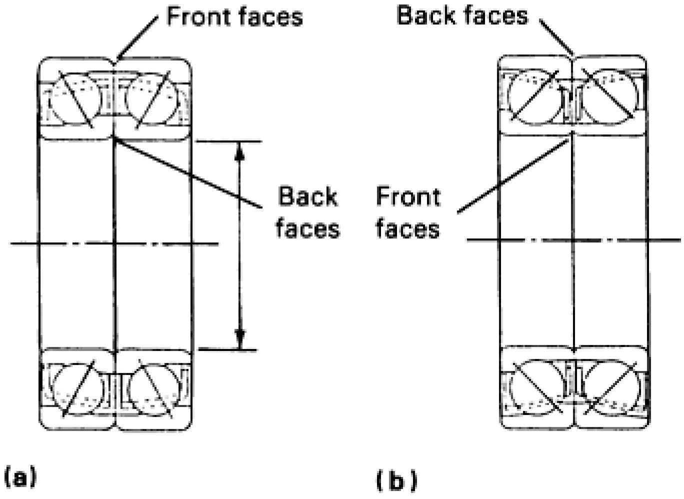

Fig. 5 Duplex angular-contact ball bearing arrangements used to accommodate thrust loading induced by applied radial loading. (a) Face-to-face mounting. (b) Back-to-back mounting

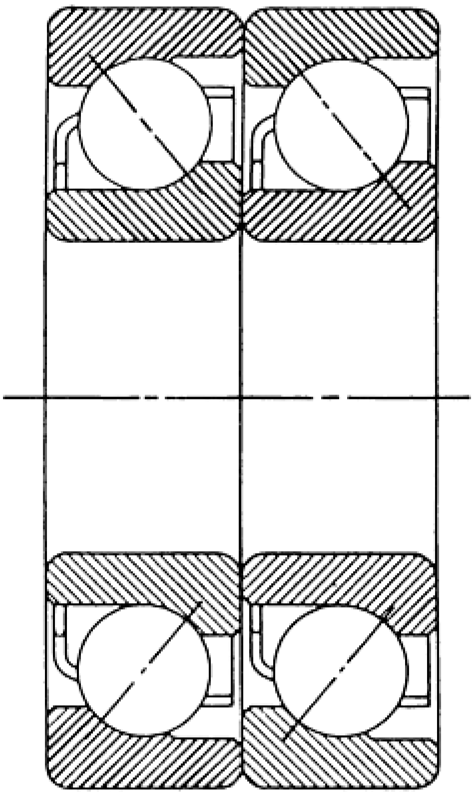

Fig. 6 Pair of angular-contact ball bearings mounted in tandem

The bearings may be assembled with one-piece pressed (stamped) or precision-machined cages fabricated from steel, brass, or bronze. Bearings having the machined cages are capable of higher speeds. Bearings can also be supplied with plastic (mainly polyamide 6/6, nylon) cages; these also have high-speed capability. The operating speed capability of angular contact ball bearings is somewhat less than that of other radial ball bearings.

Split inner ring ball bearings (Fig. 7) are double-direction angular-contact ball bearings (that is, they can support thrust load in either axial direction). When compared to duplex angular-contact bearings, however, they are narrower in width. Radial load can be supported only in conjunction with thrust loading sufficient to load all balls. Generally, the balls are spaced apart by a one-piece cage precision machined from steel, brass, or bronze. The bearings are capable of high-speed operation.

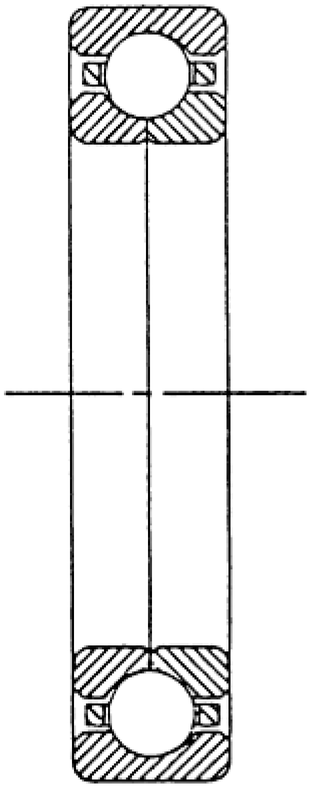

Fig. 7 Typical construction in a split inner-ring ball bearing

Thrust Ball Bearings

Thrust ball bearings (contact angles from 45 to $\leq$90°) are designed to carry predominantly axial load; 90° contact angle thrust bearings (Fig. 8) cannot carry any radial load. Owing to substantial amounts of ball spinning, they are limited to slow- to moderate-speed operation unless means to remove high friction heat associated with high-speed operation is provided.

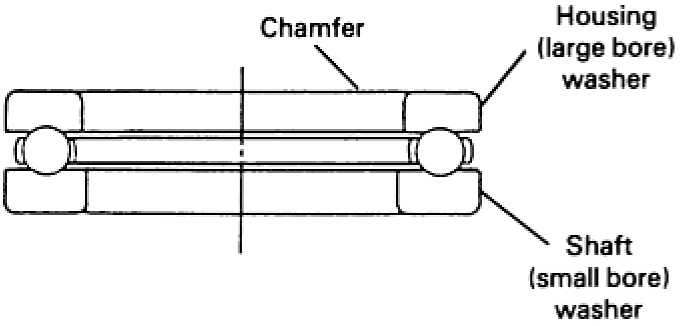

Fig. 8 Thrust ball bearing designed to carry axial load only due to 90° contact angle

Roller Bearings

Radial cylindrical roller bearings, tapered roller bearings, radial spherical roller bearings, and radial needle roller bearings comprise the radial roller bearing group.

Radial Roller Bearings. The basic type of radial roller bearing is the single-row cylindrical roller bearing, which consists of each rolling element having the basic form of a cylinder (Fig. 9). Accurately manufactured bearings have

slightly crowned rollers (Fig. 10) so that, except under extremely heavy loading and/or bearing misalignment, edge loading and its deleterious effects on bearing endurance are avoided. The bearings are capable of supporting very heavy radial loading and operating at very high speeds. They tend to be sensitive to misalignment; only a few minutes of misalignment can be tolerated without a substantial reduction in endurance. In general, the bearings permit axial float of the shaft because neither the inner ring nor the outer ring usually has any guide flanges. When both rings have guide flanges (Fig. 11), however, the bearing can support some thrust load in conjunction with a greater amount of applied radial load. The bearing can be assembled with pressed metal; precision-machined brass, bronze, or steel; or molded plastic cages, depending on the application. These bearings are manufactured in two-row and four-row versions for greater load-carrying capacity.

crowned (cylindrical roller). Roller length, *l;* roller diameter, *D;* crown radius, *R*

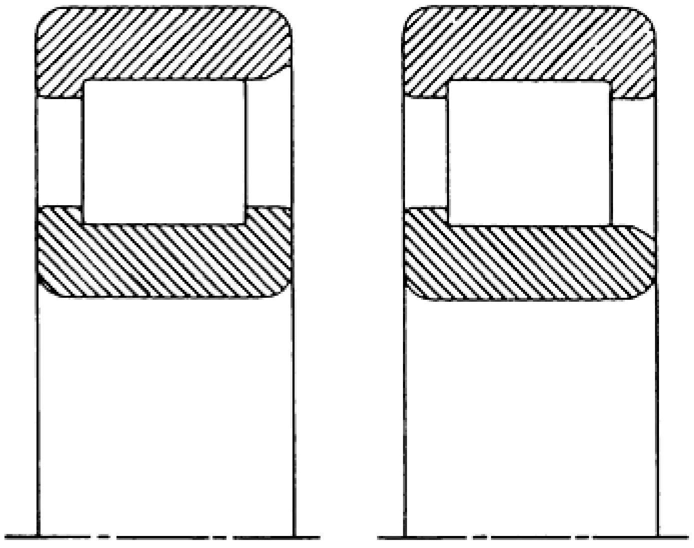

Fig. 11 Radial cylindrical roller bearing with guide flanges on both inner and outer rings

Tapered Roller Bearings. A common form of radial roller bearing is the tapered roller bearing. As shown in Fig. 12, the basic form of the tapered roller is a portion of a cone; generally the rollers are crowned. The outer and inner raceway surfaces are also portions of cones, the outer ring being called the cup and the inner ring the cone. Because the raceways are angled relative to the shaft, radial tapered roller bearings can carry combined radial and axial loading; very heavy loading can be supported. To provide increased load-carrying capacity, the bearings may be obtained in two-row and four-row units.

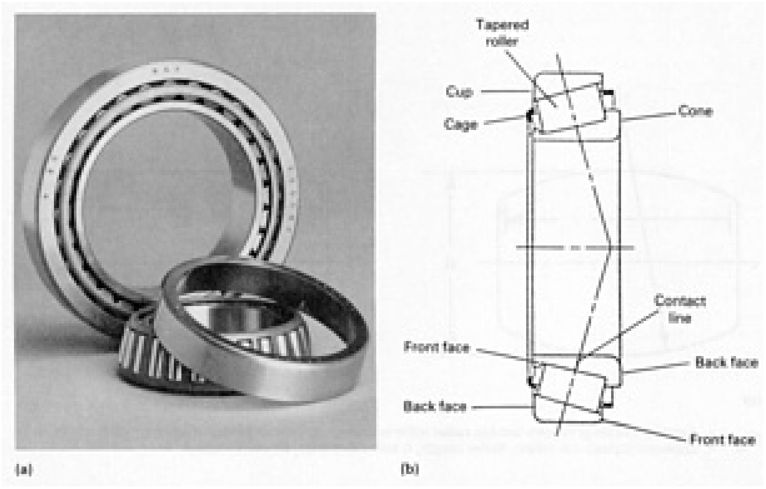

Fig. 12 Key components of a tapered roller bearing. (a) Photograph showing cone assembly and cup of the typical roller bearing shown in background. (b) Schematic of a cross section of a tapered roller bearing

The bearings are sensitive to misalignment, tending to have substantially reduced endurance under only a few minutes of misalignment. Generally, operating misalignment is limited to $\leq$3 min to achieve expected performance. Because the rolling-contact surfaces are portions of cones, the rollers are driven against a fixed guide flange during operation, usually on the inner ring. The contacts between the roller ends and the guide flange, sometimes called the large end rib, are sliding contacts creating substantial friction as compared to the raceway rolling contacts; therefore, the bearings cannot

operate at high speed without a lubrication system capable of removing the friction heat thereby generated. Generally, the bearing cages are manufactured from stamped or pressed steel.

Radial spherical roller bearings are generally two-row bearings having one raceway that is a portion of a sphere; therefore, the bearings are internally self-aligning. In their most common form, the bearings have an outer raceway that is a spherical surface, and the rollers are symmetrical or barrel-shaped (Fig. 13). In this bearing design, a floating flange is usually employed to provide roller guidance; in another design using asymmetrical rollers, the rollers (as in tapered roller bearings) are driven against, and guided by, a fixed axial central flange. Some bearings with symmetrical rollers also use a fixed central guide flange. Depending on the bearing dimension series, from 1 to 2.5° of misalignment can be accommodated without detriment to bearing endurance. Because they have design contact angles that are >0° (usually >10°), double-row bearings can support combinations of very heavy radial and thrust loading. Conversely, a single-row spherical roller bearing has a nominal 0° contact angle and can only support a small amount of thrust load in conjunction with a much greater radial load.

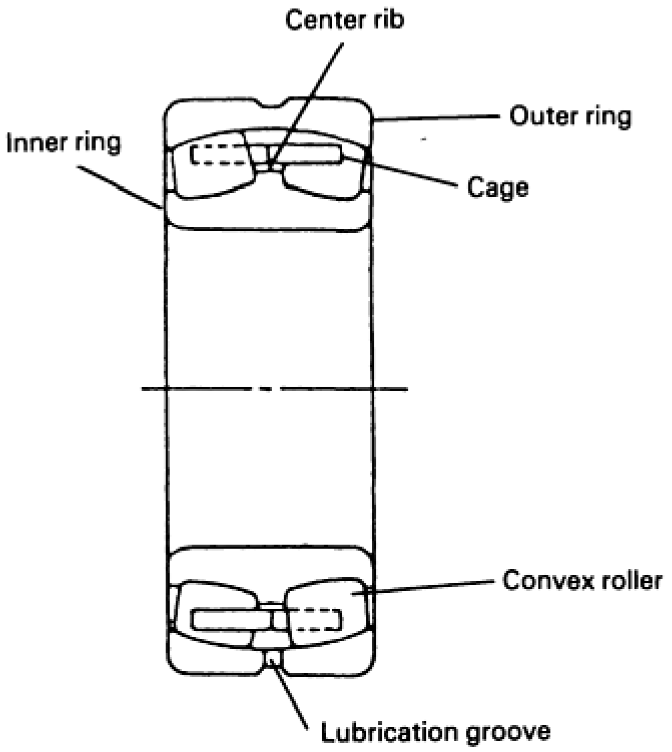

Fig. 13 Typical construction in a radial spherical roller bearing

Because of the relatively close matching of the curved roller profile to the raceways (that is, close osculations to achieve high load-carrying capacity) and bearing contact angle >0°, spherical roller bearings operate with substantial sliding in the roller-raceway contacts. Thus, the bearings are constrained to operate at relatively slow speeds unless lubrication systems are employed that can effectively remove the substantial amounts of friction heat generated. Cages in spherical roller bearings are usually either pressed steel or machined brass or bronze. Double-row bearings may be assembled with a cage for each row or with a one-piece cage.

Radial needle roller bearings (Fig. 14) are radial cylindrical roller bearings whose rollers have length/diameter ratios $\gg$1 (for example, roller length is 3*D* to 10*D*, where *D* is the roller diameter); roller diameter is generally not greater than 5 mm (0.2 in.). The bearings are used in moderate radial load and speed applications where radial space is at a premium. Needle roller bearings may be assembled as full complement bearings (that is, with no cage and a drawn steel cup outer ring or with machined and ground inner and outer rings and a pressed steel or molded plastic cage). Sometimes the bearings are supplied as outer ring-roller cage assemblies with rollers that ride directly on a properly hardened shaft.

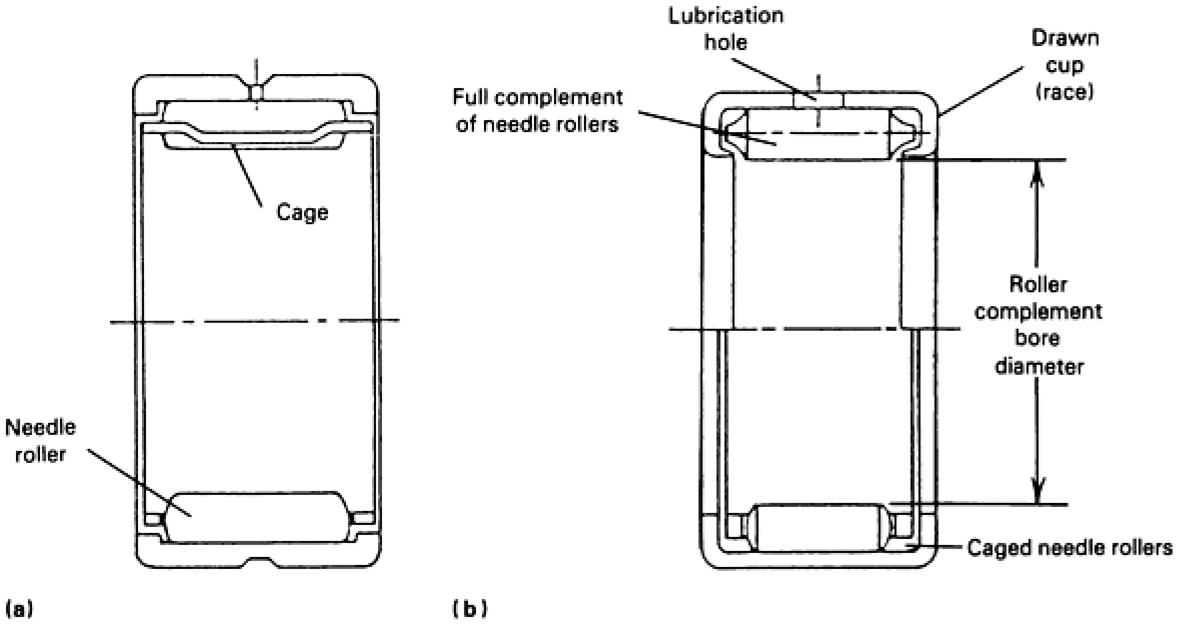

Fig. 14 Two types of radial needle roller bearing. (a) Machined ring with cage. (b) Drawn cup

The allowable operating speed of a full complement assembly is less than that of a bearing having precision-machined rings and cage; the allowable operating speeds of needle roller bearings are less than those of standard cylindrical roller bearings owing to the tendency of longer rollers to skew and cause increased friction heating.

Thrust Roller Bearings

Thrust roller bearings are available in cylindrical roller, needle roller, tapered roller, and spherical roller versions.

Thrust cylindrical roller bearings (Fig. 15) are 90° contact angle bearings designed to support axial load only. The rollers are similar to those of radial cylindrical roller bearings; however, because of the high contact angle, they operate with considerable sliding motion, causing substantial friction heating and limiting use of the bearings to slow-speed applications. To minimize friction, several rollers of relatively small length-diameter ratio may be used in a single-cage pocket as compared to use of a single roller of greater length.

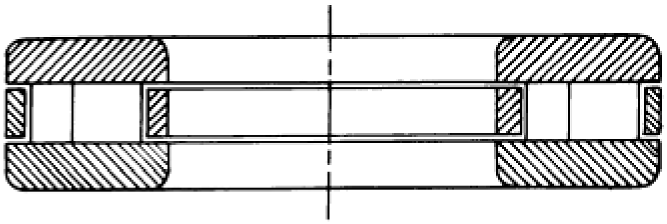

Fig. 15 Thrust cylindrical roller bearing limited to use with axial loads only due to its 90° contact angle

Thrust needle roller bearings operate with characteristics similar to those of thrust cylindrical roller bearings.

Thrust tapered roller bearings have steep contact angles to accommodate primarily axial load. However, in combination with relatively heavier axial load, thrust tapered roller bearings can also support radial load. Similar to radial tapered roller bearings, thrust tapered roller bearings are limited to relatively slow-speed operational unless means to remove friction heating are employed. This type of bearing is similarly sensitive to even small amounts of misalignment.

Spherical roller thrust bearings (Fig. 16) are usually single-row bearings with an outer raceway that is a portion of a sphere and with asymmetrical rollers that are of a continuously curved profile. They can support heavy combined thrust and radial loading, provided that thrust loading predominates and is sufficient to ensure the loading of all rollers. They are internally self-aligning and, depending on specific design, can accept 2 to 3° misalignment without detriment to endurance. They are generally constrained to relatively slow operation because of roller-raceway and roller end-flange friction heating unless means to remove such heat are provided in the application.

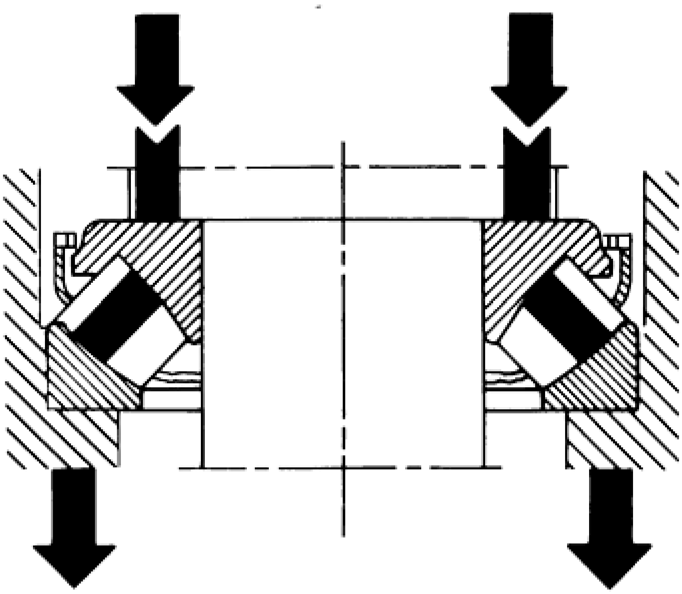

Fig. 16 Spherical roller thrust bearing, which incorporates asymmetrical rollers that tolerate a misalignment of ±3°

Bearing Component Materials

Rolling-Contact Component Steels. Most modern ball and roller bearing rings, balls, and rollers are manufactured from vacuum-processed AISI 52100, a high-carbon through-hardening steel, heat treated to at least 58 HRC. High-quality grades of this steel are required for ball and roller bearings to achieve the standard load rating generally published in the catalogs of bearing manufacturers for each bearing. The heat-treated steel is highly resistant to rolling-contact fatigue, but is considered brittle and susceptible to fracture in heavy load applications where ring bending can occur.

Some bearing types, principally tapered roller bearings, are fabricated from case-hardening steels such as SAE 4320, 4620, and 8620. These low-carbon steels are carburized (that is, heat treated in a carbonaceous atmosphere), such that the case, in which carbon is absorbed (surface and near-surface material), is hardened to $\geq$58 HRC while the remaining core is hardened to $\sim$45 HRC. This provides a case that resists rolling-contact fatigue and a core that resists fracture. The carburized bearing material has a fracture toughness of $\sim$40 MPA $\sqrt{\text{m}}$(36 ksi $\sqrt{\text{in.}}$), approximately twice that of through-hardened 52100 steel. Bearing components fabricated from both 52100 and the case-hardening steels cited above can operate continuously at temperatures up to 160 °C (320 °F) without any reduction of fatigue endurance capability.

For bearings that must operate in corrosive environments (for example, water and salt-laden atmospheres), bearings with rings and rolling elements manufactured from AISI 440C, a stainless steel, are frequently used. Instrument and miniature ball bearings, which must have smooth uninterrupted minimum friction operation at all times, are fabricated from 440C material. This high-carbon chromium-rich steel can be through-hardened to 58 HRC; however, bearing fatigue endurance is somewhat less than that of the same bearing fabricated from AISI 52100. Satisfactory bearing operation at temperatures up to 160 °C (320 °F) can be expected.

Bearings that must operate at elevated temperatures are usually manufactured from tool steels, AISI M50 being most prevalent in use. Bearings with rolling-contact components fabricated from M50 are capable of steady-state operation to

at least 300 °C (572 °F), provided that bearing internal design, cage materials, lubricants, and materials of other components associated with the bearing operation can accommodate the operating temperatures. The steel is routinely through-hardened to ≥58 HRC. M50 steel is supplied as consumable vacuum-melted (CVM) M50 and as vacuum induction melted/vacuum arc remelted (VIMVAR) highly homogeneous, minimum inclusion variants that provide exceptional resistance to rolling-contact fatigue in most applications. M50 Nil, a carburizing variant, provides similar properties in addition to increased fracture toughness.

Rolling-Element Ceramics. As an alternative to steel in machine tool bearing applications, hot isostatically pressed silicon nitride (Si_3N_4) ceramic balls are being used. Bearings with steel rings and ceramic balls are called hybrid ball bearings. Because of the lower density of silicon nitride and its increased rigidity, these high-speed bearings tend to operate with less friction, lower temperatures, and increased stiffness than bearings with steel balls. These bearings also tend to be more expensive.

Cage Materials. The most common materials used for rolling bearing cages are low-carbon steels that can be pressed or stamped (for example, AISI 1010 or 1020). Alternatively, stamped cages are fabricated from brass. Such cages can be either rolling-element riding or land riding. In many applications, molded polyamide 6/6 (nylon) is used in place of metal. The nylon is generally supplied with 25% glass fiber filling for appropriate strength and satisfactory continuous operation at temperatures up to 100 °C (212 °F); they can be used at slightly higher temperatures if operation at these temperatures is intermittent. Bearings with plastic cages tend to operate with slightly less friction and can therefore achieve higher operating speeds without special attention to friction heat removal.

Precision-machined cages are manufactured from steel (for example, AISI 4349, brass, bronze, and variations such as silicon-iron-bronze and alcop (aluminum-copper bronze). Bearings with such machined cages are either inner or outer ringland riding (Fig. 17). Bearings with such cages can generally achieve higher operating speeds than bearings with stamped metal cages. Precision cages are also machined from fabric-reinforced phenolic resin for very high-speed operating bearings (for example, for machine tool applications); however, operating temperatures are limited to 120 °C (248 °F).

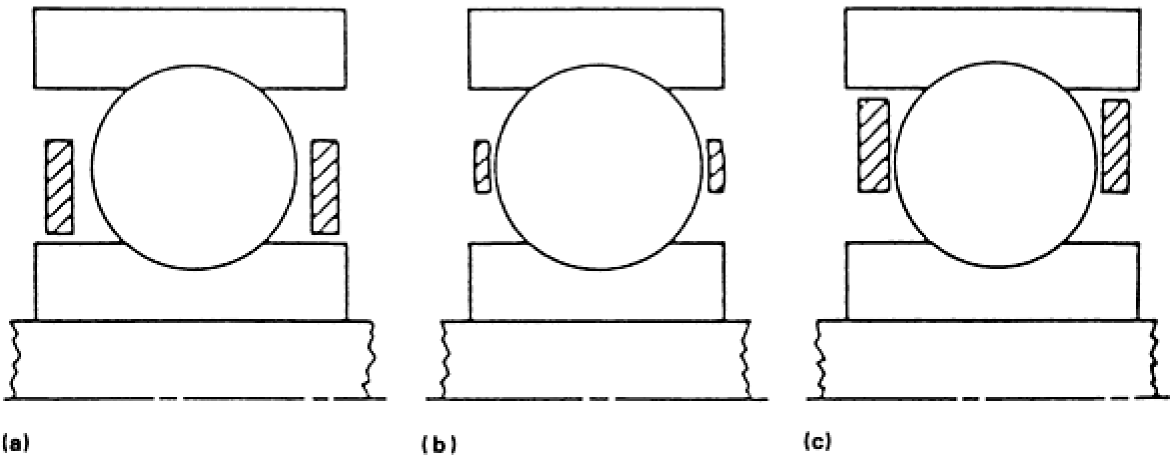

Fig. 17 Schematic showing types of rolling bearing cages. (a) Inner ringland riding. (b) Ball riding. (c) Outer ringland riding

Lubrication Requirements and Methods

To obtain satisfactory performance and rated endurance of rolling bearings, adequate fluid lubrication is necessary. The lubricant is required to:

- Form fluid films between the rolling elements and raceways, rolling elements and cage pockets, cage rails and ring lands, roller ends and abutting flanges, thereby minimizing metal-to-metal contact,

friction, and wear

- Contain chemical additives to minimize rolling-contact surface corrosion and wear
- Transport friction heat away from the bearing

In general, only a small amount of lubricant is required to perform the first two functions. In fact, too much lubricant in the bearing free space or cavity will cause excessive fluid churning, increased bearing friction, and higher operating temperatures. Therefore, the amount of circulating lubricant required to remove friction heat must be carefully determined to avoid overheating and potential early failure.

Grease Lubrication. Most rolling-element applications are lubricated with grease because such lubrication is the most economical and simplest mechanical means to accomplish the task. Greases are combinations of fluid lubricants (oils) with metallic soap thickeners; the oil contained in the grease provides most of its lubricating ability. For grease lubrication to be effective, however, bearing operating speeds must be relatively slow ($<3 \times 10^5\ n \cdot d_m$). This is due to the inability of the grease to dissipate friction heat generation caused by high speed and also its inability to replenish rolling-contact surface fluid lubricant due to insufficient bleeding (flow) rate (lubricant starvation). Heat dissipation from the bearing is achieved mainly by conduction through metal structures.

Many bearings are supplied in the greased-for-life form, in which the grease charge is kept in the bearing by integral seals (Fig. 18). The elastomeric material used as the sealing element must be compatible with the application operating temperatures and environment to obtain satisfactory seal endurance. The amount of grease charge must be carefully metered because excessive grease can cause churning (which produces immediate overheating) and insufficient grease can result in inadequate replenishment of lubricant films (which leads to eventual overheating). When operating temperatures exceed the temperature capability of the grease, aging (oxidation) occurs that reduces the capability of the grease to lubricate. Generally, the charge of grease should occupy from one-third to one-half of the free volume. Lithium soap (thickener) greases are most frequently used; the type of grease used depends on the operating temperatures and application requirements. The upper temperature limit for a grease is determined by the type of thickener. A rule of thumb is that grease life is halved with each 11 °C (20 °F) increase in bearing temperature.

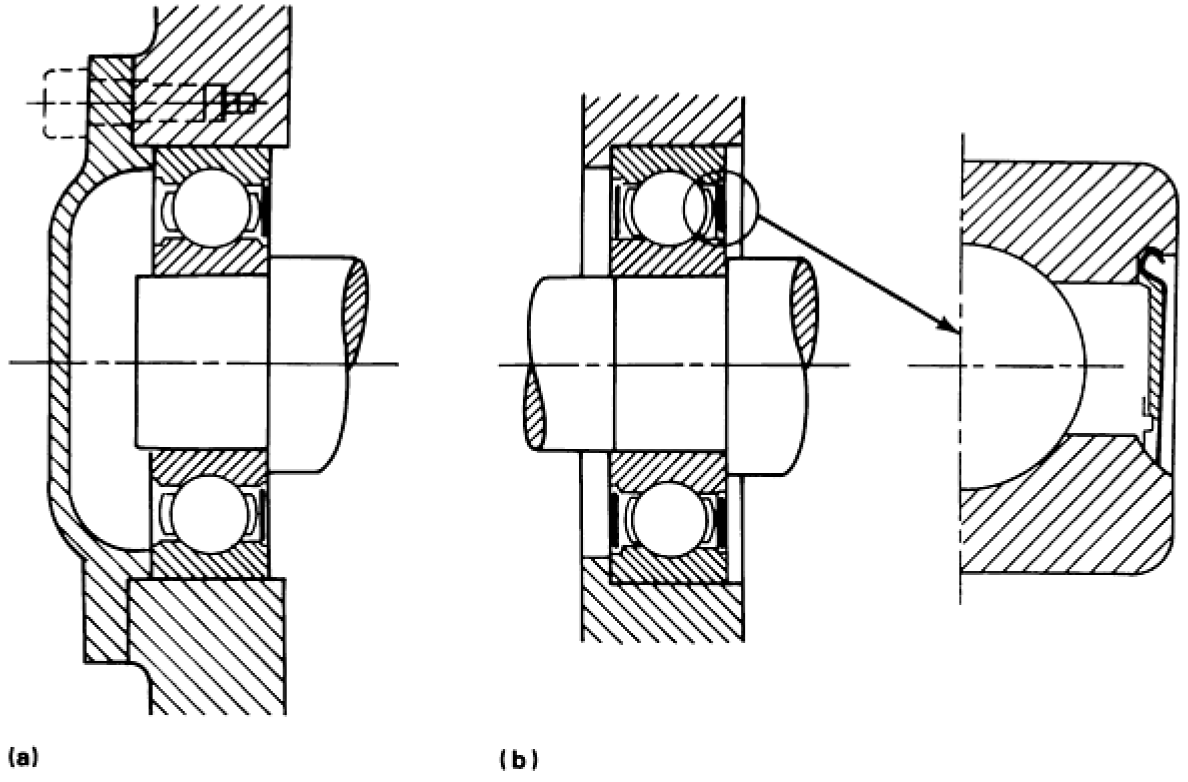

Fig. 18 Location of elastomeric integral seals in a ball bearing. (a) Single-face seal. (b) Dual-face seal

Rolling bearings are frequently mounted in pillow blocks (housings), which have fittings for regreasing (Fig. 19). In this case, the bearings are open and the pillow blocks are supplied with seals to prevent the loss of grease. Regreasing intervals, as recommended by bearing manufacturers, depend on the bearing design and application conditions. When a bearing is regreased, it is essential that the new grease pushes through the bearing and the used grease is effectively purged.

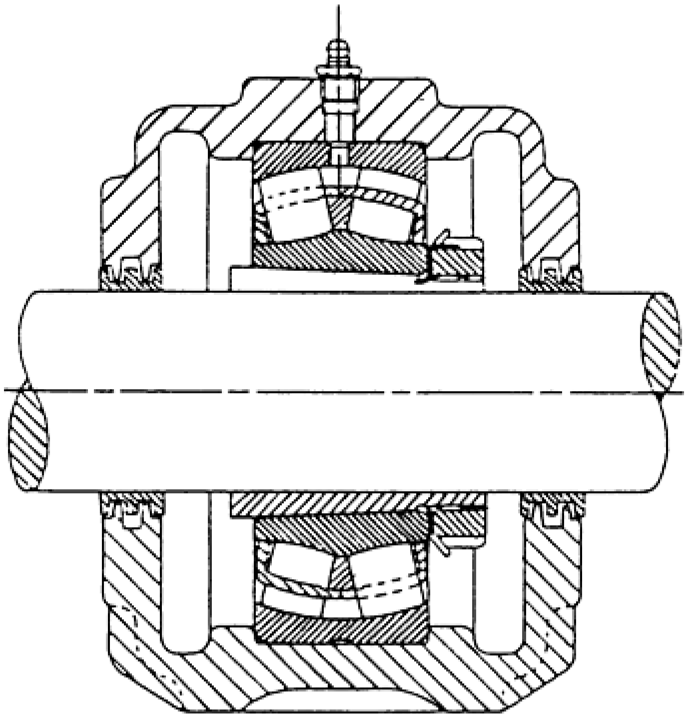

Fig. 19 Location of regreasing fitting in a pillow block mounting

For additional information about the composition and application of grease, see the article "Grease" in this Volume.

Bath Lubrication. Many rolling bearings are effectively operated using oil bath lubrication. For horizontally mounted bearings, a portion of the bearing ball or roller complement is covered by the lubricant bath (Fig. 20). As the cage-rolling element set rotates, each rolling element in succession dips into the bath, carrying sufficient oil with it to adequately lubricate the entire bearing. Lubricant returns by gravity to the bath. The level of the bath must be such that the process is achieved without lubricant starvation at the rolling contacts most remote from the bath. If the lubricant level is too high, excessive lubricant churning occurs, with potential bearing overheating and failure. In general, the lubricant level should not be higher than the center of the lowest rolling element under nonoperating conditions.

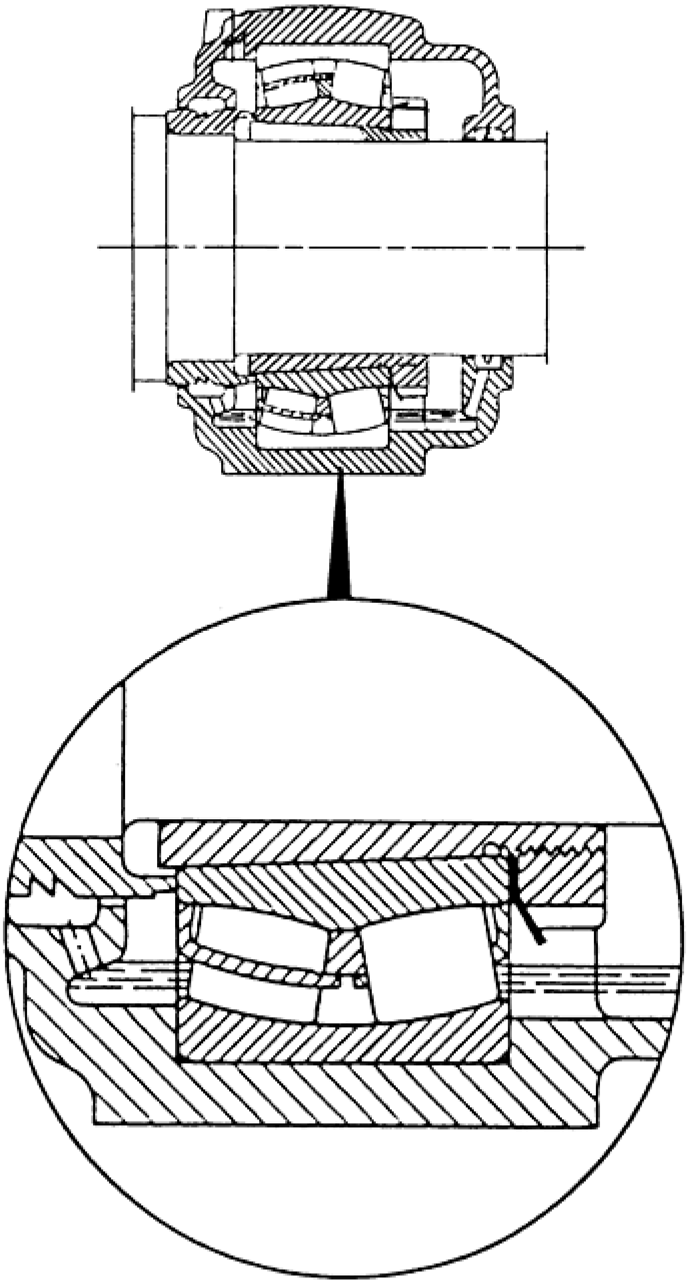

Fig. 20 Oil bath lubrication suitable for low speeds of rotation. When the bearing is not rotating, oil should come to level just below center of lowest ball or roller. When the bearing rotates, oil is drawn up by bearing moving components, transported through the bearing, and returned by gravity to the bath.

For vertically mounted bearing applications, the optimum lubricant levels must be established according to the operating speeds and bearing internal design.

Bath-lubricated bearings can operate at higher speeds than grease-lubricated bearings because the bearing components transfer most of their friction heat to the lubricant by convection. The lubricant subsequently splashes on the bearing housing internal surfaces, transferring heat by mass transfer and convection. This heat is then conducted through the housing structure for dissipation by free or forced convection to the environment.

Circulating-Oil Lubrication. When bearing operating speeds are high and applied loading is very heavy, it is frequently necessary to utilize circulating-oil lubrication. In this case, lubricant that is supplied to the bearing is subsequently passed through a heat exchanger to remove friction heat (that is, reduce the lubricant temperature prior to returning the lubricant to the bearing). In applications where the generation of friction heat is exceptionally great, a jet

supply of lubricant can be used in which one or more jets of lubricant impinges directly on the bearing rotating components (Fig. 21). Where jet supply of lubricant is used, significant amounts of lubricant churning can be expected, with attendant high friction heating. This extra heat must also be removed, increasing the bearing cooling requirements.

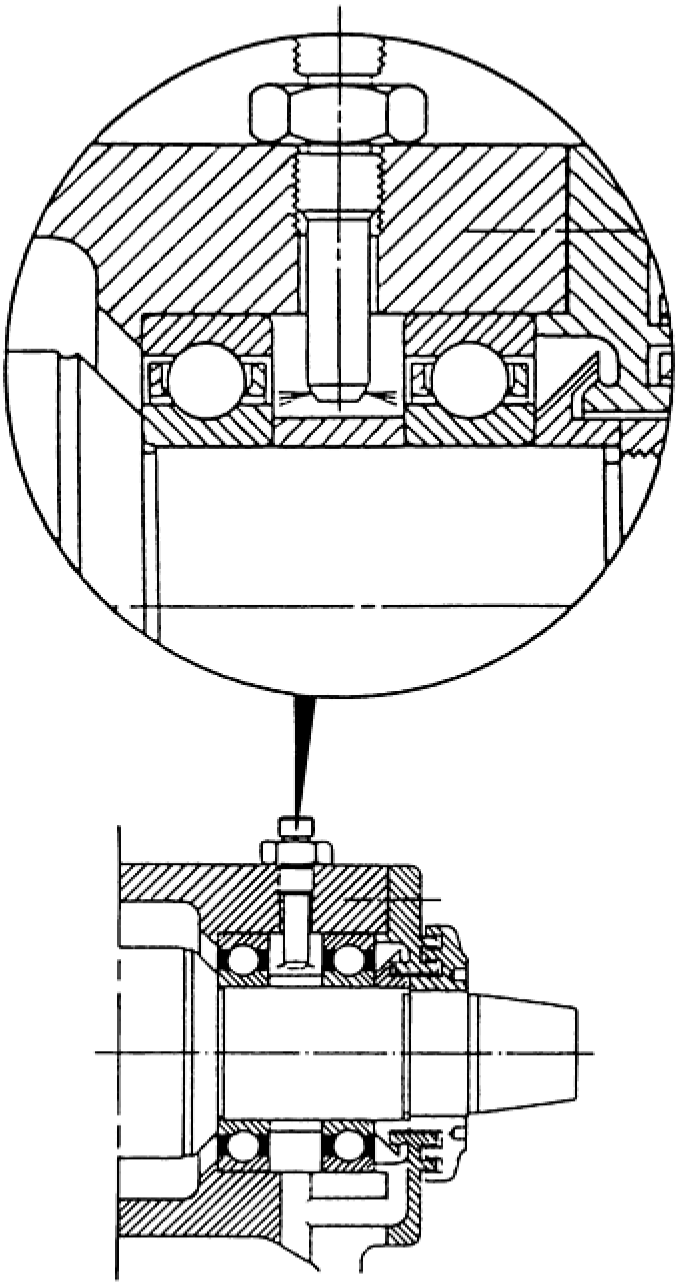

Fig. 21 Oil jet lubrication suitable for high speeds of rotation. Oil is injected into the bearing under pressure to gain access to the bearing interior to remove heat. Oil jet velocity must be high enough to piece air vortex caused by bearing rotation.

Load Ratings

In general, to satisfy application conditions, ball and roller bearings are selected from the catalogs of bearing manufacturers according to basic dynamic and basic static load ratings. For most manufacturers, these ratings are based on internationally established standard methods of calculation (Ref 2, 3, 4, 5). Basic dynamic load rating in conjunction with the applied loading is used to estimate the ability of the bearing to withstand the surface fatigue of the components in rolling contact. Basic static load rating in conjunction with the statically applied load is used to determine the ability of

the bearing to resist permanent indentations. Frequently, many other criteria must be considered to establish the suitability of a given rolling bearing for a given application (for example, elastic deflection, friction torque, friction heat generation, operating temperatures, corrosion resistance, operating vibration, noise level, and son on). Nevertheless, most bearings are selected for given applications based on their resistance to rolling-contact fatigue and permanent deformation, and based on the load ratings published in the catalogs of manufacturers.

Fatigue failure of the surfaces in rolling contact was selected as the endurance criterion for ball and roller bearings because it was considered that all other modes of bearing failure could be prevented if the bearing rolling contact components were:

- Accurately manufactured from high-quality bearing steel
- Properly lubricated
- Keep free of contaminants
- Properly mounted and operated in the application

Bearing endurance as limited by rolling-contact fatigue represented the longest period of time a bearing could reliably perform its intended function. The failure mode manifested itself as a spall or flaking of material from a rolling-contact surface. This failure mode is considered a form of wear because material is removed from the rolling-contact surfaces (Fig. 22). Moreover, bearing endurance is a statistical phenomenon; that is, apparently identical roller bearings subjected to apparently identical conditions of operation will not achieve identical failure endurance. Instead, they will tend to fail according to a statistical distribution (Fig. 23). A Weibull distribution (Ref 6) has been shown to adequately approximate the bearing fatigue life dispersion. For ball bearings, it has been demonstrated that the median life, L_{50}, is approximately equal to five times the rating life, L_{10}:

$$L_{50} = 5L_{10} \qquad \textbf{(Eq 1)}$$

Standard ball and roller bearing dynamic load ratings are based on the work of Lundberg and Palmgren (Ref 7, 8). Their method of determining basic dynamic load ratings was based on rolling-contact fatigue testing of ball and roller bearings during the 1930s and 1940s. Because of the substantial improvements in bearing steels, bearing steel processing, and bearing manufacturing methods since that time, the standard calculation methods have been modified several times to accommodate the improvements. The basic static load rating is based on the work of Lundberg *et al.* (Ref 9); the current standard method reflects relatively recent improvement in the accuracy of determining permanent deformations during testing. Both basic dynamic load ratings and basic static load ratings have undergone substantial increases since the original rating methods were established. Because bearing load ratings have increased substantially over time, it follows that to resist specific loading, smaller bearings are now being employed (that is, downsizing of bearings has occured).

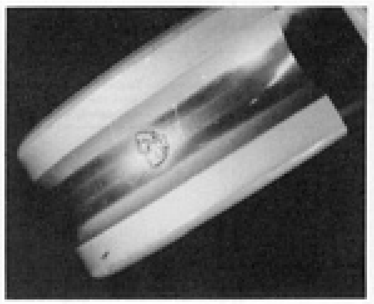

Fig. 22 Fatigue spall centered on a ball bearing race-way

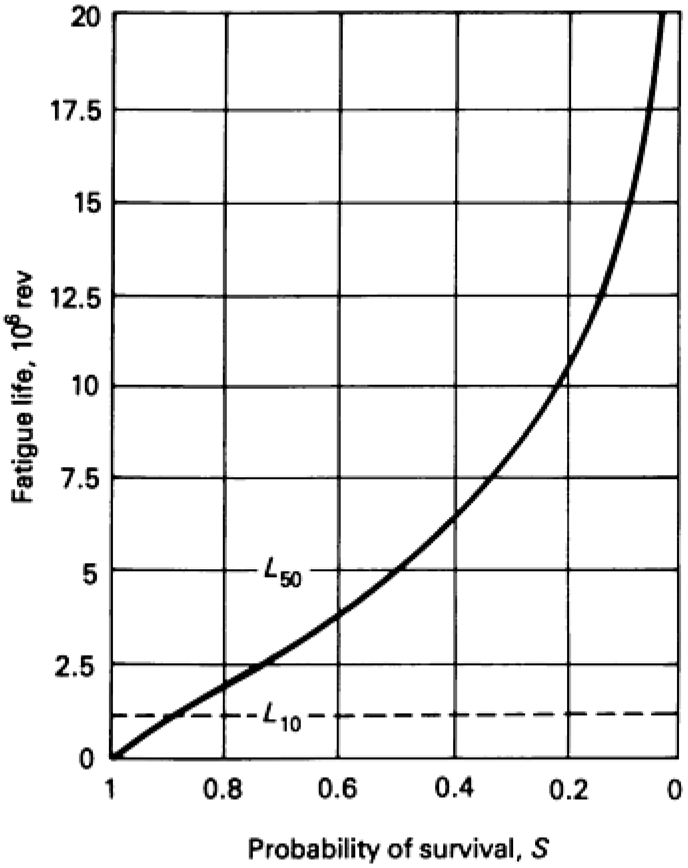

Fig. 23 Plot of fatigue life versus probability of survival to indicate rolling bearing fatigue life distribution.

Basic Load Rating

Basic load rating (also called basic dynamic load rating or basic dynamic capacity) is defined as that load which 90% of a group of apparently identical rolling bearings will survive (rolling-contact fatigue) with a life of one million revolutions. For radial ball bearings, the International Standards Organization (ISO) (Ref 2) gives the following equations:

$$C_r = b_m f_c (i \cdot \cos \alpha)^{0.7} Z^{2/3} D^{1.8} \quad D \leq 25.4 \text{ mm} \qquad \textbf{(Eq 2)}$$

$$C_r = 3.647 b_m f_c (i \cdot \cos \alpha)^{0.7} Z2/3D^{1.4} \quad D > 25.4 \text{ mm} \qquad \textbf{(Eq 3)}$$

in which

C_r = basic radial load rating (in newtons)

b_m = rating factor for contemporary, normally used material and manufacturing quality, the value of which varies with the bearing type and design

f_c = factor that depends on the composition of the material, the geometry of the bearing components, and the accuracy to which the various components are made

- i = number of rows of balls
- α= nominal contact angle (in degrees)
- Z = number of balls per row
- D = ball diameter (in mm)

b_m can be obtained from Table 1 for different bearing types, and f_c can be obtained from Table 2 as a function of the geometry parameter ($D \cdot \cos \alpha$)/d, in which d is the bearing pitch diameter (in mm). The tabular data pertain strictly to radial and angular-contact bearings having inner ring groove radii $\leq$0.52D and outer ring groove radii $\leq$0.53D and to self-aligning bearings having inner ring groove radii $\leq$0.53D.

Table 1 b_m factors for selected rolling bearing types

Bearing type	b_m
Ball bearings	
Radial and angular-contact ball	1.3
Filling slot ball	1.1
Self-aligning ball	1.3
Thrust ball	1.3
Roller bearings	
Cylindrical roller	1.1
Tapered roller	1.1
Needle roller with machined rings	1.1
Drawn cup needle roller	1
Spherical roller	1.15
Cylindrical roller thrust	1
Needle roller thrust	1
Tapered roller thrust	1
Spherical roller thrust	1.15

(a) f_c values for intermediate values of $(D \cdot \cos \alpha)/d$ are obtained by linear interpolation.

Standard Bearing Internal Geometry

The ratio of the raceway curvature radius (ring groove radius) to the ball diameter, $f = r/D$, together with the parameter $(D \cdot \cos \alpha)/d$, internal radial clearance, and applied load determine the normal stresses in the rolling element-raceway contacts. The standard formulas for basic radial load rating are based on the nominal clearance that produces a radial load distribution among the rolling elements (Fig. 24). Normal stresses depend on the contact geometry and rolling-element load; hence, maximum stress occurs colinear with the applied radial load. Moreover, the contact areas are elliptical in shape, and the distribution of stress in each contact is as shown in Fig. 25. In most bearing applications, maximum normal stress in the contacts rarely exceeds 2000 MPa (290 ksi); however, maximum stresses as high as 3300 MPa (475 ksi) can be carried (by properly hardened steel bearings) without significant permanent deformation of the contact geometry. If bearing raceway groove curvatures are different from those indicated above, then the standard load rating formulas cannot be used. If the raceway curvature radius is greater than standard, normal stresses will be greater than standard and the basic load rating can be considerably less than standard. Also, if a bearing has an internal radial clearance greater than

standard, maximum rolling-element load will be greater than standard, and the basic load rating will accordingly be less than standard. Harris (Ref 10) provides methods for rating bearings with nonstandard internal geometries.

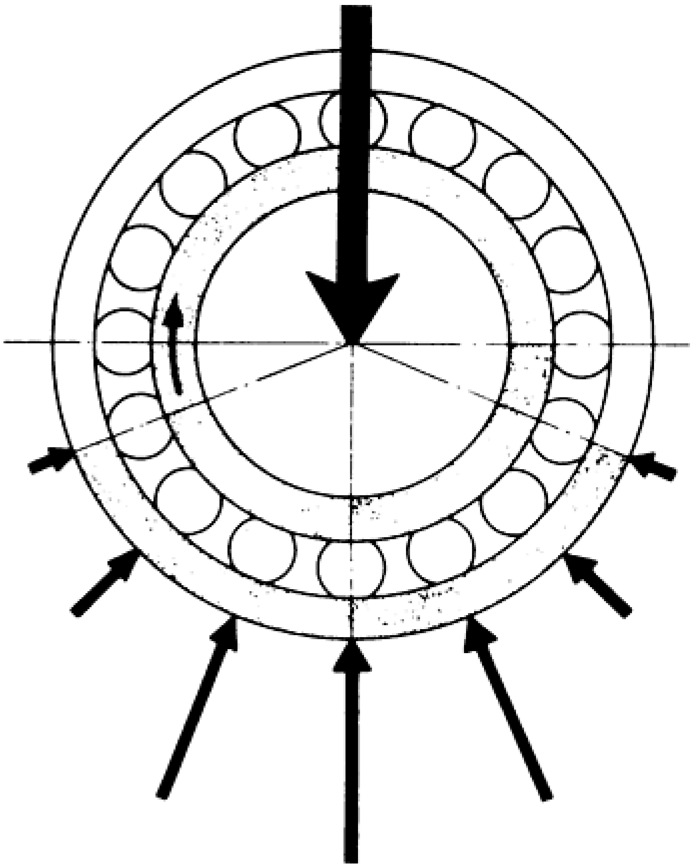

Fig. 24 Distribution of radial load among rolling elements in a bearing

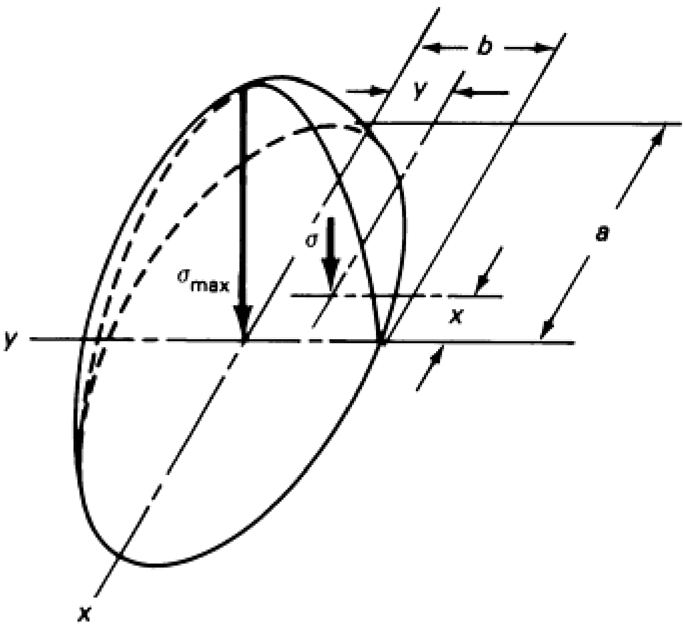

Fig. 25 Normal (Hertzian) contact stress distribution obtained over an elliptical rolling element-raceway contact area in a bearing. σ_{max} is the maximum normal contact stress at the center of contact and σ is the contact

stress anywhere else.

For thrust ball bearings the following equations pertain:

$$C_a = b_m f_c Z^{2/3} D^{1.8} \quad D \leq 25.4 \text{ mm}; \alpha = 90° \qquad \textbf{(Eq 4)}$$

$$C_a = b_m f_c (\cos \alpha)^{0.7} (\tan \alpha) Z^{2/3} D^{1.8} \quad D \leq 25.4 \text{ mm}; \alpha \neq 90° \qquad \textbf{(Eq 5)}$$

$$C_a = 3.647 \; b_m f_c Z^{2/3} D^{1.4} \quad D > 25.4 \text{ mm}; \alpha = 90° \qquad \textbf{(Eq 6)}$$

$$C_a = 3.647 b_m f_c (\cos \alpha)^{0.7} (\tan \alpha) Z^{2/3} D^{1.4} \quad D > 25.4 \text{ mm}; \alpha \neq 90° \qquad \textbf{(Eq 7)}$$

where Z is the number of balls carrying load in one direction. As mentioned earlier in the section "Basic Load Rating" in this article, b_m can be obtained from Table 1; values of f_c are given in Table 3. The tabular data pertain strictly to bearings with ring groove radii $\leq 0.54D$. For bearings with two or more rows:

$$C_a = \sum_{1}^{i} Z_n \cdot \left[\sum_{1}^{i} \left(\frac{Z_n}{C_{an}} \right)^{10/3} \right]^{-3/10} \qquad \textbf{(Eq 8)}$$

(a) f_c values for D/d or $(D \cdot \cos \alpha)/d$ and α other than shown in the table are obtained by linear interpolation or extrapolation.

(b) Values for $\alpha = 45°$ permit interpolation of values for $45° < \alpha < 60°$.

Standard Bearing Contact Geometry

As with radial ball bearings, standard formulas for thrust ball bearing load ratings apply only for bearings having standard internal geometry. Moreover, it is presumed that the thrust load carried by each ball is identical (that is, the internal load distribution shown in Fig. 26 applies).

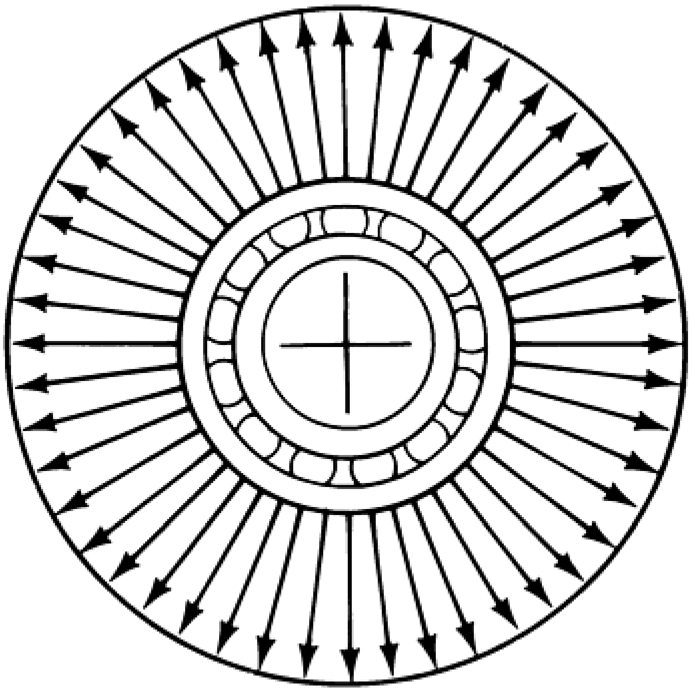

Fig. 26 Distribution of (simple) thrust load among rolling elements in a bearing

For radial roller bearings:

$$C_r = b_m f_c (il \cdot \cos \alpha)^{7/9} Z^{3/4} D^{29/27} \qquad \textbf{(Eq 9)}$$

where l is the roller effective length (in mm). Roller effective length is the total length of the roller minus corner radii or raceway undercuts, whichever length is smaller. Values of b_m are given in Table 1; f_c values are given in Table 4.

Table 4 Maximum f_c factors for radial roller bearings

(a) f_c values for intermediate values of $(D \cdot \cos \alpha)/d$ are obtained by linear interpolation.

Similarly, for thrust roller bearings:

$$C_a = b_m f_c l^{7/9} Z^{3/4} D^{29/27} \quad \alpha = 90° \qquad \textbf{(Eq 10)}$$

$$C_a = b_m f_c (l \cdot \cos \alpha)^{7/9} (\tan \alpha) Z^{3/4} D^{29/27} \quad \alpha \neq 90° \qquad \textbf{(Eq 11)}$$

Values of b_m are given in Table 1; f_c values are given in Table 5. For bearings with two or more rows of rollers:

$$C_a = \sum_1^i (Z_n l_n) \cdot \left[\sum_1^i \left(\frac{Z_n l_n}{C_{an}} \right)^{9/2} \right]^{-2/9} \qquad \textbf{(Eq 12)}$$

(a) f_c values for intermediate values of D/d or $(D \cdot \cos \alpha)/d$ are obtained by linear interpolation.

(b) Applicable for 45° < α < 60°.

(c) Applicable for 60° $\leq \alpha$ < 75°.

(d) Applicable for 75° $\leq \alpha$ < 90°

Standard Roller Geometry

Use of Eq 9, 10, 11, and 12 presumes that the rollers are crowned as in Fig. 10 so that under loads as heavy as 4*C*, where *C* is the bearing capacity, stress concentrations due to edge loading (Fig. 27) in the contacts are avoided. If appropriate crowning is not employed, basic load ratings can be significantly reduced from standard. With regard to nonstandard bearing internal clearance, the load rating situation is identical to that for ball bearings (that is, excessive clearance will result in reduced load-carrying capacity).

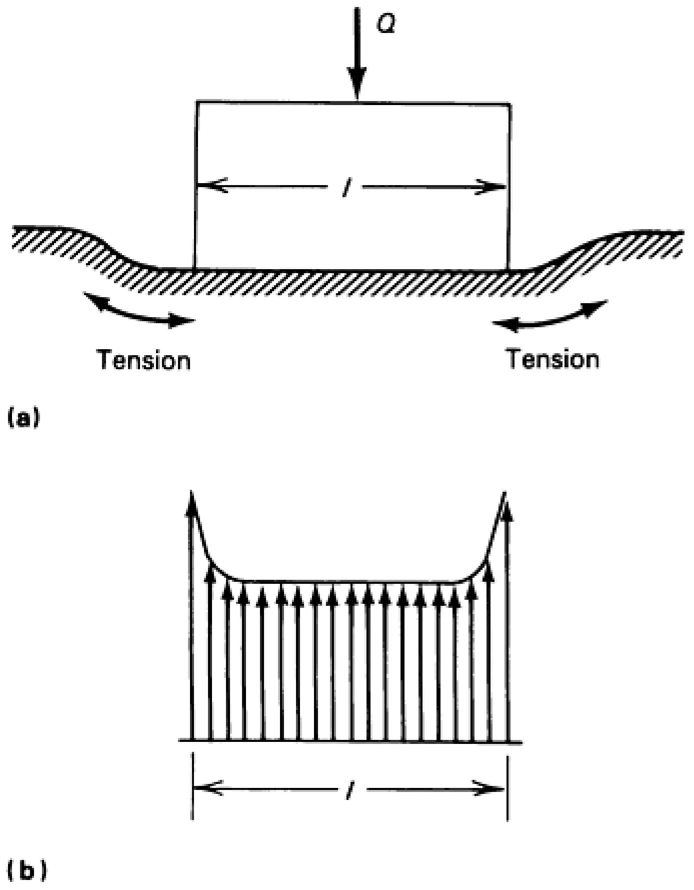

Fig. 27 Roller axial load distribution associated with edge loading. (a) Schematic showing load, *Q*, applied to roller of length, *l*. (b) Load distribution across roller

Bearing Fatigue Life

Using the basic load rating obtained either from a catalog supplied by a bearing manufacturer or from the appropriate equation, bearing rolling-contact fatigue life in a given application can be determined using the following equation:

$$L_{na} = a_1 a_2 a_3 \left[\frac{C}{P}\right]^x \qquad \textbf{(Eq 13)}$$

where

- L_{na} = bearing life (in millions of revolutions)
- a_1 = life adjustment factor for reliability
- a_2 = life adjustment factor for special bearing properties
- a_3 = life adjustment factor for operating conditions
- P = dynamic equivalent load (in N)

In Eq 13, the exponent x = 3 for ball bearings and x = 10/3 for roller bearings; a_1 values for desired levels of reliability can be obtained from Table 6.

Table 6 Life adjustment factor for reliability, a_1

Reliability, %	L_{na}	a_1
90	L_{10a}	1
95	L_{5a}	0.62
96	L_{4a}	0.53
97	L_{3a}	0.44
98	L_{2a}	0.33
99	L_{1a}	0.21

For bearings specified in the catalogs of manufacturers, a_2 factors of 1 are appropriate in the calculation of fatigue life; however, a_2 values >1 may be applicable if the bearings are fabricated from steel of particularly low impurity content or of special analysis. Conversely, if hardness reduction occurs due to a special heat treatment, $a_2 < 1$ should be used. Moreover, special internal design involving increased or reduced uniformity of stress in the rolling contacts can be accommodated by appropriate selection of a_2.

The a_3 operating conditions factor depends strongly on the effectiveness of lubrication and the presence of foreign matter (contaminants) in the application. In the calculation of bearing fatigue life, lubrication is considered normal ($a_3 = 1$) when the lubricant films generated in the rolling element-raceway contacts have thicknesses equal to, or slightly greater than, the composite root-mean-square (rms) roughness of the contacting surfaces. $a_3 < 1$ should be considered when kinematic viscosity of the lubricant at the bearing operating temperature is <13 cSt for ball bearings or <20 cSt for roller bearings and bearing operating speed in rev/min, n, times pitch diameter in mm, d_m, is $<10^4$ ($nd_m < 10^4$). When lubricant films are insufficient to completely separate the rolling-contact surfaces, it is possible that a chemical interaction will occur between the bearing material and the lubricant that will necessitate a reduction in a_2. Accordingly, it cannot be assumed that a reduced value of a_3 can be compensated by use of a steel nominally having $a_2 > 1$. a_3 values > 1 can be considered only where lubrication conditions are so favorable that the probability of failure by surface-oriented distress is virtually eliminated. Bearing manufacturers can recommend appropriate values of a_3.

Equivalent Load. The dynamic equivalent load for a radial bearing is that purely radial load which, if applied to the bearing, would result in the same fatigue life as the actual applied load. For bearings subjected to combined radial and thrust loading, it can be determined from Eq 14:

$$P = XF_r + YF_a \qquad \textbf{(Eq 14)}$$

where F_r is the applied load (in N), and F_a is the applied thrust load (in N). For radial ball and roller bearings, the factors X and Y can be obtained from Tables 7 and 8, respectively.

Table 7 *X* and *Y* factors for radial ball bearings

(a) Permissible maximum value depends on bearing design internal clearance and raceway groove depth. Use first or second column depending on available information.

(b) Values of *X*, *Y*, and *e* for intermediate "relative axial loads" and α obtained by linear interpolation.

(c) For f_o values, see Ref 3.

Table 8 *X* and *Y* factors for radial roller bearings

Bearing type	$(F_a/F_r) \leq e$		$(F_a/F_r) > e$		e
	X	*Y*	*X*	*Y*	
Single row, $\alpha \neq 0$	1	0	0.4	0.4 cot α	1.5 tan α
Double row, $\alpha \neq 0$	1	0.45 cot α	0.67	0.67 cot α	1.5 tan α

Similarly, the dynamic equivalent load for a thrust bearing is that purely thrust load which, if applied to the bearing, would result in the same fatigue life as the actual applied load. Equation 14 can be used to determine the dynamic equivalent thrust load; however, *X* and *Y* factors are obtained from Tables 9 and 10 for thrust ball and roller bearings, respectively.

Table 9 *X* and *Y* factors for thrust ball bearings

Single direction, $\alpha \neq 90°$	[a]	[a]	tan α	1	1.5 tan α

(a) $F_a/F_r < e$ is unsuitable for single-direction bearings.

Nonstandard Application Conditions. The determination of bearing load rating and fatigue life using Eq 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14 and the appropriate tables assumes that the bearing internal design and materials meet the limiting criteria and that operating conditions are not unusual; that is, they do not involve high speed, exceptionally heavy or light loading, high temperatures, and so on. Such conditions alter the bearing internal load distributions and contact stresses from those on which the load and life rating methods are based. For these situations, more sophisticated means of evaluation are available as detailed by Harris (Ref 10); these frequently require the use of a computer to perform the required analyses.

Fatigue Load Limit. Use of Eq 13 implies that even under extremely light loading, ball and roller bearing endurance is limited by rolling-contact fatigue. Ioannides and Harris (Ref 11), however, demonstrated that if a certain limiting stress is not exceeded in a given application, then rolling-contact fatigue can be eliminated as a consideration for bearing failure. This limiting stress is a function of the bearing internal design, the bearing material, and lubrication conditions. Use of a fatigue limit stress or endurance limit as a bearing selection criterion is demonstrated in Ref 12, which includes a fatigue load limit, P_u, for each bearing. Even if applied load exceeds the fatigue load limit, bearing fatigue endurance is longer than that predicted by Eq 13, depending on the magnitude of P/P_u. For $P \ggg P_u$, Eq 12 remains substantially accurate and is not conservative.

Effect of Contamination on Fatigue Life. In the selection of a bearing, the level of contamination in the application must be considered. Sayles and MacPherson (Ref 13) reported the effect of lubricant filtration on rolling-contact fatigue endurance. To obtain the fatigue lives predicted using Eq 13, especially for high-precision bearings manufactured from high-performance steels, it is necessary to minimize the contamination amount and particle size entering the bearing. Hard contaminants of sufficient size will dent the rolling-contact surfaces causing stress concentrations, interrupting lubricant film formation and reducing fatigue endurance. Hamer *et al.* (Ref 14) have shown that, depending on the application operating conditions, even soft contaminants can cause dents, thereby reducing endurance. Contamination can be precluded by providing a bearing with integral seals or by employing effective sealing means in the application. In the use of a fatigue load limit in the fatigue endurance calculation, Ref 12 takes into account the effect of contamination.

Basic Static Load Rating. According to Ref 3, 4, 5, experience shows that a total permanent deformation approximating 0.0001D at the center of the most heavily loaded rolling element-raceway contact can be tolerated in most bearing applications without impairing the operation of the bearing. Such indentation can occur due to loading when the bearing is not rotating or due to heavy shock load during operation. The basic static load rating is the load applied in such a way that it results in this permanent deformation magnitude. Furthermore, for most ball bearings, static loading that produces 4200 MPa (610 ksi) stress at the center of the most heavily loaded contact will also cause permanent deformation approximating 0.0001D. This equivalent stress is 4600 MPa (670 ksi) for self-aligning ball bearings and 4000 MPa (580 ksi) for roller bearings. Using the appropriate stress criterion, basic static load ratings are created for catalog ball and roller bearings.

For radial ball bearings, the basic static radial load rating (in newtons) can be determined from Eq 15:

$$C_{or} = f_o i Z D^2 \cos \alpha \qquad \textbf{(Eq 15)}$$

for which f_o values are given in Table 11. The values of Table 9 pertain to bearings having the same groove radii dimensional limitations as defined for basic radial load rating tabular data.

(a) f_o values for intermediate values of $(D \cdot \cos \alpha)/d$ are obtained by linear interpolation.

(b) It is assumed that load distribution results in maximum ball load of $5F_r/(Z \cdot \cos \alpha)$.

(c) It is assumed that load distribution results in maximum ball load of $F_a/(Z \cdot \sin \alpha)$.

For thrust ball bearings, the basic static axial load rating (in newtons) is given by:

$$C_{oa} = f_o Z D^2 \sin \alpha \qquad \textbf{(Eq 16)}$$

for which f_o, values are also given in Table 11 and were Z is the number of balls carrying load in one direction. The basic static radial load rating for radial roller bearings is obtained from Eq 17:

$$C_{or} = 44 \left(1 - \frac{D \cdot \cos \alpha}{d}\right) iZlD \cdot \cos \alpha \qquad \textbf{(Eq 17)}$$

Similarly, the basic static axial load rating for thrust roller bearings is obtained from Eq 18:

$$C_{oa} = 220 \left(1 - \frac{D \cdot \cos \alpha}{d}\right) ZlD \cdot \sin \alpha \qquad \textbf{(Eq 18)}$$

where Z is the number of rollers carrying load in one direction. In cases where rollers have different lengths, Zl is the sum of the lengths of all rollers carrying load in a given direction.

As with dynamic loading, a static equivalent load must be defined. For a radial bearing, it is that purely radial static load which, if applied to the bearing, would produce the same permanent deformation as the applied static loading. For a radial bearing subjected to combined radial and thrust loading, Eq 19 gives the static equivalent radial load:

$$P_{or} = X_o F_r + Y_o F_a \qquad \textbf{(Eq 19)}$$

for which the factors X_o, and Y_o can be obtained from Tables 12 and 13 for radial ball and roller bearings respectively. If $F_r > P_{or}$ as calculated using Eq 19, then $P_{or} = F_r$ is used.

Table 12 X_o and Y_o factors for radial ball bearings

Bearing type	Single-row bearings		Double-row bearings	
	X_o	Y_o	X_o	Y_o

40°	0.5	0.26	1	0.52
45°	0.5	0.22	1	0.44
Self-aligning ball bearings, $\alpha \neq$ 0°	0.5	0.22 cot α	1	0.44 cot α

(a) Permissible maximum value of F_a/C_o depends on bearing design internal clearance and raceway groove depth.

Table 13 X_o and Y_o factors for radial roller bearings with α> 0°

Bearing type	X_o	Y_o
Single-row	0.5	0.22 cot α
Double-row	1	0.44 cot α

For thrust ball and roller bearings with α< 90°, static equivalent axial load is given by Eq 20:

$$P_{oa} = 2.3F_r \cdot \tan \alpha + F_a \quad \textbf{(Eq 20)}$$

Equation 20 is valid for all combinations of radial to axial load for double-direction bearings. It is strictly valid where $F_r/F_a \leq 0.44 \cot \alpha$; it gives satisfactory (but less conservative) results for $0.44 \cot \alpha < F_r/F_a < 0.67 \cot \alpha$. Thrust bearings with α= 90° can only support axial loading; in this case $P_{oa} = F_a$.

Frequently, loading applied to the bearing is more complex than that which has been considered using Eq 15, 16, 17, 18, 19, 20. In such cases, the specific load distributions corresponding to maximum permanent deformation of 0.0001*D,* or the equivalent stress, can be determined using methods given in Ref 10.

Rolling Bearing Friction

The principal sources of friction in roller bearings are due to sliding in the contact zones. Some friction occurs due to elastic hysteresis in rolling but the magnitude is insignificant compared to that caused by sliding motions. The magnitude of component sliding friction depends on the effectiveness of lubrication. For example, if adequately thick lubricant films are formed to effectively separate the contacting surfaces, friction forces will be relatively small. In the latter case, the friction torque of a rolling bearing will be substantially less than that of an oil-lubricated hydrodynamic or hydrostatic bearing in a given application.

The sources of sliding friction in a rolling bearing are as follows:

- Sliding in rolling element-raceway contacts due to geometry of contacting surfaces
- Sliding due to deformation of contacting elements (Heathcote slip)
- Sliding between the cage pockets and rolling elements

- In bearings with land-riding cages (see Fig. 17), sliding between the cage rails and ring-lands
- In roller bearings, sliding between roller ends and guiding inner-and/or outer-ring flanges
- For bearings having integral seals, sliding between the seal lips and the mating surfaces

Other than seal friction, which is substantially greater than all of the other friction sources, sliding in the rolling element-raceway contact areas is most significant in most applications, especially when the bearing is heavily loaded. When speeds are high, however, roller end-flange friction is very large in tapered roller bearings because the rollers are driven against the outer-ring (cup) flange with substantial force. Also, when speeds are high, depending on the amount of lubricant residing in the bearing cavity (free space), viscous drag friction of the lubricant through which the rolling elements orbit can be significant. In fact, excessive lubricant in the bearing cavity during high-speed operation can cause skidding (that is, gross sliding of the rolling elements over the inner raceway). Skidding in the absence of adequately thick elastohydrodynamic lubricant films can result in substantial damage of the contact surfaces and rapid bearing failure.

Bearing Friction Torque. To accurately predict the frictional torque of a ball or roller bearing in a given application is a complex process, considering all of the friction modes. Harris (Ref 10) provides details covering the analytical methods. In lieu of the more precise analytical methods, Palmgren (Ref 15) experimentally investigated bearing friction torque and established the following empirical formula:

$$M = M_l + M_v \qquad \textbf{(Eq 21)}$$

where M is the bearing total friction torque (in N · mm), M_l is the bearing friction torque (in N · mm) due to rolling element-raceway contact loading, and M_v is the bearing friction torque (in N · mm) due to hydrodynamic fluid friction.

M_v is independent of load, being a function of the viscosity and the amount of lubricant as well as the bearing speed. It is predominant when loading is light and speed significant. Equations 22 and 28define M_l and M_v, respectively:

$$M_l = f_1 F_\beta d_m \qquad \textbf{(Eq 22)}$$

where f_1 is a factor depending on bearing design and load, F_β is the applicable load (in N), and d_m is the bearing pitch diameter (in mm).

For ball bearings

$$f_1 = z\left(\frac{P_o}{C_o}\right)^y \qquad \textbf{(Eq 23)}$$

for which values of z and y can be obtained from Table 14 for various types of ball bearings. Table 15 gives values of f_1 for various roller bearing types with the exception of spherical roller bearings. Spherical roller bearings vary significantly in internal design, and therefore, the catalogs of manufacturers must be consulted for appropriate friction torque calculational methods. SKF uses the following formula:

$$M_l = f_1 F_\beta^a d^b \qquad \textbf{(Eq 24)}$$

for which f_1, F_β, a, and b values can be obtained from Ref 12for the different series of SKF spherical roller bearings.

Table 14 z and y factors for ball bearings

Bearing type	α(°)	z	y
Deep-groove	0	0.0002-0.0004[a]	0.55
Angular-contact	30, 40	0.001	0.33
Thrust	90	0.0008	0.33
Self-aligning	10	0.0003	0.4

(a) Lower values pertain to light-series bearings: higher values to heavy-series bearings.

Table 15 f_1 factors for roller bearing types

Bearing type	f_1
Cylindrical with cage	0.0002-0.0004[a]
Cylindrical, full complement	0.00055
Tapered	0.0004
Cylindrical roller thrust	0.0015
Spherical roller thrust	0.00023-0.0005[a]

(a) Lower values pertain to light-series bearings; higher values to heavy-series bearings.

Values of F_β can be obtained from the following equations. For ball bearings

$$F_\beta = 0.9F_a \cdot \cot \alpha - 0.1F_r \qquad \textbf{(Eq 25)}$$

If $F_r > F_\beta$, use $F_\beta = F_r$. For deep-groove ball bearings with 0° nominal contact angle, use

$$F_\beta = 3F_a - 0.1F_r \qquad \textbf{(Eq 26)}$$

For radial roller bearings:

$$F_\beta = 0.8F_a \cdot \cot \alpha \qquad \textbf{(Eq 27)}$$

Again, if $F_r > F_\beta$, use $F_\beta = F_r$. For either thrust ball or thrust roller bearings use $F_\beta = F_a$.

Equations 28 and 29are used to give estimates of viscous friction torque:

$$M_v = 10^{-7} f_v (vn)^{2/3} d^3 \quad vn > 2000 \qquad \textbf{(Eq 28)}$$

$$M_v = 160 \cdot 10^{-7} f_v d^3 \quad vn \leq 2000 \qquad \textbf{(Eq 29)}$$

where v is the kinematic viscosity of the lubricant (in cSt) at bearing operating temperature, and n is the bearing speed (in rev/min). Values of the factor f_v, a constant dependent on bearing type and lubrication, for different bearing types and various methods of lubrication are given in Table 16.

Table 16 f_v factors for bearing type and lubrication method

Bearing type	Type of lubrication			
	Grease	**Oil mist**	**Oil bath**	**Oil bath (vertical shaft) or oil jet**
Deep-groove ball[a]	0.7-2[b]	1	2	3-4[b]
Self-aligning ball[c]	1.5-2[b]	0.7-1[b]	1.5-2[b]	3-4[b]
Thrust ball	5.5	0.8	1.5	3
Angular-contact ball[a]	2	1.7	3.3	6.6
Cylindrical roller With cage[a]	0.6-1[b]	1.5-2.8[b]	2.2-4[b]	2.2-4[b] [d]
Full complement	5-10[b]	. . .	5	. . .
Spherical roller[c]	3.5-7[b]	1.7-3.5[b]	3.5-7[b]	7-14[b]
Tapered roller[a]	6	3	6	8-10[b] [d]
Needle roller	12	6	12	24
Thrust cylindrical roller	9	. . .	3.5	8
Thrust spherical roller	. . .	. . .	2.5-5[b]	5-10[b]
Thrust needle roller	14	. . .	5	11

(a) Use $2 \cdot f_v$ value for paired bearings or double-row bearings.

(b) Lower values pertain to light-series bearings; higher values to heavy-series bearings.

(c) Double-row bearings only.

(d) For oil bath lubrication and vertical shaft, use $2 \cdot f_v$.

Radial cylindrical roller bearings with flanges on both inner and outer rings can carry thrust load in addition to radial load. In this situation, the roller ends are loaded against one flange on each ring. Friction torque due to roller end-flange sliding depends on specific design of the roller end and flange geometries. In most cases, the roller corners bear on flanges that are angled a few minutes from radial planes. References 10and 12 can be consulted for further details regarding calculation of friction torque due to roller end-flange sliding under thrust loading.

Wear

Wear (in regard to rolling-element bearings) is the loss or displacement of material from any of the rolling bearing internal contact surfaces. Material loss can be in the form of loose debris, whereas material displacement can occur by local plastic deformation or transfer of material from one location to another by adhesion. When wear has occurred to the extent it threatens the essential bearing function, the bearing is considered failed. Bearing engineers recognize the wear modes listed below as contributing to bearing failure:

- Mild mechanical wear
- Adhesive wear
- Smearing
- Corrosive wear
- Plastic flow
- Surface indentation
- Abrasive wear
- Surface distress
- Pitting
- Fatigue spalling

These failure modes are defined without presupposing the exact mechanisms that cause them. They are defined in engineering terms based on observations of the evidence remaining from complex sequences of events involving many physical and chemical processes. Some of these occurred in the manufacturing of the original surfaces. Associated with

these physical/chemical interactions are several mechanistic wear processes (for example, adhesion, chemical reaction, plastic flow, and fatigue). These wear processes are described in the Sections on wear in this Handbook.

Recognized wear modes in ball and roller bearings (for example, smearing and pitting) are not uniquely associated with any of the wear processes but rather with their interactions. Attempts are made in the following discussion to connect the wear process to the failure mode to best determine how to eliminate or minimize wear through improved lubrication, alternate material selection, and application design.

In rolling bearings, smearing (also called galling or scuffing) is adhesive wear on a macroscopic scale. Smearing occurs when sliding is substantial and lubricant film thicknesses in the rolling contacts are insufficient to adequately separate the rolling bodies. It is accompanied by severe plastic deformation, and it involves the gross failure of the surface, increased friction, and increased contact temperatures. These phenomena can lead to rapid bearing failure. Figure 28 is an example of smearing on a cylindrical roller surface.

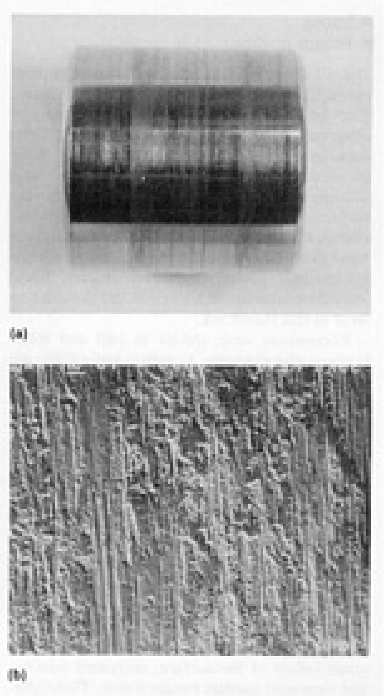

Fig. 28 Smearing (severe mechanical wear) on the surface of a cylindrical roller shown at two magnifications. (a) 4×. (b) 410×

As indicated above, if a rolling bearing is overloaded while not rotating, plastic deformation (Brinelling or denting) of the rolling surfaces can occur that leads to noisy operation and possible failure. Denting can also occur as a result of overrolling solid contaminants. Once the wear process has begun, these phenomena can be augmented by wear debris. Figure 29 illustrates hard-particle contaminant denting in a raceway surface. Plowing occurs due to displacement of bearing material by a hard particle in the presence of sliding. Figure 30 depicts such damage in a bearing ball surface. Abrasive wear, such as plowing, sometimes occurs when hard surfaces interact with softer surfaces in the presence of a contaminant; the softer cage materials are especially susceptible.

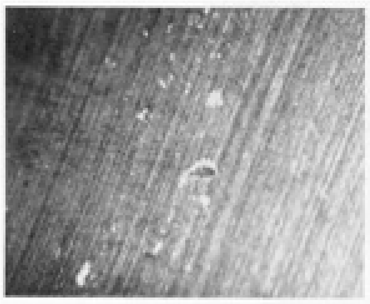

Fig. 29 Ball bearing raceway denting caused by hard particle contaminant. 15×

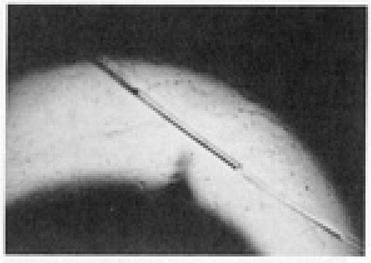

Fig. 30 Plowing damage generated on the surface of a bearing ball. 11×

Rolling-contact fatigue has been described in the section "Load Ratings" in this article. When loading is heavy and after a sufficient number of load cycles has been accumulated, spalling can occur (Fig. 22). In a well-designed and well-lubricated bearing application, the maximum shear stresses occur below the rolling-contact surfaces. In such cases, a spall is a pit that commences as a crack below the rolling-contact surface. After repeated over-rollings, the crack propagates and some material is expelled. In the presence of substantial sliding (in addition to rolling), the maximum shear stresses move closer to the surface and pitting can occur directly at the surface (Fig. 31).

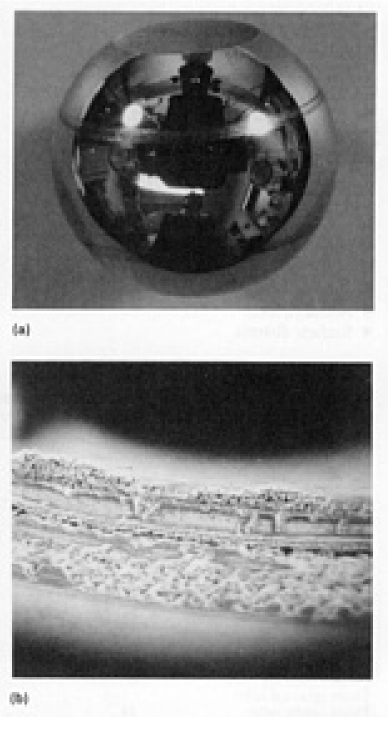

Fig. 31 Pitting (surface distress) generated on a rolling-contact surface. (a) Ball used in V-groove testing machine. (b) Pit produced on ball. 28×

Wear Control

Wear control in rolling bearings is accomplished by effective separation of contacting surfaces by lubricant films generated by hydrodynamic and elastohydrodynamic fluid action. In the absence of such processes, wear will occur in varying degrees and rates depending on the effectiveness of boundary lubrication and solid-film lubrication schemes. Numerous methods exist for increasing wear performance (for example, utilizing additives in lubricants, changing material pairs, modifying contacting surfaces, and so on). Unless effective surface separation is achieved, however, wear will occur. In general, significant wear does not occur during the operating lifetime of well-designed and manufactured ball and roller bearings that are properly lubricated with viscous oil-type fluids. Therefore, most rolling bearing manufacturers do not provide information regarding the wear rate to be expected in properly designed applications. An exception to this is Ref 16. However, in using this reference it should not be presumed that the data apply to the rolling bearing products of other manufacturers.

Lubricant Film Thickness. To avoid bearing wear in a given application, it is necessary for the rolling-contact surfaces to be almost completely separated by lubricant films. Using the method of Hamrock and Dowson (Ref 17), the minimum lubricant film thickness can be estimated for rolling bearing point contacts:

$$H = \frac{2.69\bar{U}^{0.67}G^{0.53}(1 - 0.61e^{-0.73\kappa})}{\bar{Q}_e^{0.067}} \quad \textbf{(Eq 30)}$$

in which:

$$H = \frac{h}{R_e} \quad \textbf{(Eq 31)}$$

where h is the minimum lubricant film thickness (in mm) and R_e is the equivalent radius of curvature (in mm), and in which:

$$R_e = \frac{1}{\dfrac{1}{r_I} + \dfrac{1}{r_{II}}} \quad \textbf{(Eq 32)}$$

$$\bar{U} = \frac{\eta_0 U}{2\,E'R_e} \quad \textbf{(Eq 33)}$$

$$G = \lambda E' \quad \textbf{(Eq 34)}$$

$$E' = \frac{E}{1 - \xi^2} \quad \textbf{(Eq 35)}$$

$$\bar{Q}_e = \frac{Q}{E'R_{ex}R_{ey}} \quad \textbf{(Eq 36)}$$

where r_I is the radius of rolling body I (in mm), r_{II} is the radius of rolling body II (in mm), E is the modulus of elasticity (in MPa), ξ is Poisson's ratio $\overline{U}$ is the rolling velocity (dimensionless), η_0 is the absolute viscosity at contact inlet (in N · s/mm^2), λ is the pressure coefficient of viscosity in MPa^{-1}, and $\overline{Q}_e$ is the contact stress (dimensionless); and in which:

$$\kappa = \frac{a}{b} \qquad \textbf{(Eq 37)}$$

where κ is the ellipticity ratio of the contact area, a is the semimajor axis of the elliptical contact area (in mm), and b is the semiminor axis of the elliptical contact area (in mm); and in which:

$$U = \frac{u_I + u_{II}}{2} \qquad \textbf{(Eq 38)}$$

where u_I is the surface velocity of body I in the rolling direction (in mm/s), and u_{II} is the surface velocity of body II in the rolling direction (in mm/s).

Equation 30 pertains to Fig. 32, which shows two bodies in rolling contact. To use Eq 30 for a rolling bearing, it is necessary to determine the distribution of the applied load among the rolling elements and also the speeds of each of the rolling components. This is a rather complex process, and rigorous analytical methods of evaluation are given in Ref 10. Once the load distribution has been determined, it is only necessary to establish the adequacy of the lubricant thickness at the maximum-loaded rolling element to determine whether the bearing is lubricated sufficiently. In lieu of the rigorous calculation method, for simple radially loaded bearings, the maximum rolling-element load can be approximated by:

$$Q_{max} = \frac{5F_r}{iZ \cdot \cos\alpha} \qquad \textbf{(Eq 39)}$$

For a simple thrust-loaded bearing:

$$Q_{max} = \frac{F_a}{Z \cdot \sin\alpha} \qquad \textbf{(Eq 40)}$$

Bearing internal speeds can be estimated from the following equations:

$$n_m = \frac{[n_i(1 - \gamma) + n_o(1 + \gamma)]}{2} \qquad \textbf{(Eq 41)}$$

$$n_{RE} = \frac{d}{2D}(1 - \gamma)(1 + \gamma)(n_o - n_i) \qquad \textbf{(Eq 42)}$$

where n_m is the cage speed (rolling-element orbital speed), n_i is the inner ring speed, n_o is the outer ring speed, and n_{RE} is the ball or roller speed about its own axis.

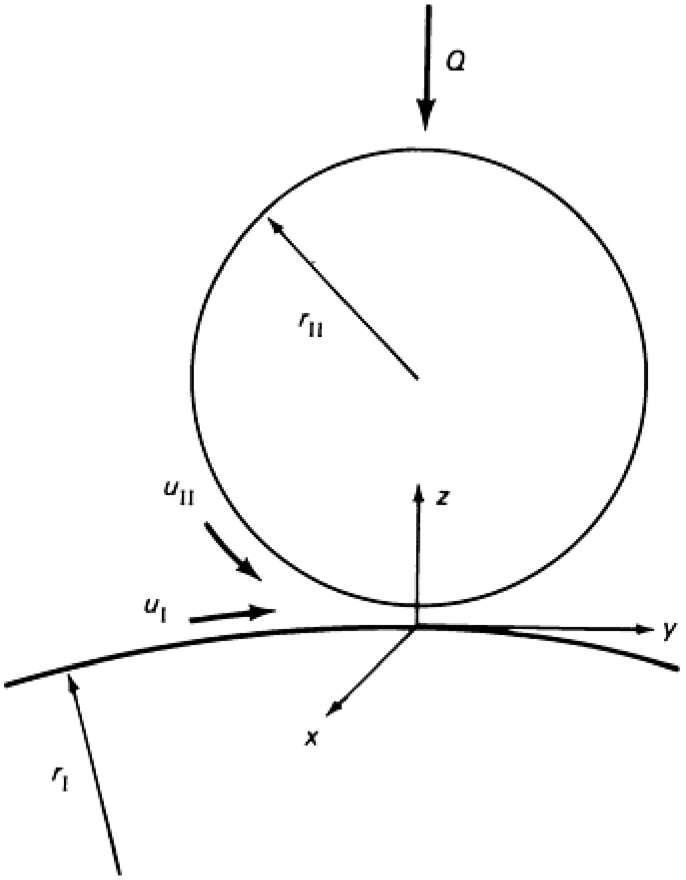

Fig. 32 Measurable parameters present when two bodies of radius r_I and r_{II} are in rolling contact with each other

Using the rolling-element and bearing ring radial dimensions, it is possible to estimate average surface velocities u_I and u_{II}. Surface velocities can also be determined in a more precise manner (Ref 10); however, for many applications, the approximate calculation method will suffice.

To determine whether the rolling elements are separated adequately from the raceway surfaces by lubricant films, it is necessary to compare the calculated lubricant film thickness to the composite roughness of the mating surfaces. The rms value is used such that:

$$\sigma_e = \sqrt{\sigma_I^2 + \sigma_{II}^2} \qquad \textbf{(Eq 43)}$$

where σ_I is the surface roughness of body I and σ_{II} is the surface roughness of body II; and:

$$\Lambda = \frac{h}{\sigma_e} \qquad \textbf{(Eq 44)}$$

In the section "Bearing Fatigue Life" of this article, it was indicated that when lubrication conditions are very favorable and contamination is minimal, extended bearing rolling-contact fatigue lives can be obtained in an application. This means that virtually complete separation of rolling elements from raceways by lubricant films has been achieved and frictional heating is effectively accommodated. In this situation, wear of rolling-contact surfaces has also been virtually eliminated.

When lubricant film thicknesses are insufficient to obtain complete separation, fatigue life can still be satisfactory, provided that contamination is minimal and gross sliding in the contacts does not occur. Microslip in the contacts will still occur owing to contact deformations that preclude achievement of pure rolling. However, in the absence of gross sliding and contamination, for $0.4 \leq \Lambda \leq 1$, wear will generally not be significant. If either of these conditions is prevalent, distress of the rolling-contact surfaces can be anticipated. This distress can lead to early bearing fatigue failure or thermal imbalance and ultimate bearing seizure. Contamination can be prevented from entering the bearing by effective filtration of the lubricant, by sealing the bearing, or by both. Gross sliding is a function of bearing design and operating conditions, and it tends to occur in high-speed applications when the bearing applied load is relatively light. Harris (Ref 10) demonstrates analytical methods to predict whether gross sliding (skidding) will occur during steady-state operation. In such cases, preloading of the bearing or of selected rolling elements can be used to minimize the amount of sliding. Gross sliding can also occur, however, during rapid accelerations and decelerations of bearing speed or rolling-element speeds. For example, smearing damage can occur during slow-speed operation of radially loaded large roller bearings.

In addition to achieving adequate separation of rolling-contact surfaces, effective lubrication of cage-rolling element and cage rail-ringland sliding surfaces must be achieved. In the case of roller bearings, adequate lubrication of the roller end-guide flange contacts must be provided. Insufficient lubrication of these principally sliding contact surfaces can result in excessive friction and wear, particularly when contamination is present. Excessive roller end-flange friction can result in roller skewing and rapid bearing failure. Furthermore, wear debris from such inadequately lubricated surfaces can enter the bearing, subsequently affecting rolling-contact surface distress and bearing failure. To ensure adequate lubricant flow, the lubrication system and bearing design can be arranged to direct the lubricant to the sliding surfaces. For example, oil flow can be directed first through passages under the bearing and then through radial holes drilled between the bearing bore and the inner raceway undercuts to ensure roller end-flange lubrication in cylindrical and tapered roller bearings. Oil jets can be directed to impinge on cage rail-ringland interfaces. In a similar way, critical sliding surfaces can be lubricated to prevent excessive friction and wear. In all cases, minimization of contamination is essential in order to bring about minimization of friction and wear.

Friction and Wear of Sliding Bearings

Ron Pike and J.M. Conway-Jones, Glacier Vandervell Inc.

Introduction

SLIDING BEARINGS (plain bearings) are designed to transmit force between two surfaces that are in relative motion. The simplest forms of sliding bearings are used unlubricated and thus suffer from the penalty of high friction and wear. Providing lubricant under favorable conditions separates the surfaces and reduces the coefficient of friction by a factor of $\geq$100, and reduces the rate of wear by many orders of magnitude. In order to optimize the performance of sliding bearings, a variety of materials have been used (see the article "Friction and Wear of Sliding Bearing Materials" in this Volume).

A bearing may be an integral part of the equipment, but it is usually a separate component either in the form of a round bushing, a half bearing, a thrust washer, a flanged bearing (which can accommodate both radial and axial loads), or a wear plate. These components are generally classified as thin wall if their thickness is $\leq$5 mm ($\leq$0.2 in.) and heavy wall if their thickness is >5 mm (>0.2 in.). Bearings with diameters >150 mm (>6 in.) are mostly in the heavy-wall class. For special-purpose applications, the bearing surface may be divided into a number of elements or tilting pads, either for relatively highly loaded high-speed thrust bearings, or for lightly loaded journal bearings where the increased resistance to oil-film whirl provided by these bearings is required (as in vertical-shaft high-speed pumps, turbo compressors, and so on).

Sliding bearing performance is substantially affected by the lubrication regime. Three categories of lubrication regimes will be discussed in this article:

- Rubbing (dry or boundary lubrication)
- Full film (surfaces separated by lubricant film)
- Mixed film (load partly carried by rubbing and partly by fluid film)

Effect of *PV* Factor on Rubbing Bearing Performance

The potential for wear and friction depends on the intensity of contact between the surfaces. Heat generated through rubbing contact depends upon the load, the speed, and the coefficient of friction (μ). Because the first two parameters can vary over many orders of magnitude, it is common to categorize the severity of applications in terms of the *PV* factor (Fig. 1):

$$\frac{\text{Work}}{\text{Area}} = \frac{\mu WV}{A} \quad \textbf{(Eq 1)}$$

$$\text{Heat generated } \alpha PV \quad \textbf{(Eq 2)}$$

where *P* is the specified load or unit load; *W* is the load; *A* is the projected area ($A = d \times b$, where *d* is the diameter and *b* is the width for a journal bearing); and *V* is the rubbing velocity.

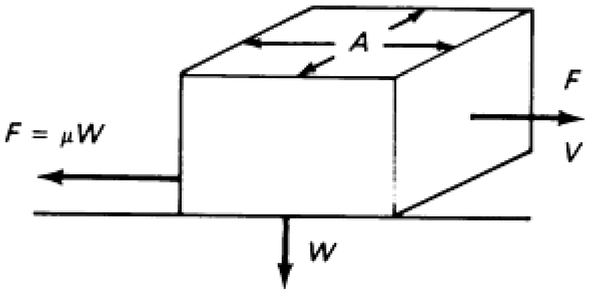

Fig. 1 Schematic showing key components required to calculate work done against friction. *F,* frictional force; μ , coefficient of friction; *W,* load; *V,* velocity; *A,* area of rectangle

The coefficient of friction will depend on the material composition of the surfaces, the surface finish, the temperature, and the effectiveness of the lubrication. For a dry bearing (no fluid lubricant used), any heat, *Q,* generated by friction must be dissipated by conduction, and the temperature rise of the surface, T_s, above that of the environment, T_E, can be related to the *PV* factor by (Fig. 2):

$$Q = \frac{kA'(T_s - T_E)}{t} = \mu PVA \quad \textbf{(Eq 3)}$$

$$(PV)_{max} \propto \frac{k}{\mu t}\left(\frac{A'}{A}\right)(T_s - T_E)_{max} \quad \textbf{(Eq 4)}$$

where *k* is the thermal conductivity; *t* is the material thickness; and *A*' is the area shown in Fig. 2.

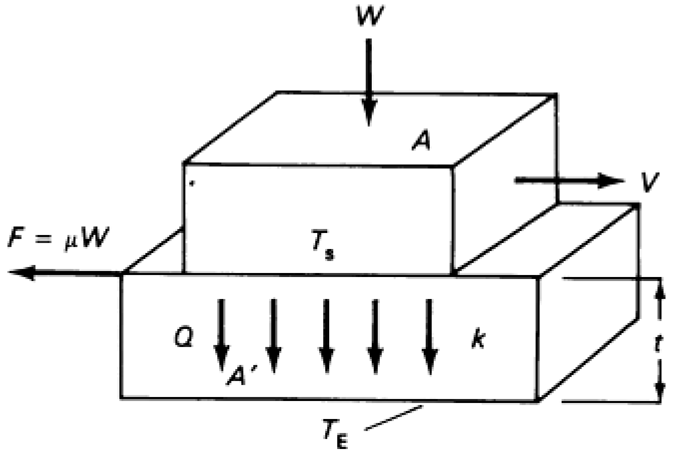

Fig. 2 Schematic showing parameters that affect frictional heat dissipated by conduction. *Q,* heat generated by friction; *A*', area of larger rectangle; *k,* thermal conductivity; T_s, surface temperature; T_E, temperature of environment

Thus, for rubbing contacts at high specific loads or high velocities, the bearing materials are required to have a high thermal conductivity, a low coefficient of friction, and the ability to accept high surface temperatures. If the bearing material has a low thermal conductivity (for example, polymers), it is preferable that the thickness is very small; otherwise the permissible *PV* factor will be correspondingly limited.

Wear Rate for Dry Rubbing

After an initial break-in (bedding-in), the rate of dry wear, *H/t,* for many materials becomes constant (that is, proportional to the *PV* factor). Thus:

$$H/t = K \cdot PV \qquad \textbf{(Eq 5)}$$

Table 1 defines the terms in Eq 5 in both English and metric units.

Table 1 Nomenclature and units for calculating specific wear rate of sliding bearings

Parameter	Symbol	SI units	English units
Depth of wear	*H*	m	in.
Time	*t*	s	min
Specific wear rate	*K*	$m^3/N \cdot m$	$in.^3/lbf \cdot ft$
Specific load	*P*	N/m^2	psi
Rubbing velocity	*V*	m/s	ft/min

The specific wear rate is the volumetric wear divided by the load and distance rubbed. The allowable specific wear rate is:

$$K_a = H_a/PVt_r \qquad \textbf{(Eq 6)}$$

where H_a is the allowable depth of wear and t_r is the required life. The specific wear rate also increases with the surface temperature and the surface roughness and can also depend upon the material of the mating surface.

Metallic Bearings. For metals with high thermal conductivity, the preferred method of improving *PV* capability and reducing the wear rate is to reduce the coefficient of friction by the addition of lubricants. For low speeds (typically, <0.5 m/s, or 100 ft/min), this may take the form of greases or solid lubricants such as graphite. At high speeds, oil can be used if provision is made to recirculate the oil. Thus, the bearing can be made porous, such that the oil is retained by capillary action (for example, porous bronze bearings used in small electric motors with typical shaft sizes of $\leq$6 mm, or $\frac{1}{4}$ in.). In larger electric motors (for use with bearings that accommodate shaft diameters to $\leq$15 mm, or $\frac{5}{8}$ in.), babbitt-lined bearings with wick lubrication can be used. The bearing housing is packed with cotton waste or a proprietary cellulose material that is soaked in oil and that collects the oil expelled form the end of the bearing and recirculates it to a large hole in the unloaded surface by capillary action.

Table 2 indicates typical coefficient of friction values and permissible *PV* factors for bearings that rely on conduction for heat dissipation. Depending upon the compatibility of the surfaces (for information about mutual polishing and nonscoring surfaces, refer to the article "Friction and Wear of Sliding Bearing Materials" in this Volume), the coefficient of friction may decrease after the initial break-in period but will increase towards the end of the useful life of the bearing. This increase in friction may be accompanied by an increase in the rate of wear, in scoring, and so on, which may be related to the deterioration of the lubricant or loss of the lubricant by evaporation, and so on. The life of greased bearings can often be enhanced by regreasing at regular intervals. Providing indentations or large grooves in the surface to retain the grease is also beneficial.

Table 2 Typical parameters for selected metallic and polymer bearings rubbing against ground steel shaft with R_a of 0.4 μm

Bearing Material	Lubrication	Coefficient of friction[a]	Permissible *PV*		Specific wear rate, *K*[b]
			MPa · (m/s)	**[psi · (ft/min)] × 10^3**	
Cast iron and lead bronze	Dry	0.2-0.5	0.1	3	10-1000
Cast iron and lead bronze	Greased	0.05-0.15	1	30	0.01-1
Porous bronze, graphite impregnated	Dry	0.1-0.4	0.2	6	0.5-5
Porous bronze	Oil impregnated	0.01-0.1	1	30	0.001-0.01
Babbitt metal (steel backed)	Wick lubricated	0.005-0.1	2	60	0.001-0.01
Polytetrafluoroethylene (PTFE), 3 mm ($\frac{1}{8}$ in.) thick	Dry	0.05-0.3	0.05	1.5	10-1000
Steel-backed porous bronze impregnated with PTFE and lead	Dry	0.05-0.3	1	30	0.03-0.3
Polyoxymethylene (POM) 0.2 mm (0.008 in.) thick bonded to porous bronze with steel backing	Indentations greased during assembly	0.05-0.15	1.5	45	0.003-0.03

(a) For dry rubbing, the coefficient of friction will generally be higher at low loads, high speeds, high temperature, and for rougher surface finishes. Except for PTFE, the static (breakaway) coefficient of friction is 30 to 50% higher than the dynamic coefficient. For lubricated rubbing, the coefficient of friction may be higher at high loads.

(b) For SI units, multiply *K* by 10^{-15} to obtain $m^3/N \cdot m$; for customary units, multiply *K* by 0.8×10^{-10} to obtain $in.^3/lbf \cdot ft$.

Polymer Bearings. Although polymer materials have poor thermal conductivity, experience has shown that if used in the form of a thin layer bonded to a steel backing (generally through a layer of sintered porous bronze), polymer materials can provide adequate performance for a wide range of applications; these can operate dry or with initial lubrication only. Dry polymer material applications include car door hinges, office machinery, heat-sealing packaging machines, pneumatic equipment, and aerospace applications. Because of the wide range of contributing factors, it is not possible to quote rates of wear except in very specific circumstances. Successful operation is based largely on previous experience or simulated test conditions. Table 2 can provide only a general indication of the specific wear rates. Many proprietary dry bearing formulations have been developed, and further details of the performance of these materials can be obtained from manufacturer catalogues or from Ref 1.

Full-Film Lubricated Bearings

The presence of oil between rubbing surfaces not only reduces the coefficient of friction but, if supplied continuously and in sufficient quantity, can act as an additional method of heat removal. Under favorable conditions, sufficient oil can be provided to completely separate the rubbing surfaces, thereby minimizing wear and, principle, allowing the bearing to operate for many thousands or even hundreds of thousands of hours. In fact, it is not possible to quote a rate of wear. For such bearings, wear only occurs during starting and stopping or as a result of deterioration or loss of the lubricant, contamination by abrasive particles, and so on. The bearing life may be terminated by other conditions such as corrosion or, for a dynamically loaded bearing, by cavitation erosion or fatigue. These factors will be considered in later sections of this article. Additional information is available in the Section "Wear and Surface Damage Overview" in this Volume.

The maintenance of a full film separating surfaces requires:

- Adequate and continuous supply of lubricant
- Speed to drag sufficient oil into the loaded area
- Convergence between the bearing and mating surface such that pressure is built up in the lubricant film to oppose the load

This is known as hydrodynamic lubrication and relies on the viscosity of the oil to provide the oil's resistance to escape, thereby generating high oil film pressure between the closely converged surfaces. The convergence is achieved by

providing a clearance between the journal and the bearing, typically 0.001 mm/mm of diameter. Under the influence of load, the journal moves to an eccentric position within the bearing, thereby causing convergence of the oil film and generating pressure that balances the load. For a flat surface, such as a thrust washer, if specific loads >1 MPa (>150 psi) are to be supported, it is advisable to machine a series of tapered lands on the surface with a taper of 0.001 mm/mm. Alternatively, a number of tilting pads can be arranged with crowned surfaces (or flat with offset pivots) such that the pads tilt to form the necessary convergence of the oil film. For a journal bearing, as the load increases the journal moves to greater eccentricity such that the minimum oil film thickness, h_{min}, decreases.

In hydrodynamic lubrication theory, the relationships among the variables have been expressed in a series of equations, all of which involve the dimensionless group $\eta N/P$ multiplied by the ratio $(d/c_d)^2$, which is a form of the Sommerfeld number and where d is the shaft diameter and c_d is the diametrical clearance. (Additional information can be found in Ref 2.) Various equations, computations, and graphical representations have been established for the relationship between the ratio of minimum oil film thickness to radial clearance (h_{min}/c_r) and the Sommerfeld number. Although these parameters are useful if the viscosity is known, it will be recognized that as the speed increases and the rate of shear increases, heat will be generated within the oil and the effective viscosity will be reduced. It is necessary to carry out a heat balance in order to establish the appropriate value of the Sommerfeld number. A rigorous method of doing this for steadily loaded bearings has been published in Ref 3, and a series of design charts have been prepared by F.A. Martin and D.R. Garner (Ref 4). Figure 3 is based on Ref 4 with provision made for the specification of oil by ISO viscosity grade (centistokes, cSt, at 40 °C, or 105 °F). In using this chart, it should be noted that it is not necessary to estimate the effective operating viscosity because this has already been derived during the preparation of the chart (assuming oil is supplied at 50 °C, or 122 °F).

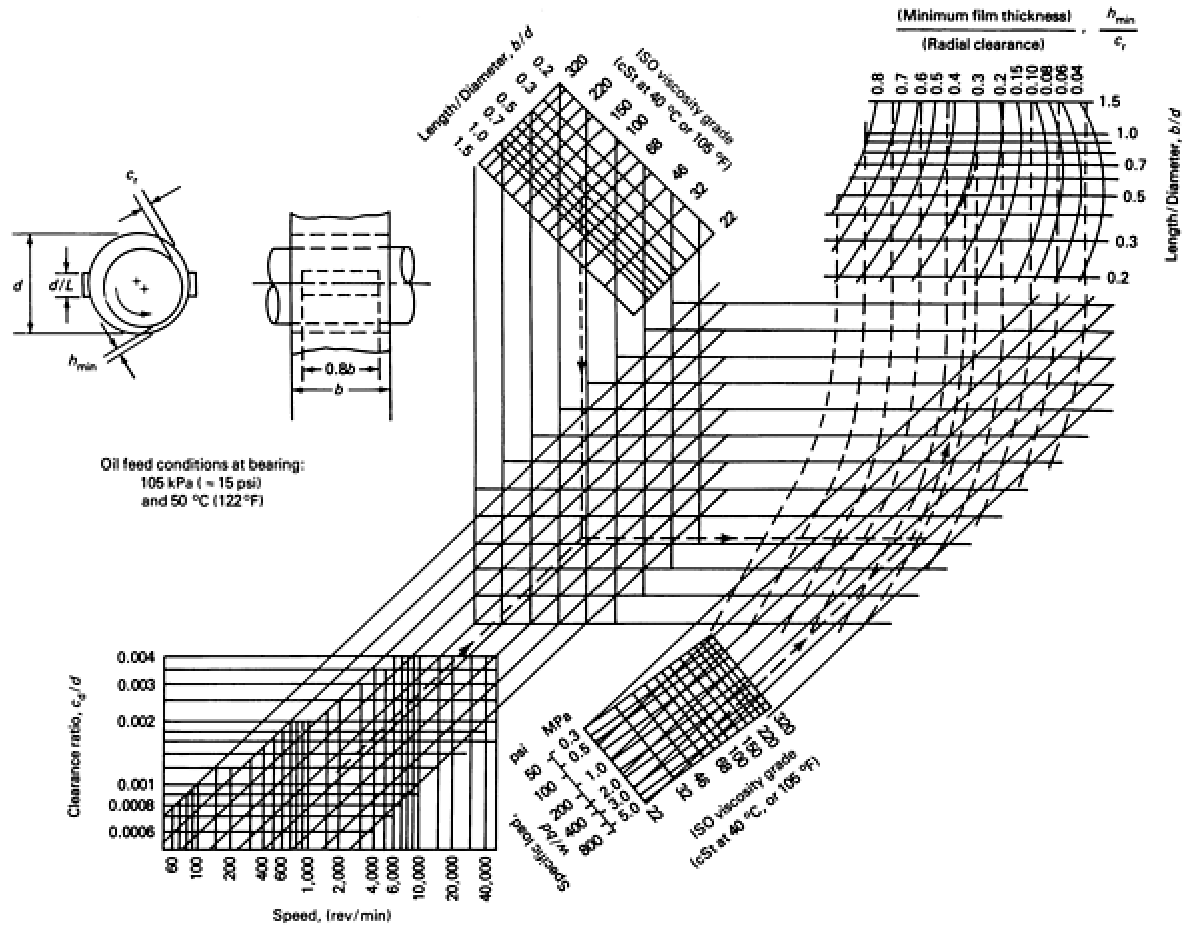

Fig. 3 Nomographs used to predict minimum oil film thickness for steadily loaded bearings

Permissible Minimum Oil Film Thickness. Typical values of h_{min}/c_r for steadily loaded hydrodynamic bearings are in the range of 0.4 to 0.2. For higher ratios at higher speed (typically >3000 rev/min), oil film whirl is a possibility (Ref 2) and a bearing with noncircular bore or tilting pads may be required. If the value of the ratio is <0.2, there is the possibility

of asperity contact, which can lead progressively to increased friction and wear, overheating, and possibly seizure (particularly if some misalignment, waviness, or other local geometric deviations are present from faulty assembly, and so on).

Depending on the selection of bearing materials and the operating conditions, it may be possible for the bearing to break-in (bed-in) during initial running and develop a geometry that conforms more closely with the alignment of the journal. Furthermore, if a bearing material is chosen that is compatible with the journal, it is possible that some asperity polishing will occur, reducing the sum of the initial heights of the asperities on the journal and the bearing so that full hydrodynamic separation is established for $h_{min}/c_r \leq 0.1$.

Effect of Asperity Height (Shaft Roughness). Typically, the minimum permissible oil film thickness calculated from hydrodynamic theory for steadily loaded journal bearings is in the range of 0.0025 to 0.025 mm (0.0001 to 0.001 in.). This can be related to the sum of the maximum heights of the asperities on the shaft (e_s) and bearing (e_B) by the Lambda ratio (Fig. 4):

$$\lambda = h_{min}/(e_s + e_B) \qquad \textbf{(Eq 7)}$$

Instead of basing the value of λ on the arithmetic sum of asperities, some engineers prefer to use the statistical sum $\sqrt{(e_S^2 + e_B^2)}$ instead of the arithmetic sum shown in Eq 7. The statistical sum may be appropriate for static or rolling contact, but the implied interlocking of the surface profiles is not appropriate for surfaces that are moving past each other; for these surfaces, the arithmetic sum is more relevant.

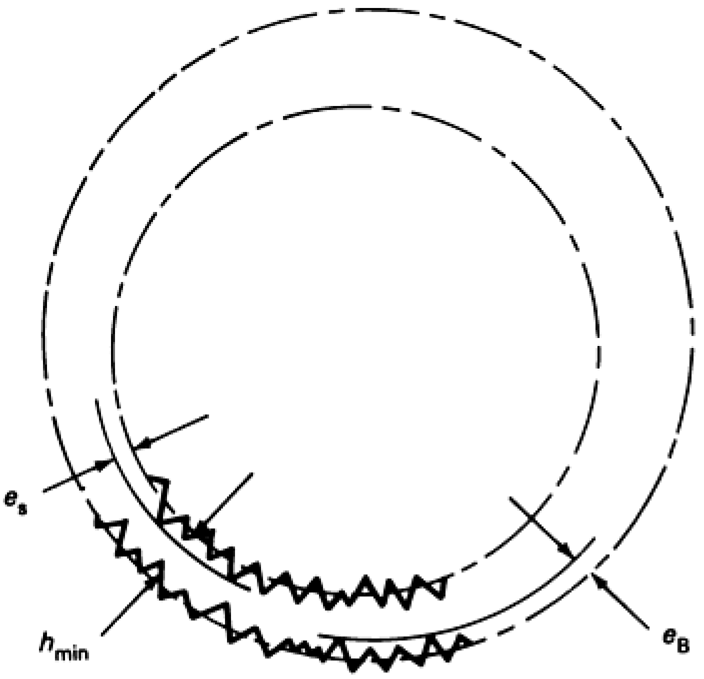

Fig. 4 Typical surface asperities on a bearing and its mating shaft

Of primary importance is the appropriate parameter for defining the maximum height of the asperities above the average level of the surface. The single predominant peak height (R_p), or "leveling depth" (Ref 5), may not be relevant because it can easily be rubbed off. A more typical value is the mean height of the highest peaks on five adjacent sampling lengths, R_{pm} (Fig. 5a). For a ground surface with normal (Gaussian) distribution of asperity heights, this is about four times the arithmetic average height above the mean line, R_a (or AA) (Fig. 5b), or about 3σ, where σ is the standard deviation or

root-mean-square roughness, R_q. If e_s and e_B are based on R_{pm} values of surface finish, the surfaces will be separated by the oil film if $\lambda R_{pm} > 1$. Some authorities base e_s and e_B on σ, in which case $\lambda\sigma > 3$.

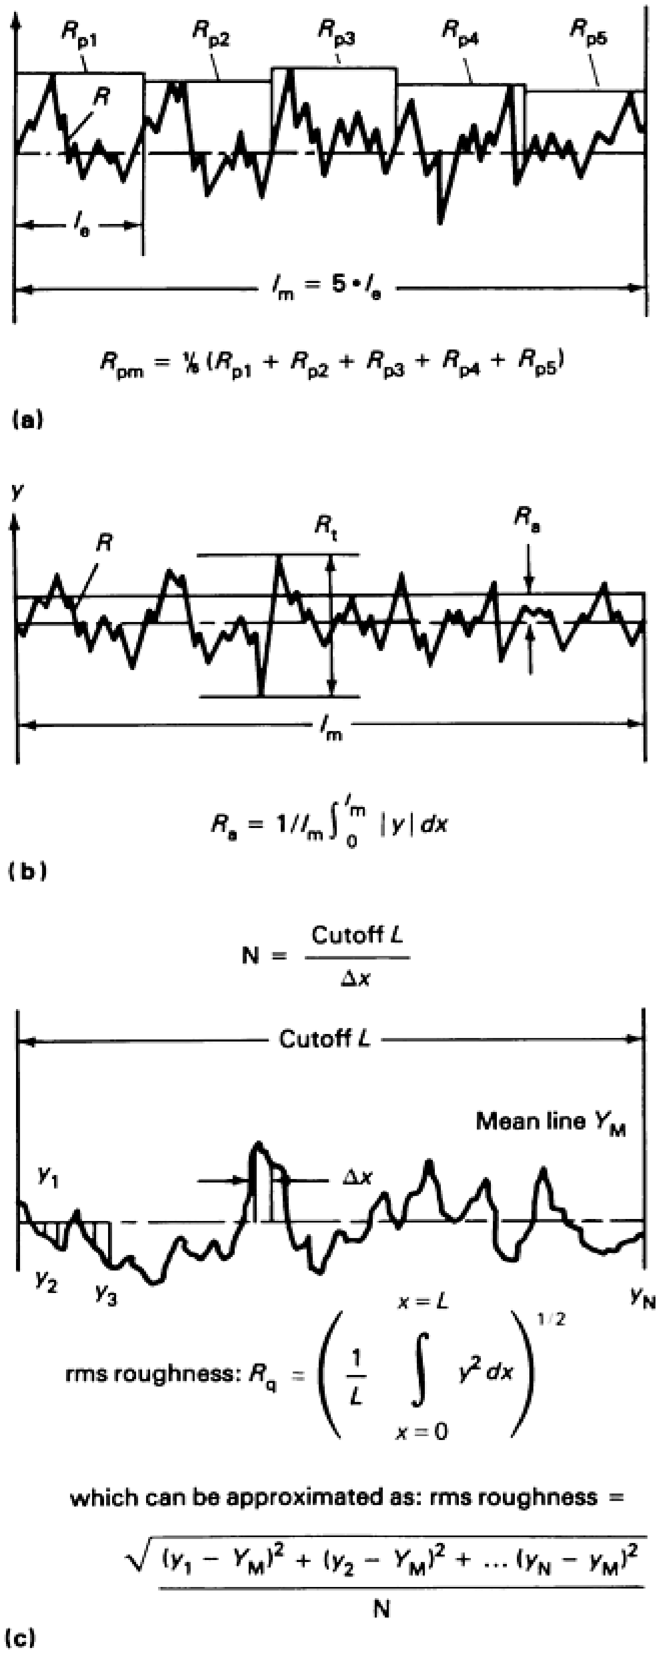

Fig. 5 Surface roughness parameters for bearings and bearing shafts. (a) Average leveling depth (R_{pm}), which is the mean of the individual leveling depths of five successive individual sample lengths (l_e) in the roughness profile. (b) Average roughness (R_a), which is the arithmetic mean of all deviation of the roughness profile *R*from

the mean line within the total measuring length (l_m). (c) Root-mean-square (rms) roughness (R_q)

Example 1: Maximum Roughness for Full-Film Lubrication (λ > 1) in the Case of a Steadily Loaded Journal Bearing with Good Alignment and Conformability.

Bearing dimensions include a shaft diameter, *d*, of 50 mm (2 in.); diametral clearance, c_d, of 0.050 mm (0.002 in.); and radial clearance, c_r, of 0.025 mm (0.001 in.). If (h_{min}/c_r = 0.1, then h_{min} is 0.0025 mm (0.0001 in.). For the λratio to be >1, the sum of the asperity heights must be <2.5 μm (<100 μin.). If the asperity heights on the shaft and the bearing are equal, the maximum asperity height on the shaft is <1.25 μm (<50 μin.). If the shaft is ground, it has a finish of R_{pm} < 1.25 μm (50 μin.), R_a < 0.3 μm (12 μin.), and σ_{rms} < 0.4 μm (16 μin.).

Significance of Low h_{min} Values. If the minimum oil film thickness drops to the extent that it is less than the value in Example 1, there is a progressive increase in asperity contact and the coefficient of friction will increase from ~0.001 to ≥0.05 (indicating that the heat generated during bearing operation has increased by a factor of 50).

Typical values of shaft surface finish are:

- R_a: 0.1 to 0.4 μm (4 to 16 μin.)
- R_q: 0.15 to 0.5 μm (6 to 20 μin.)
- R_{pm}: 0.4 to 0.6 μm (16 to 63 μin.)

As supplied, bearings can have a finish of 0.4 to 0.8 μm (16 to 32 μin.) R_a; however, because they are softer than the shaft, they rapidly polish down during break-in to have a roughness similar to that of the shaft.

Effect of Friction. When the mating surfaces in a steadily loaded journal bearing are fully separated by a film of oil, the friction is very low and depends primarily on the viscous shear of the oil film. The frictional heating can be calculated as a power loss that increases with speed and decreases with increased clearance, but that is substantially controlled by the value of h_{min}/c_r (Fig. 6). It should be noted that the chart in Fig. 6 assumes that the surfaces are sufficiently well aligned and smooth so that there is no asperity contact. The coefficient of friction is obtained from

$$\mu = \frac{H}{\pi d N W} \quad \textbf{(Eq 8)}$$

where *H* is the power loss (in watts), *d* is the diameter (in meters), *N* is the speed in (rev/s), and *W* is the load (in newtons).

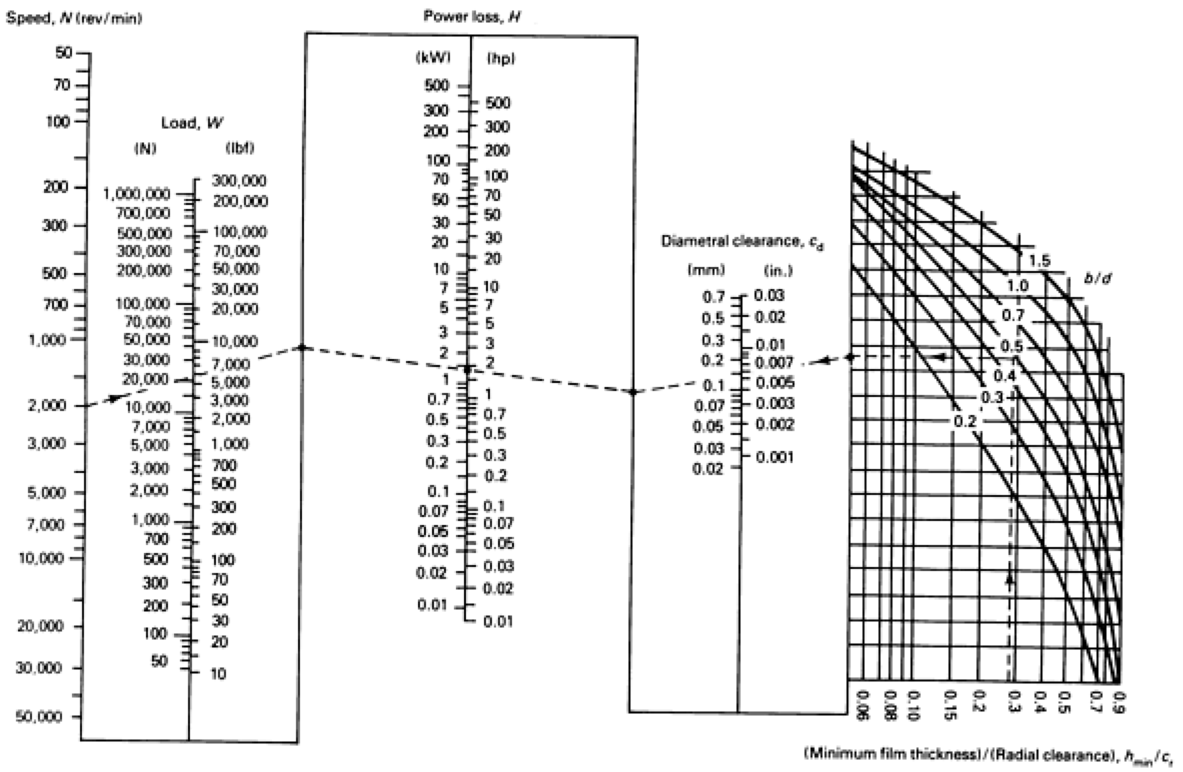

Fig. 6 Nomographs used to predict power loss in steadily loaded bearings. Source: Ref 4

Example 2: Calculation of Coefficient of Friction from Power Loss in a Full-Film Bearing.

The following parameters (Fig. 6) apply to an operational journal bearing:

Parameter	Value
Shaft diameter (*d*), mm (in.)	125 (5)
Diametrical clearance (C_d, mm (in.)	0.15 (0.006)
Speed (*N*), rev/s (rev/min)	33.33 (2000)
Load (*W*), N (lbf)	2.2×10^4 (5.0×10^3)
Width (*b*), mm (in.)	62.5 (2.5)
b/d	0.5
Specific load, MPa (psi)	2.8 (400)
Oil feed temperature, °C (°F)	50 (122)
Oil grade at 40 °C (105 °F), cSt	84
h_{min}/c_r	0.28
h_{min}, mm (in.)	0.021 (0.0008)
Power loss (*H*), kW (hp)	1.4 (1.9)

The coefficient of friction with hydrodynamic oil film is obtained by substituting the appropriate values into Eq 8:

$$\mu = \frac{1.4 \times 10^3\ W}{(3.1416)\ (0.125\ \text{m})\ (33.3\ \text{rev/s})\ (2.2 \times 10^4\ \text{N})} = 0.005$$

Friction and Wear under Mixed-Film Lubrication

The transition region between full-film lubrication (surfaces completely separated by fluid film) and boundary lubrication (load completely carried by rubbing contact) is known as mixed-film lubrication. Under these conditions part of the load is carried by asperity contact and part of the load is carried by the fluid film.

The coefficient of friction is often expressed in terms of a Stribeck curve plotted against the Sommerfeld number (Fig. 7). As the load increases, or speed and viscosity decrease, the coefficient of friction drops until a transition point is reached when the oil film is so thin that asperity interaction occurs. As the λR_{pm} ratio drops to <1, the asperities carry a progressively increasing proportion of the load and the friction rises to that of boundary lubrication (Ref 6). Because the rate of heat generation may increase 10 to 50 times, it is essential that for high-duty applications the proportion of time spent under boundary lubrication is minimized. The *PV* factor for that part of the load carried by the asperities must be within the capability of the bearing/shaft system to absorb/conduct away the heat produced without generating excessive temperatures.

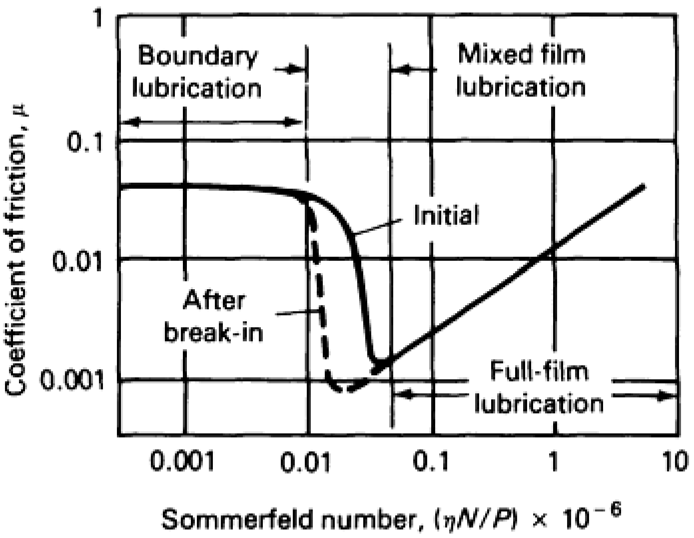

Fig. 7 Stribeck curve of coefficient of friction versus Sommerfeld number. (*S*), where *S* = η*N/P. N,* shaft speed; *P,* average pressure between shaft and bearing due to applied load; η, lubricant viscosity

For materials with good compatibility, the surfaces may break-in to the degree that asperity polishing reduces the effective height of the asperities. Thus, it may be found that the point of minimum friction for a well run-in bearing may occur at one-half or one-third of the Sommerfeld number for new components. Hence, for applications where frequent starts and stops under load are required, babbitt metal is a preferred material.

If, however, start-up specific loads are >1.5 MPa (>200 psi), significant wear may occur during start-up and wiping may occur on extended rundown (particularly if the shaft is hot; that is, 120 °C, or 250 °F). In these circumstances it is advisable to inject high-pressure oil ("jacking oil") for start-up and rundown. For continuous high steady loads (that is, 10 to 20 MPa, or 1.5 to 3.0 ksi) and low speeds (such that $h_{\mathrm{min}}/c_{\mathrm{r}}$ is unacceptably low), it may be necessary to inject high-pressure oil continuously (that is, a hydrostatic bearing configuration); an example is a rolling mill bearing. The oil supply pressurefor a hydrostatic bearing must be two to three times the maximum specific load. The friction and wear for a hydrostatic bearing or for bearing with an effective oil jacking oil system will be very low (that is, μ< 0.001 at low speeds).

Oil Additives and Surface Treatments

Although reference has been to "asperity contact," there will be lubricant molecules attaching to the asperities that will, to a greater or lesser extent (depending upon the formulation of the oil), modify the friction an wear. Thus, it is difficult to give even general guidelines concerning wear rates under boundary or mixed-film conditions because these area critically

dependent, not only upon the bearing material and the mating surface but also upon the lubricant itself and the extreme-pressure additives present in the lubricants formulated for any specific application. Wear cn also be significantly modified by surface treatment of the mating surface (for example, hardening, nitriding, an so on).

Dynamic Loads

In reciprocating machinery (internal combustion engines, reciprocating compressors, and so on), the loads on the bearings vary in both magnitude an direction during each revolutions (two-stroke engines) or alternate revolutions (four-stroke engines) (Fig. 8). Details of a procedure for calculating the performance of a dynamically loaded bearing can be found in Ref 7.

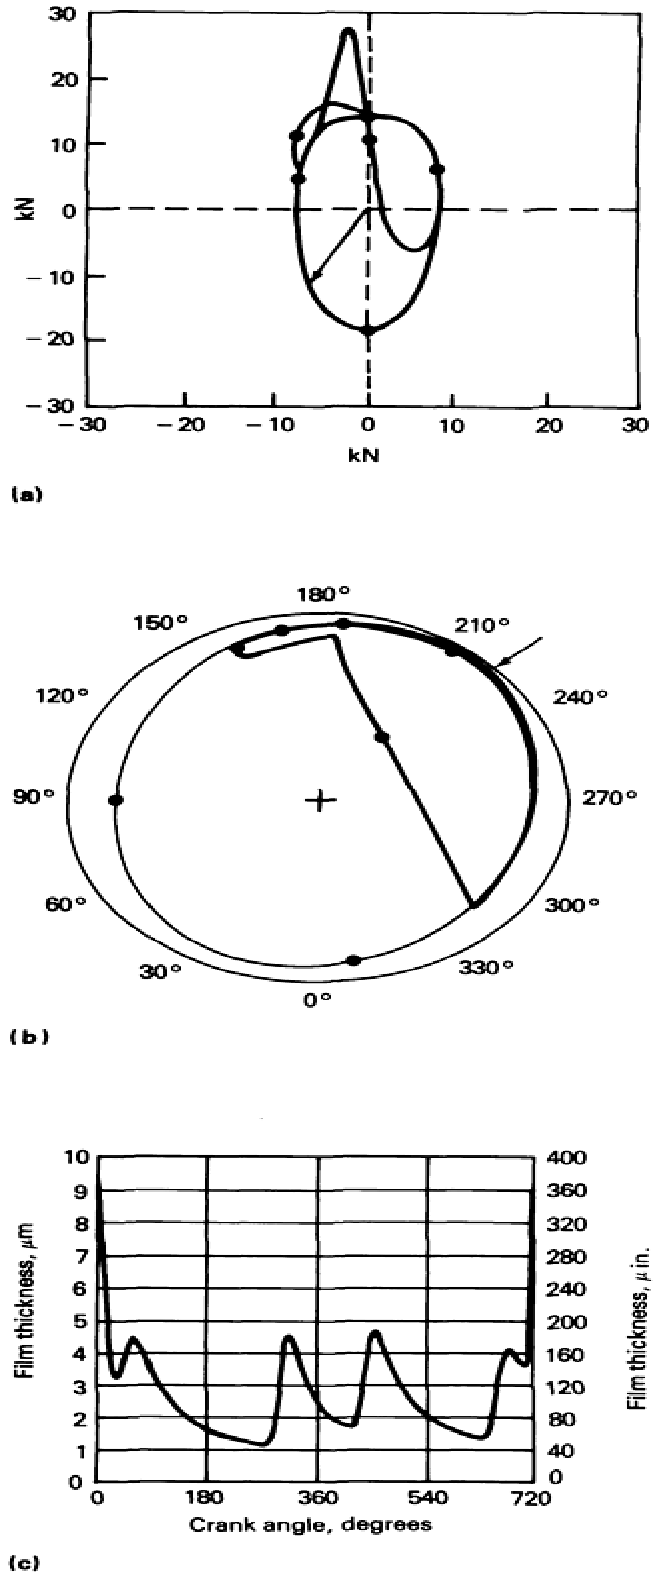

Fig. 8 Monitoring of parameters that measure the performance of a dynamically loaded bearing. (a) Polar load diagram showing how load on the connecting rod bearing varies in magnitude and direction during consecutive revolutions (720°) of the crankshaft in a four-stroke gasoline engine operating at 5250 rev/min. (b) Journal center orbit within the bearing clearance circle. (c) Oil film thickness. The minimum oil film thickness drops to <1.5 μm (<60 μin.) for two periods of a few milliseconds duration during each cycle. Source: Ref 7

Rapid displacement of the journal within the bearing is resisted by the lubricant, and relatively high loads can be carried for brief periods during each revolution. Typically, the maximum specific loads can each 30 to 60 MPa (4.5 to 9 ksi) in

connecting rod bearings, and thus the material must be chosen to have sufficient fatigue strength. Additional information is available in the article "Friction and Wear of Sliding Bearing Materials" in this Volume.

As is evident from their reliability, bearings for reciprocating machinery operate for the majority of their life under full-film lubrication conditions. However, the development of the internal combustion engine and, in particular, the requirement for good fuel economy has resulted in a reduction in the size and the weight of engines coupled with an increase in specific rating. This has resulted in bearings being required to operate with progressively thinner minimum oil film thickness. For the majority of each revolution, the surfaces are separated. However, intermittent asperity contact may occur during various periods of the operational envelope:

- Initial break-in
- At start-up
- At sustained high speed

Sustained High-Speed Operation. The minimum oil film thickness generally occurs at high speeds due to the inertia forces being at maximum. With time, the temperature rises (over a few minutes) to the point that the correspondingly reduced viscosity may be insufficient to maintain an adequate oil film, and asperity contact and wear may occur.

Start-Up Operations. During start-up, there may not be adequate oil supply because in many machines the pump is driven by the shaft; thus, for the first few revolutions, the bearing may have to operate with the oil that remains by capillary action from previous operation. If the engine is cool, there is generally sufficient lubrication. However, repeated "hot" starts may result in excessive wear. At very low temperatures (-20 °C, or -4 °F), the oil may become waxy and the oil pump may not be able to circulate the oil, necessitating the use of a special winter grade oil.

Initial Break-In Operation. The initial break-in period is an important factor in bearing performance. Minimum oil film thickness in automotive internal combustion engines may be as low as 0.001 mm (0.00004 in.), and it is important that crankshafts are not only ground, but also lapped in order to minimize the height of the surface asperities above the mean level of the surface. For such a thin oil film, the typical height of the asperities on the crankshaft and bearing should be <0.5 μm (<20 μin.) R_{pm} after break-in (that is, the sum of e_s + e_b should be <1 μm, or 40 μin.). It may not be economical to achieve such fine finishes in production, and it is normal to rely on the compatibility of bearing material and shaft to achieve a mutual polishing to reduce the height of the asperities and produce a "plateau" or "negatively skewed" distribution of surface heights (Ref 8, 9).

Effect of Operating Conditions on Lubricated Bearing Performance

Imperfections in Geometry. Any deviation from plane, cylindrical, and parallel surfaces in excess of the minimum oil film thickness will result in asperity contact. If initial operating conditions are benign, opportunity exist for asperity polishing (break-in compatibility) or local wear (bedding-in comformability). The bearing assembly can accommodate minor misalignments and faults in assembly (for example, bore distortion, waviness, "barrel"-shaped shaft, and so on). If the defects are excessive, too much of the load may be carried by localized rubbing contact, which leads to overheating, more rapid wear, scuffing, or possibly seizure. Some bearing materials (for example, babbitt metal) may accommodate relatively large geometrical defects by "wiping"(partial melting) or plastic deformation.

Dirty Environment. Any hard particulate contaminants with dimensions in excess of the minimum oil film thickness can be expected to cause plowing wear or scoring of the soft surface of the bearing. Larger particles may become embedded in the bearing and lap or score the mating shaft. Bearing assemblies should be sealed against the ingress of particulate contaminants; if the assembly is lubricated, the oil should be filtered.

Corrosion. Gases and fluids that contaminate lubricants may reduce bearing life by corrosion. Typical examples include water in turbines causing tin oxide formation on tin-base babbitt, and refrigerants corroding babbitt containing copper. Lubricants for engines are provided with additives to inhibit oil oxidation and to minimize corrosion of trimetal bearings; however, dilution with fuel, water, or excessive piston blow-by gas may neutralize the effect of the additives.

Dynamic Loading. Repetitive loading may lead to fatigue of the softer bearing materials. This may occur in reciprocating machinery or occasionally in a high-speed rotating plant due to lack of balance or oil film instability (whirl).

Lack of balance is observed at synchronous frequency and may be attributed, for example, to a thermally bent shaft (labyrinth seal rub) or unsymmetrical aggregation of deposits, erosion on turbine blades, and so on.

Oil film whirl (or "whip") generally occurs at one half synchronous frequency or less and requires a redesign of the bearing (that is, multi-lobe, tilting pad journal, and so on).

Cavitation Erosion. Shaft vibration resulting from dynamic loading may contribute to cavitation erosion of soft bearing surfaces (for example, trimetal bearings), particularly if clearance is excessive (>0.002 mm/mm, or 0.002 in./in.). However, cavitation erosion is more often due to interruptions in the oil supply (as in partially grooved crankshaft bearings) or low oil supply pressure.

Inadequate Lubrication. If wear and friction are to be reduced to minimum, it is essential that sufficient lubricant be supplied to separate the asperities of the mating surfaces. In some machinery, experience has shown that it is possible to obtain an adequate bearing life even when the bearing is operated under oil starvation conditions. Traditional reciprocating steam engines, for example, were able to operate with oil supplied from wick or drip feed lubricators that were topped up hourly or daily. The *PV* factor for such applications was generally <1 MPa · m/s (<3.5×10^4 psi · ft/min), and provision was made to adjust the clearance (take up the slack). For bearings required to operate at a much higher *PV* rating, the oil should be supplied continuously at a minimum pressure of 105 kPa (15 psi) at the entrance to the bearing. When allowance is made for pressure loss in oilways, such conditions generally require a minimum of 210 kPa (30 psi) pressure leaving the oil pump for rotating plant and 310 to 415 kPa (45 to 60 psi) for reciprocating engines. A temporary loss of pressure, even for a few seconds, may lead to overheating and seizure in highly rated bearings.

For light duties, where the *PV* factor is low and heat can be dissipated by conduction, lubricant is provided principally to reduce friction. In such cases, it may be in the form of splash feed, drip lubrication, wick, or self-lubricated (for example, oil-impregnated porous bronze) system. For high loads, particularly those in oscillating pivots, grease is preferred. The presence of indentations or deep grooves to retain and distribute grease may extend the period of bearing operation before regreasing is required.

All bearings in which the asperities are not completely separated by a lubricant film can be expected to wear at a rate that will depend on the application, materials, temperature, lubrication, and so on. Because of the wide range of operating environments, the data given in this article should be considered as an initial guide only. The suitability of a bearing system for any particular application must be based on relevant experienced or established by test.

Friction and Wear of Gas-Lubricated Bearings

Dudley D. Fuller, Columbia University

Introduction

AIR-LUBRICATED BEARINGS have along been a source of interest, but it was not until World War II that a serious concerted effort was initiated to develop the potential of gas-lubricated bearings. The occasion was the Manhattan Project devoted to the creation of the atomic bomb. It is well known that for both domestic power generation and for military purposes, a form of enriched uranium hexafluoride is required (Ref 1). The most significant source of this enriched fuel is the gaseous diffusion plant. These plants provide the enriching process by pumping uranium hexafluoride through a cascade of successive diffusion stages. Several thousand in series may be needed to achieve the desired composition. To avoid unacceptable high energy losses and inevitable contamination of the product associated with the use of conventional oil-lubricated bearings and seals, the pumping equipment bearings are instead lubricated by gaseous uranium hexafluoride.

In 1957 a coordinated research program on gas lubrication was initiated by the Office of Naval Research (ONR). The activity soon became international--with an equivalent group in the United Kingdom working, sharing, and meeting with ONR alternately in England and the United States. Two international symposia were held (Ref 2, 3) with participants from all over the world. In 1981, the sponsorship of the coordinating meetings was assumed by Wright-Patterson Air Force Base, where it continues as of this writing.

Presently, gas-lubricated bearings are found in:

- High-speed grinding spindles
- Sliding ways on machine tools for avoiding stick-slip vibration
- Bearings for precise linear and rotational indexing metrology devices
- Hermetically sealed high-speed blowers and compressors using the process gas as the lubricant, essential for gas-cooled reactors and for cryogenic and pyrogenic turbomachinery where great temperature extremes are encountered
- High-precision inertial guidance instruments such as gyroscopes and accelerometers
- Foil-type gas bearings for air-cycle turbomachines on aircraft and space-borne power-generating components (the immediate goal is to produce 300 kW, or 400 hp, from a unit with a volume of only 0.03 m^3, or 1 ft^3)
- Computer peripheral devices, including magnetic memory devices, tapes, disks and drums, read-write heads "flying" with an air gap <0.25 μm
- High-speed dental and orthopedic drills and cutters that operate at up to 500,000 rpm with quiet, oil-free performance

At the other end of the precision spectrum, externally pressurized air-lubricated membrane bearings are used commercially to support and position large machine tools, heavy die blocks, and even full-scale railroad cars, on the factory or shop floor.

Advantages and Disadvantages

The advantages of gas-lubricated bearings over liquid-lubricated fluid-film bearings are now well understood. These include:

- Cleanliness. Elimination of contamination caused by more traditional lubricants

- Reduction (often elimination) of the need for bearing seals
- Stability of lubricant. No vaporization, cavitation, solidification, decomposition, or phase change over extreme ranges of temperature, from cryogenic (-270 °C, or -450 °F) up to approximately 1650 °C (3000 °F). Operation at these extremes of temperature is a current research goal
- Low friction and heating with little or no cooling generally required. Permits practical attainment of high speeds (700,000 rpm)

Disadvantages of gas-lubricated bearings are recognized as resulting from the relatively low viscosity and damping of gas films. Thus, gas-lubricated bearings have a reduced load-carrying capacity compared to liquid-lubricated bearings, especially with self-acting or hydrodynamic bearings. For acceptable application, therefore, the bearings are necessarily larger and operate with thinner hydrodynamic films than their liquid-lubricated counterparts.

Thinner films demand closer control of manufacturing tolerances, surface finishes, and possible thermal and elastic distortions and alignments, to prevent rubbing contact. With compliant surface bearings, as with foil bearings and membrane bearings, rigid specifications regarding design and manufacture can be dramatically relaxed. The membrane bearing, for example, operates very satisfactorily over a typical factory floor.

The low damping of the gas film makes it necessary to carefully analyze the dynamic characteristics of the mechanical system employing the gas bearing, since if a critical speed or instability is encountered, there may not be enough damping to suppress it or control it. With liquid-lubricated bearings these instabilities might not have been suppressed or passed over unnoticed because of the greater damping action that inherently exists with liquids. Much recent research has been devoted to the dynamics of gas bearings and their associated mechanical systems.

Gas-lubricated bearings have been characterized as being less forgiving than oil-lubricated bearings. This is certainly true for self-acting or hydrodynamic bearings. They are less forgiving of errors in estimating loads, of deviations from specifications during manufacture and installation, and of distortions and dirt that may afflict the rotor.

Compressibility Numbers

Gas is, of course, compressible and this effect must be included in the derivations for various forms of bearings--whether hydrodynamic (self-acting) or hydrostatic (externally pressurized). The extent of compressibility (represented by the compressibility number, Λ) is determined by a dimensionless group of parameters that actually evolves from the mathematical analysis. It takes on several forms depending on the geometry of the bearing.

For journal bearings (Fig. 1), the value of $\Lambda$is:

$$\Lambda = \frac{6\mu\omega}{p_a}\left(\frac{r}{c}\right)^2 \qquad \textbf{(Eq 1)}$$

where c is the machined-in radial clearance, p_a is the absolute ambient pressure, $\omega$is the angular velocity of the journal (rad/s), $\mu$is the absolute viscosity, and r is the radius of the shaft.

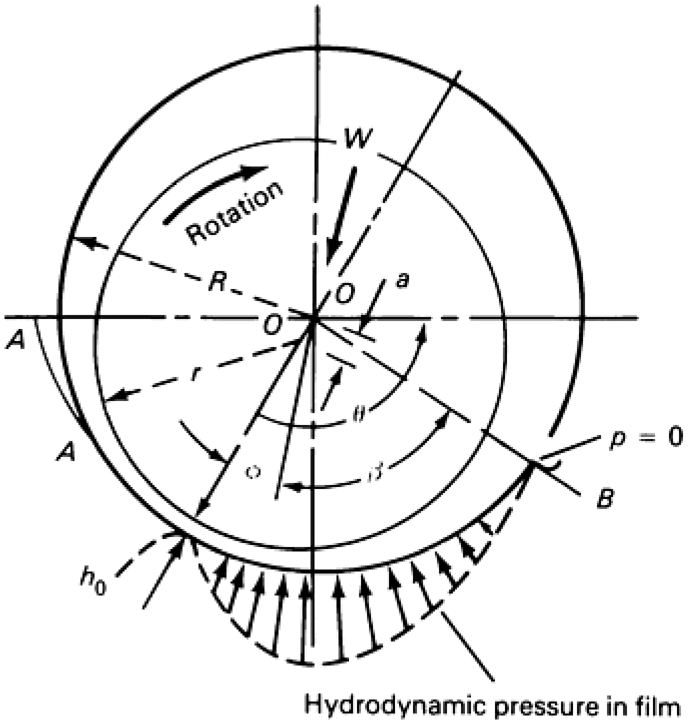

Fig. 1 Journal in full 360° bearing

For a tilting-pad thrust bearing (Fig. 2), the value of Λ is:

$$\Lambda = \frac{6\mu u l}{h_2^2 p_a} \quad \textbf{(Eq 2)}$$

where l is the length of the pad in the direction of sliding (sometimes designated as L), and h_2 is the minimum film thickness (sometimes referred to as h_0), and u is the velocity of the runner past the shoe.

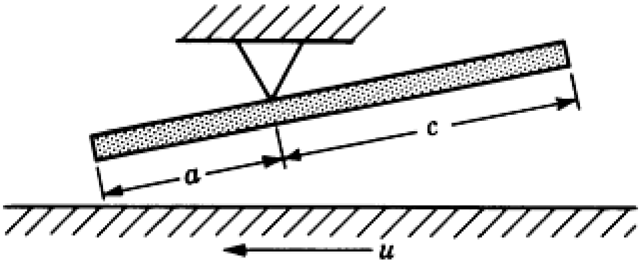

Fig. 2 Representation of pivoted shoe

For a Rayleigh step bearing (Fig. 3), the value of Λ is:

$$\Lambda = \frac{6\mu U l}{h_2^2 p_a} \quad \textbf{(Eq 3)}$$

where l is the length of the pad in the direction of sliding, U is the velocity of the runner past the pad, and h_2 is the minimum film thickness.

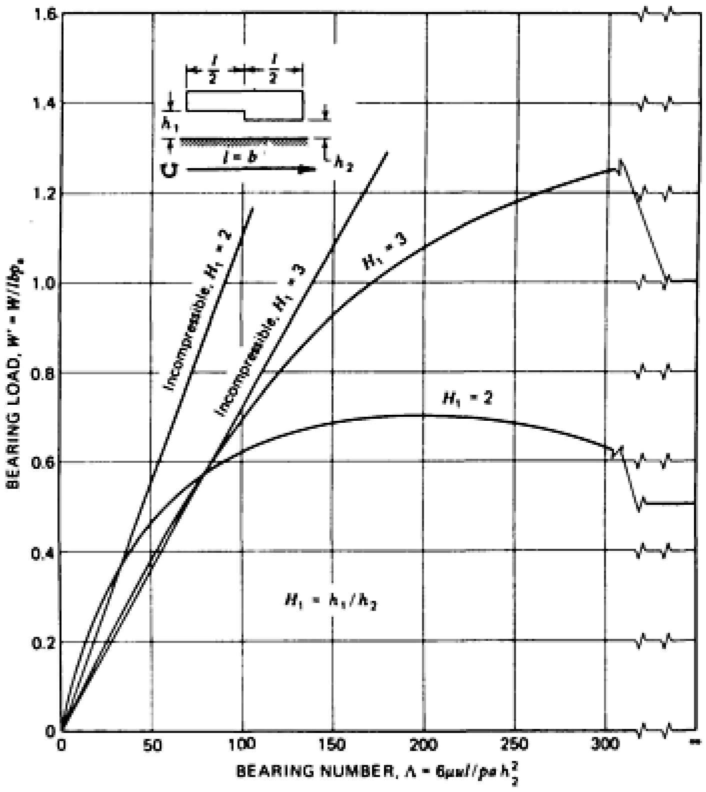

Fig. 3 Effect of bearing number on isothermal load for square-step slider bearings with film thickness ratios h_1/h_2 = 2 and 3. Source: Ref 4

When Λ approaches 0, operation of the gas-lubricated bearing approaches that of the liquid-lubricated (incompressible) case. As a Λ gets larger, as with lower ambient pressure or higher speed, the compressibility effects become very significant and must be included. For example, with journal bearings it can be shown that the equations for determining the load-carrying capacity for liquids and gases are essentially the same up to a value of Λ= 1 (Fig. 4). For tilting-pad bearings, the identity remain up to a value of about 15 (Fig. 5).

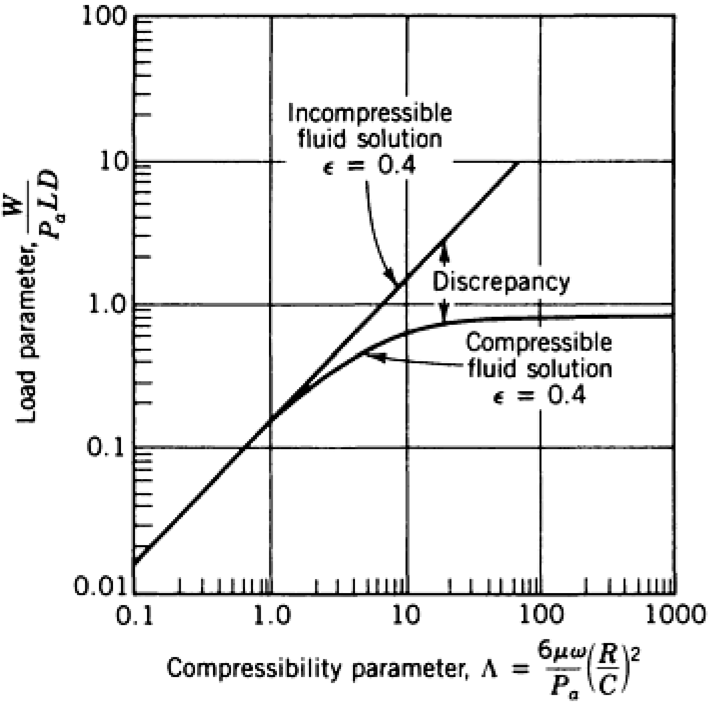

Fig. 4 Discrepancy in load capacity between results based on incompressible and compressible lubricants. Source: Ref 5

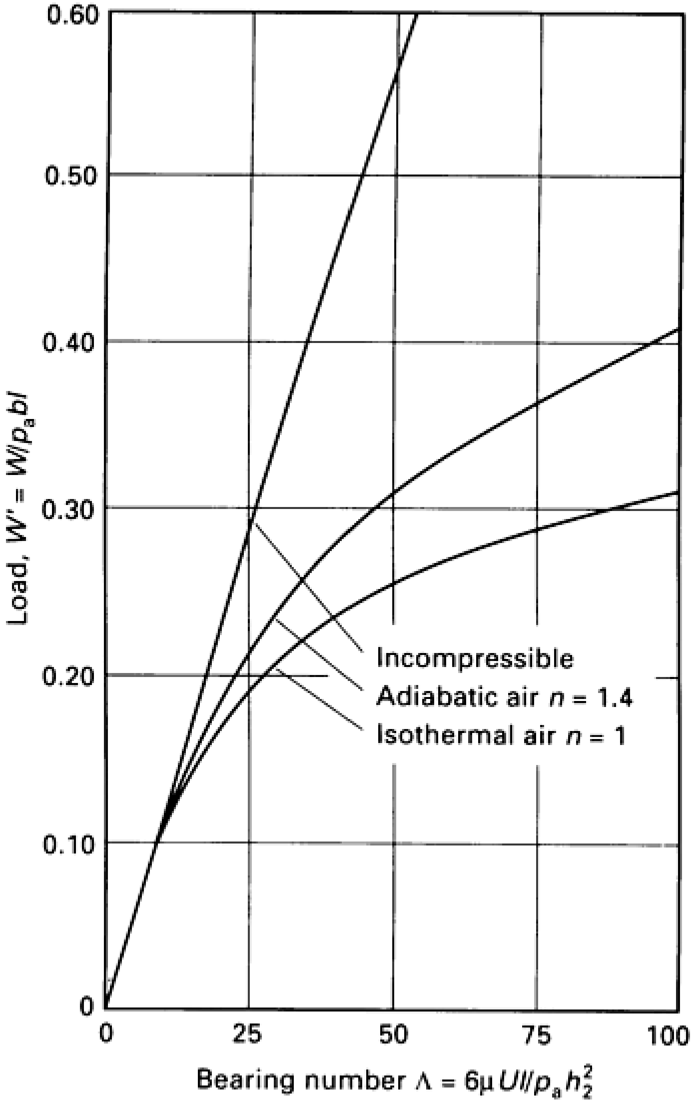

Fig. 5 Effect of bearing number on isothermal and adiabatic load for plane slider bearing operating in air with film thickness ratio h_1/h_2 = 2. Length-to-breadth ratio l/b = 1. Source: Ref 6

An interesting experimental demonstration is illustrated in Fig. 6, which shows the relationship between load-carrying capacity, *W*, and Λ for a hydrodynamic gas-lubricated journal bearing. Speed, viscosity, and eccentricity ratio were held constant while the ambient pressure was reduced, thus producing higher values of Λ. Notice that when the ambient pressure was reduced to 9% of atmospheric, the load-carrying capacity was lowered by 40%.

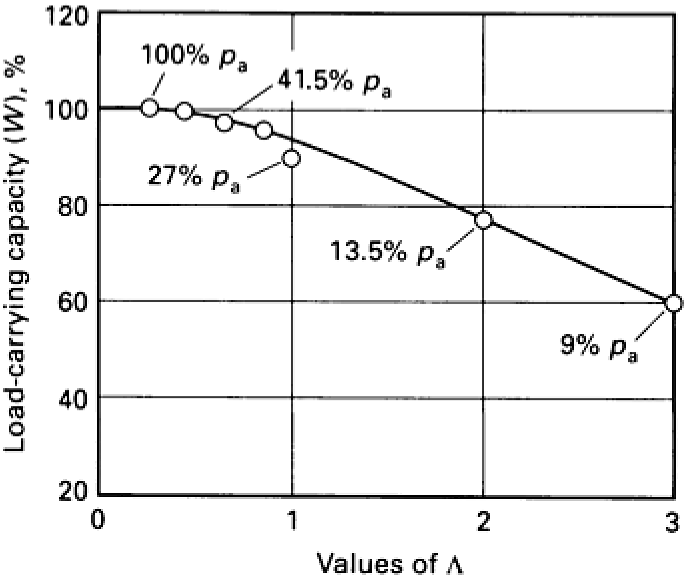

Fig. 6 Example of relationship between load-carrying capacity, *W*, and Λ for self-acting gas-lubricated journal bearing. Speed, viscosity, and eccentricity ratio held constant. Ambient pressure varied. Source: Ref 7

Definitions of Eccentricity Ratio and Clearance Modulus

In Fig. 1, *O* represents the center of the bearing and *O*' the center of the shaft. The distance *O*-*O*' is also designated as *a;* for light loads and high operating speeds, the center of the shaft and bearing coincide, and *a* approaches zero. The ratio of the distance *a* for any given operating condition to the machined-in radial clearance *c* of the bearing is called the eccentricity ratio, ϵ.

For heavy loads or extremes of operation, such as low speed or very low viscosity, the journal becomes more eccentric in the bearing and the distance *a* increases. The limit is where the journal just begins to make solid contact with the bearing, or the distance *a* equals the radial clearance. The eccentricity ratio is then 1. The radial clearance in the journal bearing is often designated as *mr,* where *m* is the clearance modulus of the bearing and *r* is the radius of the shaft or journal. The value of *m* will usually range between 0.0005 and 0.003 mm/mm, with typical industrial-type bearings running between 0.001 and 0.0025 mm/mm.

In the analysis of fluid-film bearings using incompressible lubricants, the continuity relationship was satisfied by saying that the volume of lubricant leaving the bearing was the same as the volume entering. With gas, of course, the volume changes, so that continuity must be based on equality of mass. Thus the mass of lubricant leaving equals the mass entering.

The basic Reynolds equation then becomes (Ref 8):

$$\frac{\partial}{\partial x}\left[\frac{\rho h^3}{\mu}\frac{\partial p}{\partial x}\right] + \frac{\partial}{\partial z}\left[\frac{\rho h^3}{\mu}\frac{\partial p}{\partial z}\right] = 6U\frac{\partial \rho h}{\partial x} \quad \textbf{(Eq 4)}$$

where ρ is the mass density, *x* is the coordinate along the film in the direction of motion, *z* is the coordinate along the bearing dimension perpendicular to the direction of motion (sometimes called the length of the bearing, *l,* or the width of the bearing, *b*), *p* is the differential pressure, and *h* is the local differential film thickness.

Except for a few restricted solutions with no side flow in the *z* direction, solutions are only possible through extended iterative computer solutions. The order of magnitude of the solutions, however, can often be checked by reference to results for incompressible lubricants, especially for cases of low Λ(Ref 9).

Tilting-Pad Bearings

Some marked differences in behavior exist between tilting-pad gas-lubricated bearings (Fig. 2) and liquid-lubricated bearings. The expected pressure is somewhat modified, as shown comparatively in Fig. 7. The peak pressure is shifted toward the trailing edge of the shoe. This means that the pivot position for a gas-lubricated bearing is not the same as for a liquid-lubricated bearing. Figure 8 shows quantitative values for a tilting-pad gas-lubricated bearing for various values of Λ(Eq 2). In this case, $\Lambda$was reduced by lowering the ambient pressure.

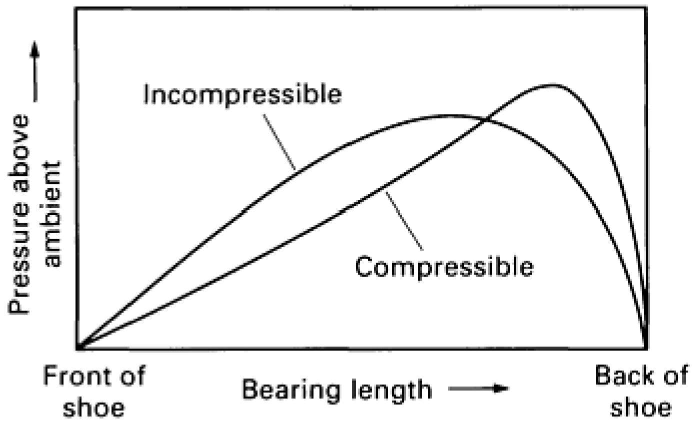

Fig. 7 Comparative pressure distribution for compressible and incompressible lubrication. Source: Ref 6

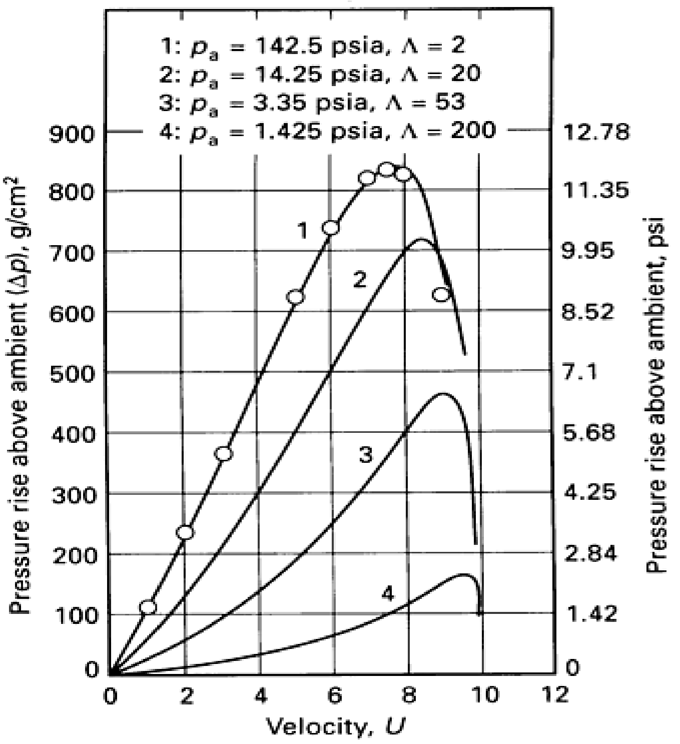

Fig. 8 Gas pressure distribution in flat tilting-pad bearing. Note open circles (data points) for theoretical liquid case. Source: Ref 7

Notice that for high values of Λ, the center of pressure moves toward the trailing edge or the back of the pad. For each designated operating condition, the pivot should be located at the center of pressure. Thus, if the ambient pressure, the speed, or the load is subject to change, a fixed pivot position will be optimum for only one set of operating conditions. This is a disadvantage.

In contrast, with incompressible lubricants, the tilting pad will react to a change in load or speed so that the ratio of inlet-to-outlet film thickness remains constant, even with the minimum film thickness getting smaller with increasing load. Thus, with liquid lubricants, once the pivot position is chosen, it will remain optimized for all changes of load, speed, or viscosity.

With gas-lubricated tilting-pad bearings, yet another complication arises. As the load increases, the minimum film thickness decreases, but since the pivot location is fixed, the pad angle of inclination begins to get smaller and eventually becomes parallel to the runner. An unstable condition will result, and the bearing will be unable to support the load and will collapse completely.

Collapse of the gas film will not occur for a convex curved surface on a tilting pad (Fig. 9). Because of the geometry, neglecting the influence of surface roughness asperities, a wedge must always be developed no matter how thin the film. An experimental study by Brunner *et al.* (Ref 12) shows that for a pad 19 mm ($\frac{3}{4}$ in.) wide by about 13 mm ($\frac{1}{2}$ in.) long in the direction of motion, even a crown height, δ, of as little as 0.25 μm will prevent collapse of the film and produce a load-carrying characteristic that continues to rise as the film reduces. Experience has shown that crown heights for optimum load-carrying capacity are approximately equal to the minimum film thickness, or about 7.5 to 10 μm.

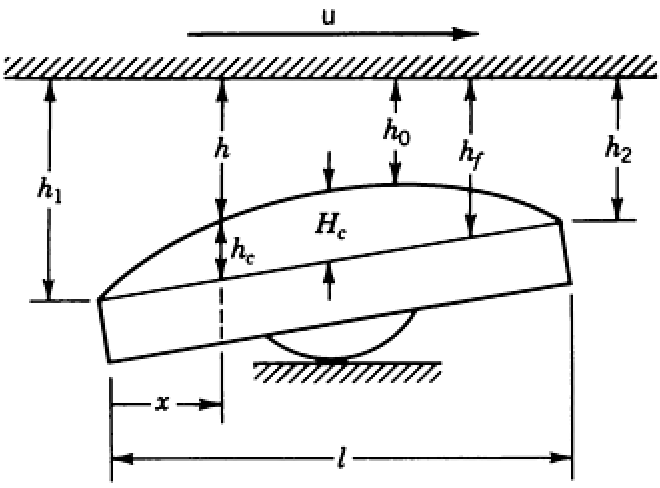

Fig. 9 Nomenclature for crowned tilting-pad bearing. Source: Ref 11

A thorough analysis of optimum crown heights and pivot positions can be found in Ref 4. Experimental verification of the theory has been especially good. Figure 10 shows values of the dimensionless load-carrying function as a function of the compressibility number for shoes having cylindrical crowns. The pivot position is not identified, but a value of about 0.6 is typical. That means, in Fig. 2, *c* is 0.6 of the length in the direction of motion and *a* is 0.4 of the length. The pivot is always between the midpoint and the trailing edge.

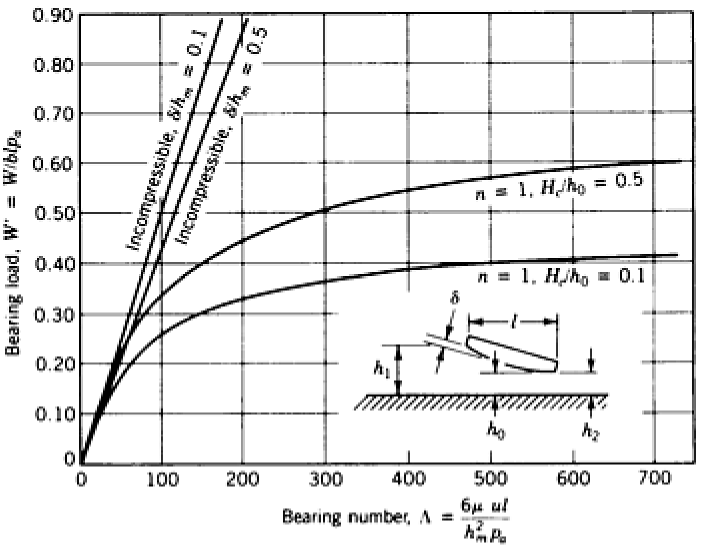

Fig. 10 Effect of bearing number on isothermal load for cylindrically crowned slider bearing, b/l = 1, h_1/h_m = 2, and H_c/h_0 = 0.1 and 0.5. Source: Ref 4

Effect of Mean Free Path

When gas films become very thin, as for example, when operating in a partial vacuum, the gas may no longer be considered as a continuous fluid, having the bulk viscosity of that fluid. Effects take place that can no longer be explained by continuous theory. Slip occurs at the boundary between the bearing surface and the gas and must be introduced into the calculation.

The measure of this slip condition is determined by the Knudsen number (K_n). This is the ratio of the mean free path of the gas (λ) to the film thickness in the bearing (h). Thus, $K_n = \lambda/h$. When K_n is less than 0.01, the gas flow can be treated as a continuum and slip flow ignored. When K_n is in the range of 0.01 to 1.5, slip flow increases and should be considered. When K_n is greater than 1.5, slip flow becomes significant and fully developed molecular flow results.

Typical values of mean free path at atmospheric conditions are:

Gas	Typical mean free path value	
	in. × 10^{-6}	**μm**
Hydrogen	4.43	0.1125
Helium	7.32	0.186
Air	2.52	0.064
Neon	5.20	0.132

Thus, with an air-film thickness of 2.5 μm (0.0001 in.), the value of K_n would be 2.52 × 10^{-6}/100 × 10^{-6}, or 0.025. The slip effect would be small but not negligible.

Many tilting-pad-type thrust bearings with air lubrication are used in magnetic storage devices for computers, where they "fly" at film thicknesses of about 0.5 μm (20 μin.). At these very small film thicknesses, surface roughness can become a significant factor because no surfaces are perfectly smooth. This effect can be analyzed and included in predicting load-carrying capacity.

Rayleigh Step Bearings

This type of bearing is shown in Fig. 3. Analytical results for a square-step bearing (width equals length) are shown in Fig. 11 for lubrication with gas. A dimensionless load function *W*' is plotted against the compressibility number established for step bearings (see Eq 3).

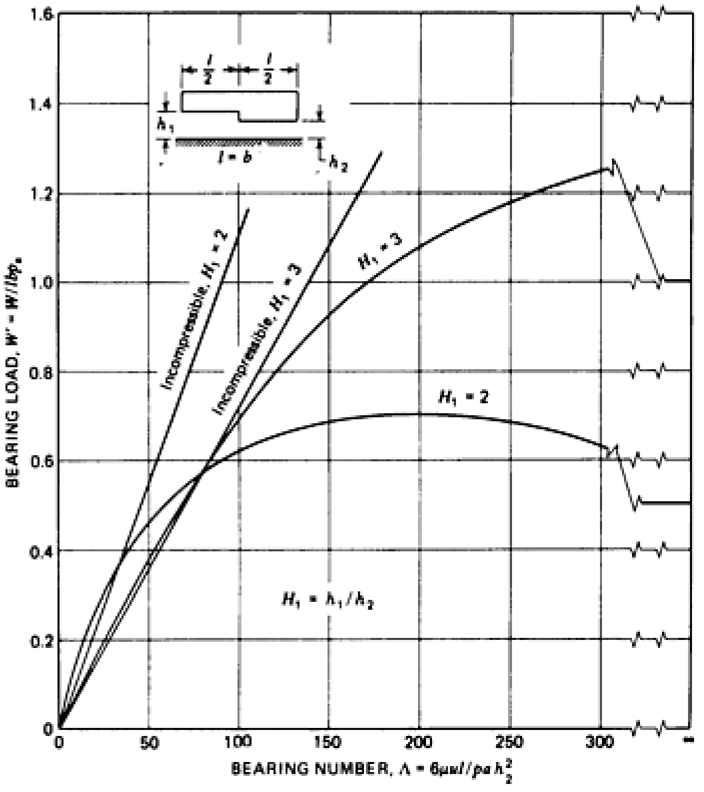

Fig. 11 Effect of bearing number on isothermal load for square-step slider bearings with film thickness ratios h_1/h_2 = 2 and 3. Source: Ref 4

Journal Bearings

This was the geometry first used to demonstrate true load-bearing ability by Kingsbury in 1897 (Ref 13). The same concept was used by Brubach (Ref 14) in utilizing inexpensive hypodermic syringes as air bearings. These are precision-made plungers in closely fitting barrels that perform remarkably well as hydrodynamic journal bearings.

Brubach has used these syringes as bearings for small centrifugal blowers running at 6000 rpm (Fig. 12). Perhaps his most important application has been in the measurement of gas leaks at very low pressures. Figure 13 shows the apparatus used for this purpose. The plunger of the syringe is caused to rotate by air impinging on the Scotch tape vanes. Due to this rotation, the plunger acts as an air bearing and is separated from the barrel by a hydrodynamic air film. Because the surfaces are separated from the barrel by a thin air film, the force required to move the plunger along the axis of the barrel actually approaches zero.

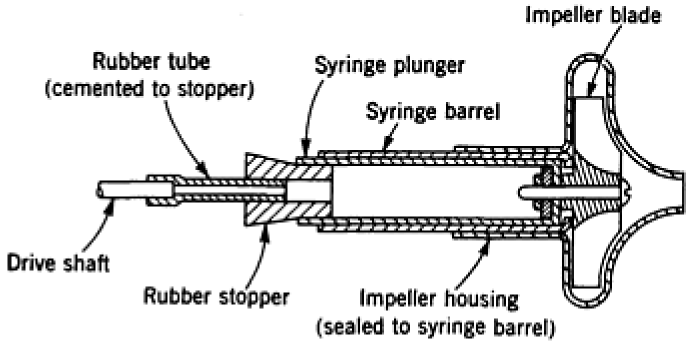

Fig. 12 Centrifugal blower using hypodermic syringe as air-lubricant bearing. Source: Ref 14

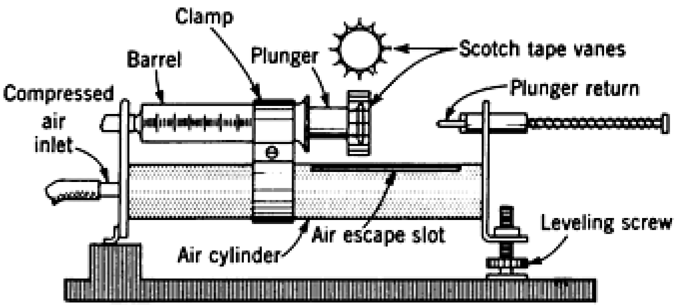

Fig. 13 Sensitive pressure-measuring apparatus using hypodermic syringe as air-lubricated bearing. Source: Ref 14

As an illustration of the sensitivity of this apparatus, it was connected to a tank of 100 L (26 gal) capacity. Then 0.1 mL (0.06 in.^{3}) of air was introduced into the tank. Immediately the plunger moved a corresponding 0.1 mL (0.06 in.^{3}). The theoretical pressure increase resulting from the injection of 0.1 mL (0.06 in.^{3}) into 100 L (26 gal) is about 0.01 mm (0.0004 in.) of water, and yet the low friction of the rotating plunger permitted it to respond instantly to this exceedingly small pressure differential.

Journal bearings are also influenced by compressibility of the gaseous lubricant. The value of Λ was given in Eq 1. Ford, Harris, and Pantall (Ref 7) show experimental correlation of the load-carrying parameter *W'* plotted against Λ (Fig. 14). For values of Λ greater than 1, the relationship is no longer linear. The deviation from a straight line indicates the point at which the compressibility effects make their influence felt.

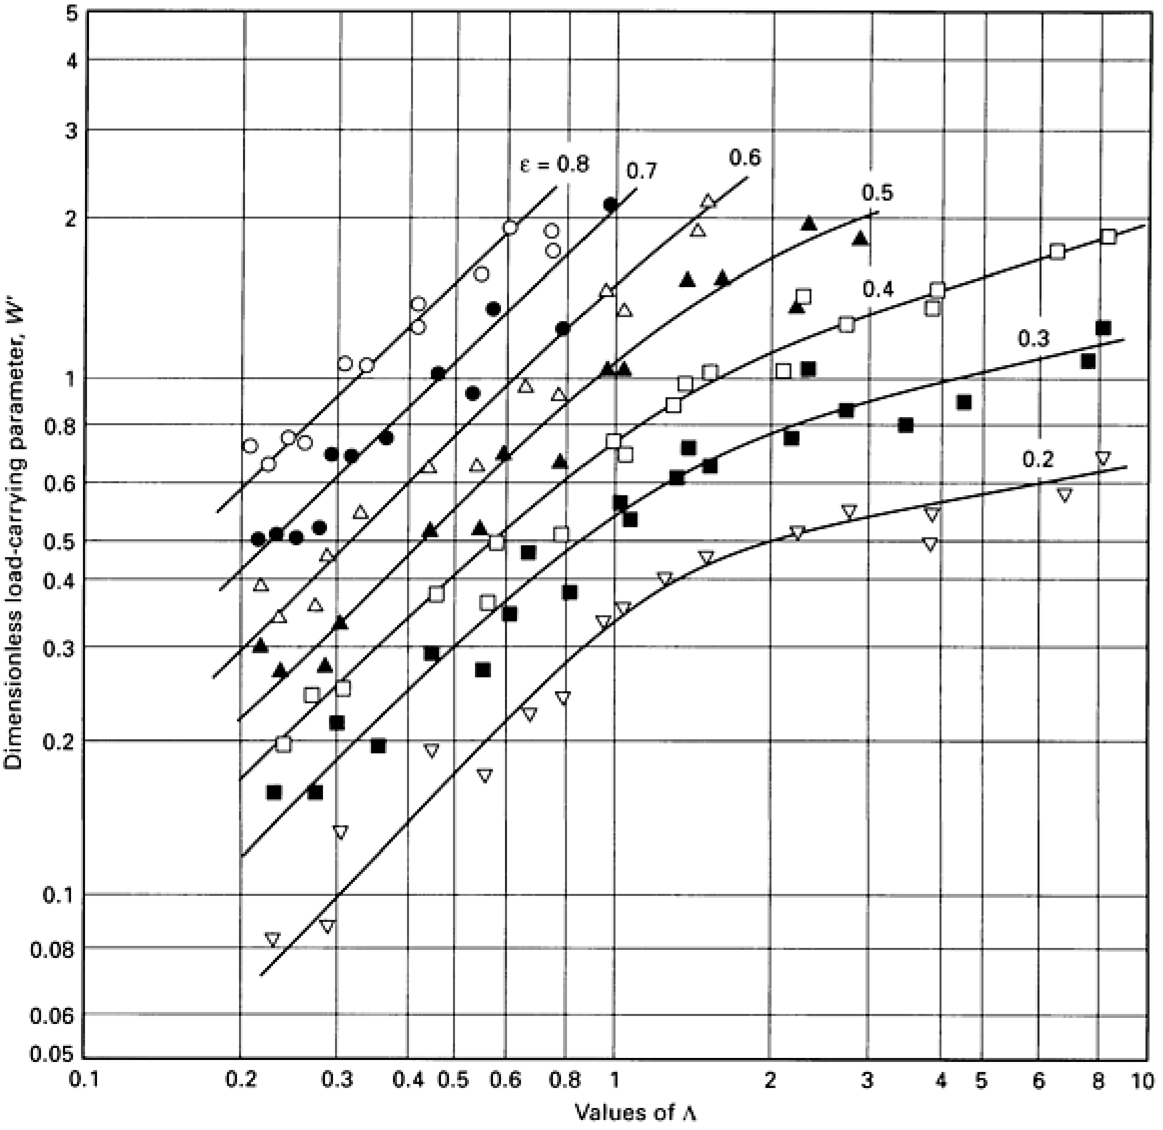

Fig. 14 Load parameter *W*' evaluated in terms of Λ and ϵ. Source: Ref 7

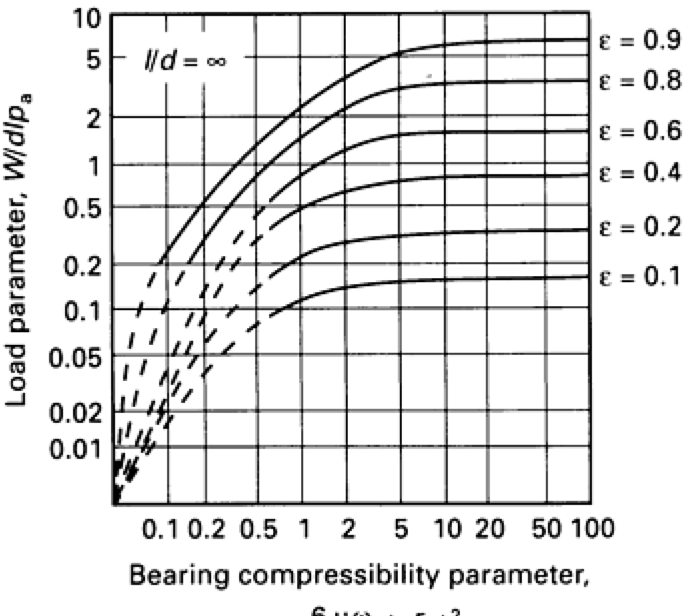
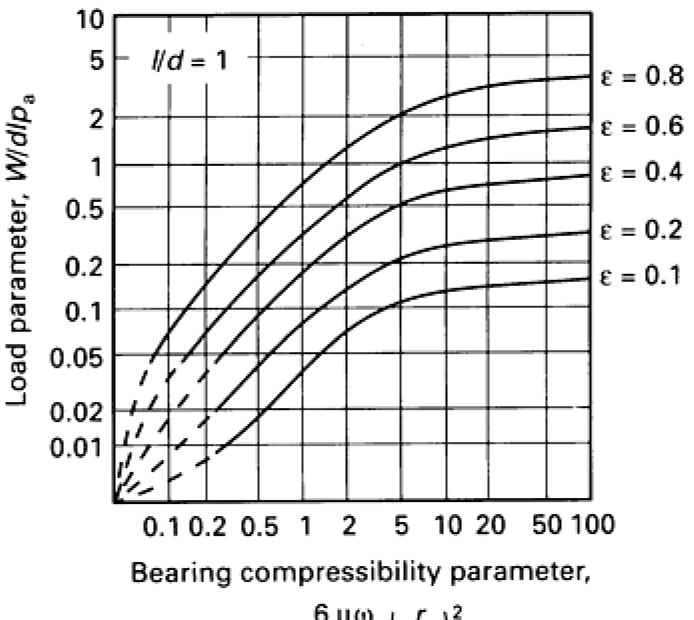
Another important variable in journal bearing analysis, especially stability analysis, is the attitude angle. In Fig. 1 this angle is shown as the angle, ϕ, between the line of load action, *W*, and the line of centers of the bearing, *O*-*O*'. The attitude angle will vary with load, speed, and other operating conditions, and also will depend on the geometrical configuration of the bearing itself. In general, if the attitude angle is small, the bearing is more stable against self-excited whirl. If the attitude is large, the bearing will be less stable against self-excited whirl.

For load-carrying capacity, the accumulated results of Gross (Ref 4), Elrod and Malanoski (Ref 15, 16), Elrod and Burgdorfer (Ref 17), and Raimondi (Ref 18) can be used as a general design approach for complete (360°) journal bearings. Figures 15, 16, and 17 show typical results from these analytical evaluations.



$$\Lambda = \frac{6\,\mu\omega}{p_a}\left(\frac{r}{c}\right)^2$$

Fig. 15 Theoretical load-carrying parameter versus compressibility number for full journal bearing with *l/d* = ∞



$$\Lambda = \frac{6\,\mu\omega}{p_a}\left(\frac{r}{c}\right)^2$$

Fig. 16 Theoretical load-carrying parameter versus compressibility number for full journal bearing with *l/d* = 1

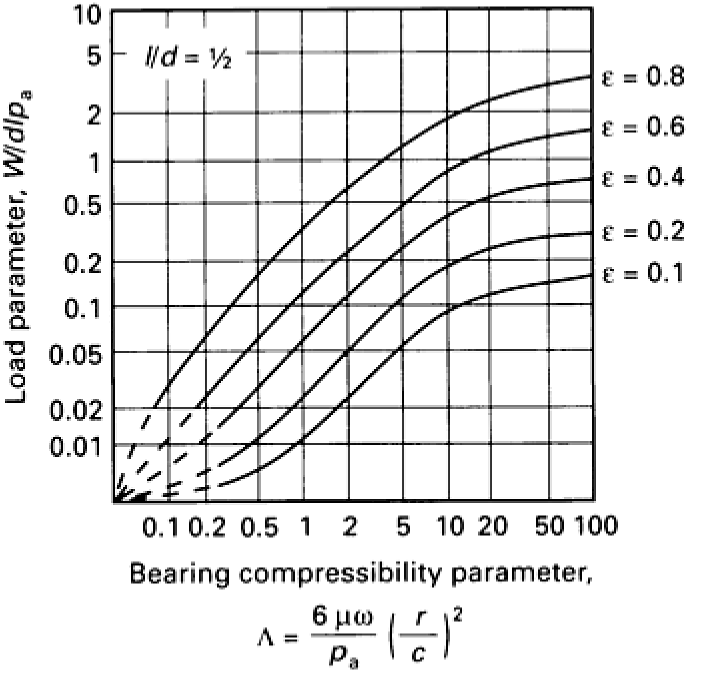


Fig. 17 Theoretical load-carrying parameter versus compressibility number for full journal bearing with *l*/*d* = $\frac{1}{2}$

Friction in Gas-Lubricated Journal Bearings

Of interest in some design applications is the power loss in the bearing due to friction resulting from viscous drag effects of the gas. Raimondi (Ref 18) has graphs of friction factors applicable to four *l*/*d* ratios, namely ∞, 2, 1, and $\frac{1}{2}$ for values of ϵ.

Specifically, the dimensionless friction factor for a plain journal bearing of ∞length is defined as:

$$C_f^{\infty} = \frac{M_J}{2\pi\mu U r^2 l/c} \qquad \textbf{(Eq 5)}$$

where,in English units, M_J is the frictional moment on the journal (in. · lbf). Figure 18 shows the friction factor plotted against the compressibility parameter.

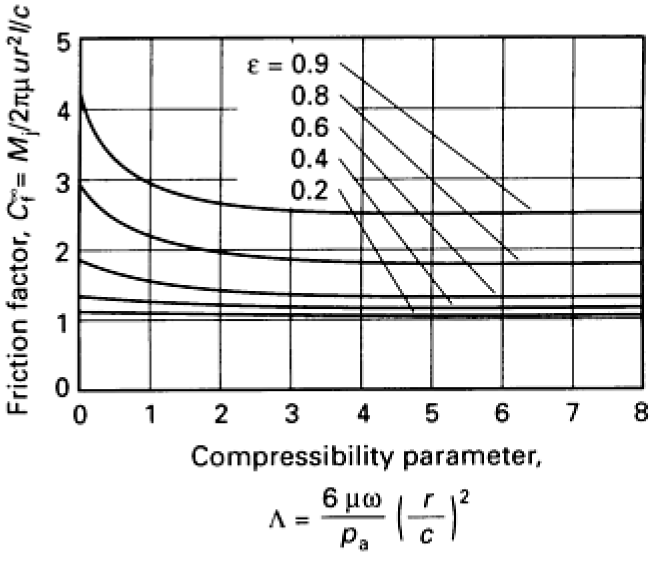

Fig. 18 Friction factor for full bearing of infinite length. Source: Ref 16

It can be seen from Fig. 18 that the friction loss is quite independent of Λ up to values of ϵ about 0.5. This means that for many bearings with low ϵ, values of friction can be reasonably estimated by using only simple Newtonian viscous shear. That would be shown by:

$$M_J = \mu A r \frac{v}{h} \quad \textbf{(Eq 6)}$$

where *A* is the swept area, which equals 2 πrl; *v* is the linear surface velocity; and *h* is the radial clearance, which equals *c*.

Synchronous Whirl

Synchronous whirl is a term used to describe a vibration condition in a fluid-film bearing where the mass of the rotor, combined with the spring stiffness of the bearing fluid film, can result in a natural frequency of vibration that is troublesome. If this natural frequency is the same as the rotational speed of the shaft, very large motions may be produced, resulting in possible bearing failure. If this natural frequency is below the operating speed, then it is necessary to pass through this resonant condition when approaching bearing speed.

Synchronous whirl can take the form of a translatory whirl, where the center line of the shaft describes the locus of a cylinder, or synchronous whirl can be conical. The conical mode form would resemble a bow tie, where there is no displacement at the center, only at the ends of the rotor. The displacement at the ends of the rotor would be out phase with each other.

If the bearing housing itself is elastically supported, it may also be capable of vibrating in either translatory or conical modes of vibration. These phenomena are analyzed in considerable detail in Ref 9.

A generally satisfactory approach is to estimate the quasi-static stiffness of the bearing film and then, in conjunction with the mass of the rotor, evaluate the natural frequency of vibration. It is a method that has proven its value over dozens of applications; Ref 9 provides examples of analyses that demonstrate the procedure.

Tilting-Pad Journal Bearings

One favored bearing design to achieve rotor stability is to use tilting-pad journal bearings. Considerable analytical and experimental work has been devoted to these bearings, both in the liquid- and gas-lubricated forms. These bearings also offer circumferential and axial misalignment capabilities.

Placing a resilient support (like a spring) under one pad of a three-pad bearing permits accommodation of centrifugal growth of the shaft at high speed or thermal or elastic dimensional changes in both shaft and bearing housing. When properly designed, this bearing is very forgiving. Many succesful applications have been made.

When using gas as the lubricant, some designs will include an auxiliary hydrostatic lift for starting (Fig. 20), which will reduce initial solid contact friction and protect the surfaces. The complete design is quite complex and an area of great specialization. Design guides for gas-lubricated journal and thrust bearings can be found in Ref 21, 22, 23, 24, and 25.

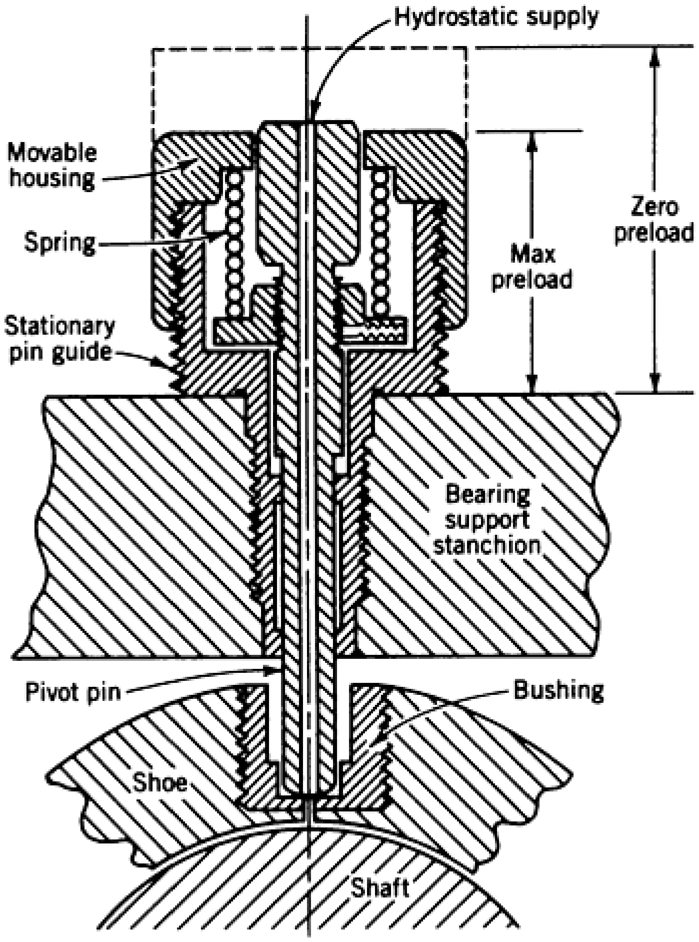

Fig. 20 Cross-sectional view of a spring-mounted pivot assembly. Source: Ref 21

A few fundamental concepts are critical in the design of a tilting-pad journal bearing. Of primary importance are yaw stability, pivot circle clearance, and pivot design. Other design features--such as film stiffness of combined bearing, minimization of bearing friction, the effect of clearance on minimum film thickness, shoe pitching frequency, and rotor critical speeds--are examined in the referenced design manual (Ref 21).

Yaw Stability. A pivoted shoe (or pad) has three degrees of freedom. It can pitch and roll like a ship, and it can yaw. To yaw is to act like a boat rotating about a vertical axis through its center of gravity. Any such rotation will lead to film rupture at the outer corners of th pad, with resulting solid contact. To provide for yaw stiffness in the bearing pad, the angle of wrap of the shoes should be no less than 90° of circumferential arc. With shorter arcs, the pad rapidly loses its ability to provide a resisting moment.

Pivot Circle Clearance. One of the crucial parameters governing the operation of the bearing is the setting of the pivot circle clearance (C' in Fig. 21). If the shaft always remained in the central concentric position, then C' could equal the actual clearance in the bearing, designated by C. That is to say, the radius of curvature of the shoe equals the radius of curvature of the shaft, R, plus the clearance C. The radius of curvature of the shoe is thus greater than the radius of curvature of the shaft. This produces the same phenomenon as having a crowned tilting pad. The load-carrying film cannot collapse even if the film becomes very thin.

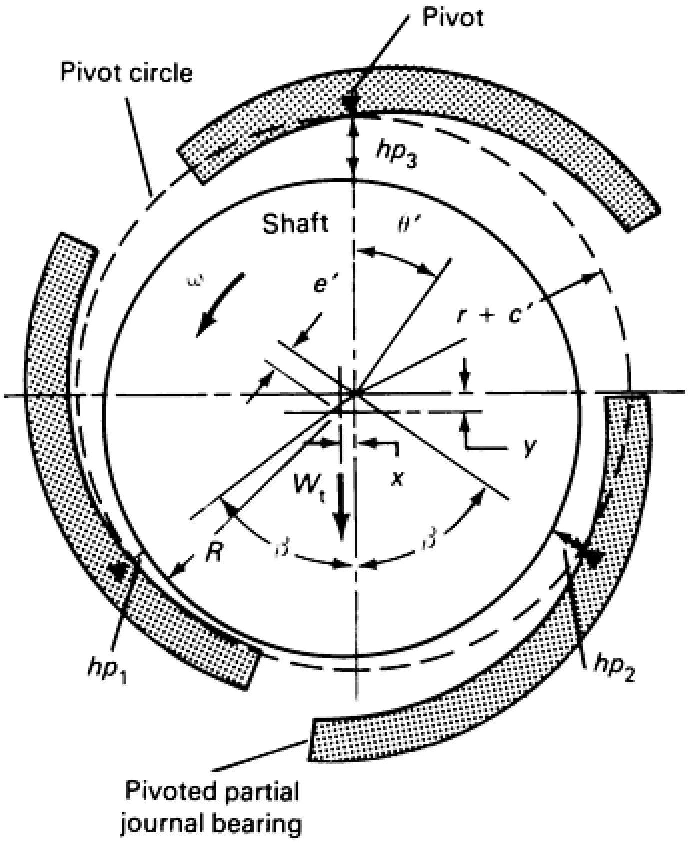

Fig. 21 Pivoted-pad journal bearing with three shoes. Source: Ref 21

However, with the journal bearing under load, and with low speeds, the eccentricity of the shaft can become great enough so that it moves away from the top (unloaded) tilting pad, so that the pad will lose its converging wedge and become unstable. To avoid this possibility, the shaft is preloaded by squeezing the pads radially inward, making C' less than C. The measure of this is the ratio C'/C, which should be less than 1. This is a design parameter and depends on the expected range of eccentricity ratios to be encountered.

Pivot Design. The third important concept is the design of the actual pivot. A ball and socket joint will not be satisfactory because of the frictional resistance to sliding. As the pad assumes its equilibrium position, its righting capacity goes to zero. Any residual friction in the pivot will prevent the pad from ever reaching its equilibrium design inclination. Figure 22 shows a recommended configuration utilizing rolling friction rather than sliding friction. Incidentally, the surfaces should be smooth and very hard to prevent fretting corrosion.

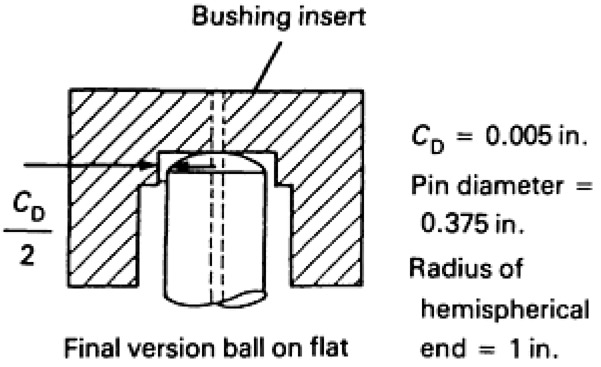

Fig. 22 Bushing insert for pivoted-pad hydrostatic journal bearing. Source: Ref 21

Three-Sector Journal Bearing

This journal bearing, with three equally spaced axial grooves, has shown some degree of stability against self-excited whirl. Castelli and Pirvics (Ref 26) have presented comprehensive numerically computed performance characteristics for three- and four-axial grooved gas-lubricated journal bearings. Angular extent of each groove is considered to be 5°. Thus for a three-sector bearing, the arc length of a sector would be 120 - 5 = 115°.

Figure 23 lists results in terms of the dimensionless load capacity parameter $W' = W/p_a\ rl$ plotted against the bearing compressibility number Λ. Note that the value of Λ used here is actually the same as in Eq 1. The applied load is directed toward the center of one sector. Evaluating W' and Λ will determine the eccentricity ratio and thus the minimum film thickness.

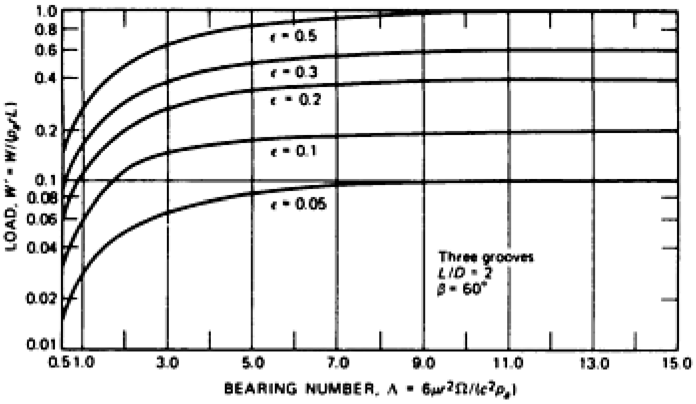

Fig. 23 Load function W' versus Λ for three-groove journal bearing. Source: Ref 26

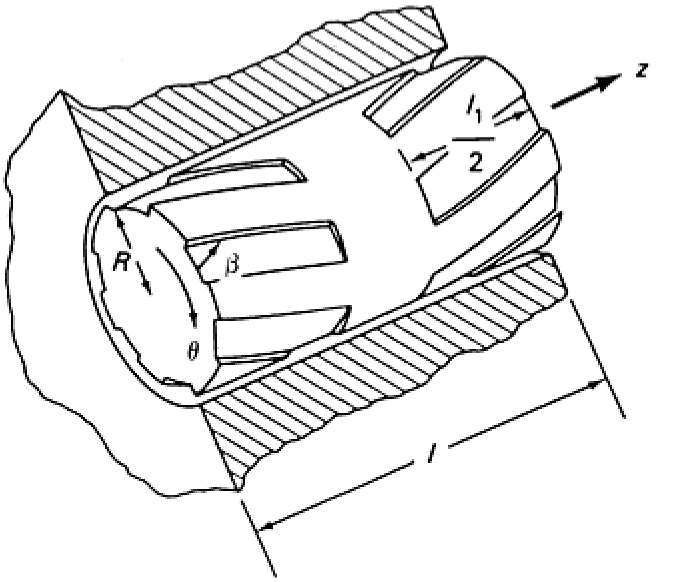
Information on many other sizes, load directions, and attitude angles can be found in Ref 26 and 27.

Helical-Grooved Journal Bearings

The helical grooving in this type of journal bearing enhances stability by reducing the attitude angle below that obtained from a plain cylindrical journal bearing. These bearings are known for their stability and are often used as a possible substitute for tilting-pad journal bearings.

Castelli and Vohr (Ref 28) solved the appropriate equations numerically for load capacity and attitude angle for the case of l/d = 1.0, with various values of Λ. Figure 24 lists the geometric parameters for the spiral-grooved bearing as used in Ref 28. Figure 25 lists the results showing the load parameter $W' = Wp_a$ as a function of Λ with the eccentricity ratio ϵ as the third variable. Malanoski (Ref 29) shows good comparison between the theoretical predictions of Castelli and Vohr and his own measured results for helical-grooved journal bearings.



$$\alpha = \frac{a_g}{a_g + a_r} \qquad \bar{z} = \frac{l_1}{l} \qquad \Gamma = \frac{h_g}{h_r}$$

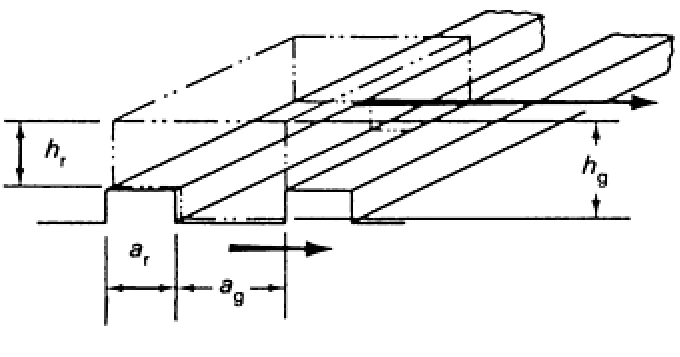


Fig. 24 Geometry of spiral-groove bearing, using notation of Castelli and Vohr (Ref 28)

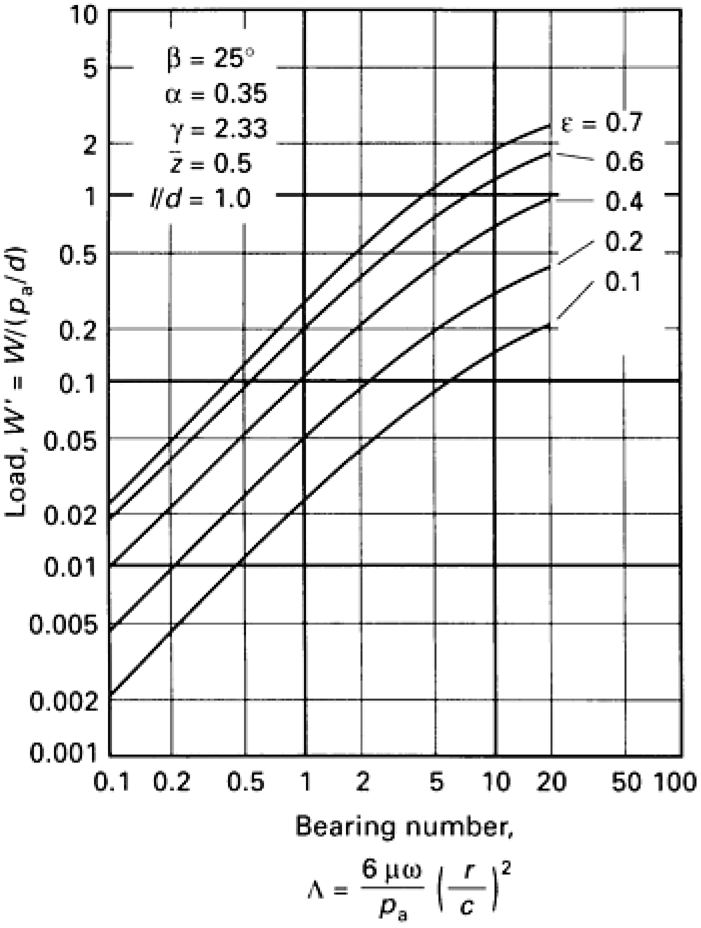

Fig. 25 Load capacity of spiral-groove journal bearing as a function of bearing number and eccentricity ratio. Source: Ref 28

Hydrostatic Gas-Lubricated Bearings

The many advantages of externally pressurized bearings are well known (Ref 9). With gas they have the added benefit of extreme cleanliness, and the use of gas enables them to operate over a wide range of temperatures.

However, analytical and design complications arise because of the compressibility of the gas. At low supply pressures (gage) equal to or less than ambient pressure (absolute), the system can be very simple; for example, supply pressure 70 kPa (10 psig) with an ambient pressure of 100 kPa (14.7 psia).

With high feed pressure, the gas flow in the entrance section is extremely complicated and may involve choked flow, shock waves, vortex formation, and boundary layer growth. Many comprehensive studies have been made of supersonic pressure depression in the feeding region of externally pressurized bearings (Ref 30, 31, 32, 33, 34).

These bearings do not involve a constant volume of flow as is the case with many liquid-lubricated hydrostatic bearings. Therefore, in order to achieve stiffness, they must have some kind of upstream restrictor in the feed line (Fig. 26). The flow restrictor can be an orifice or a capillary, and the bearing is then described as being restrictor compensated; the orifice restrictor area is equal to $\pi d_0^2/4$ (Fig. 26).

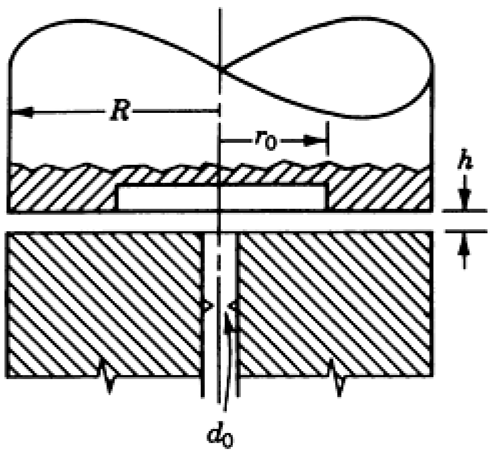

Fig. 26 Flow-restricted hydrostatic gas-lubricated bearing

Sometimes, the resistance to flow at the entrance to the film itself may dominate. In that case the bearing is identified as having inherent compensation. Many bearings are of this type. The inherent restrictor area would then be the circumferential annulus $\pi r_0 h$ at the entrance to the film (Fig. 26).

A typical pressure profile is shown in Fig. 27 for a simple circular thrust bearing with a central feed source. With a supply pressure of 480 kPa (70 psig) and a film thickness on the "sill" of h = 0.05 mm (0.002 in.), the effect of sonic velocity is seen. The minimum pressure measured on the sill (p_s) is 76 kPa (11.01 psia), indicating a partial vacuum. The maximum recovery pressure on the sill is 101 kPa (14.6 psig).

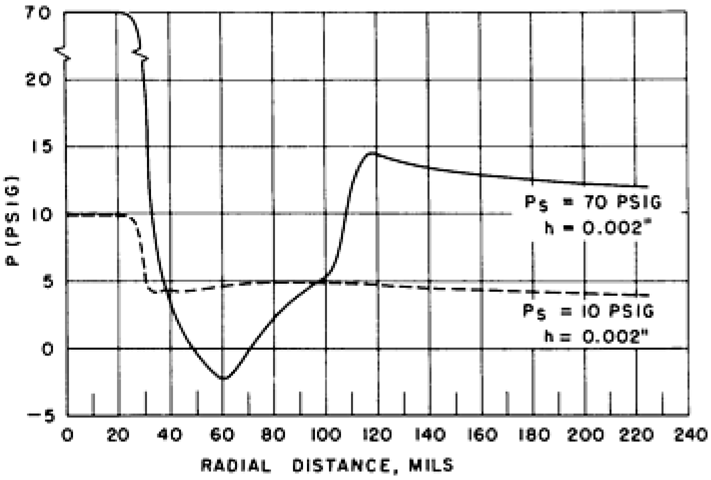

Fig. 27 Experimental pressure profiles for simple area 2 $\pi r_0 h$ externally pressurized thrust bearing

However, notice in Fig. 27 that the radial distances are measured in mils (0.001 in. = 0.025 mm), so that all of this "micro-aerodynamic" activity has taken place within a radius of 120 mils, or about 3.2 mm. The remainder of the bearing area can thus be treated as laminar isothermal gas flow and analyzed accordingly.

The dashed line in Fig. 27 shows the pressure profile when the bearing feed pressure was 70 kPa (10 psig). There is no sonic flow. Allowing for the pressure drop in the restrictor, either external or inherent, the bearing characteristics can be obtained in a relatively simple manner.

Figure 28 is a sample of the excellent program conducted by Laub (Ref 35) on thrust bearings and journal bearings intended for metrology applications. The pressure profiles show no indication of significant flow restriction and localized pressure loss because of bearing geometry and low pressure levels that were used. Flow evaluation, however, must include compressibility effects.

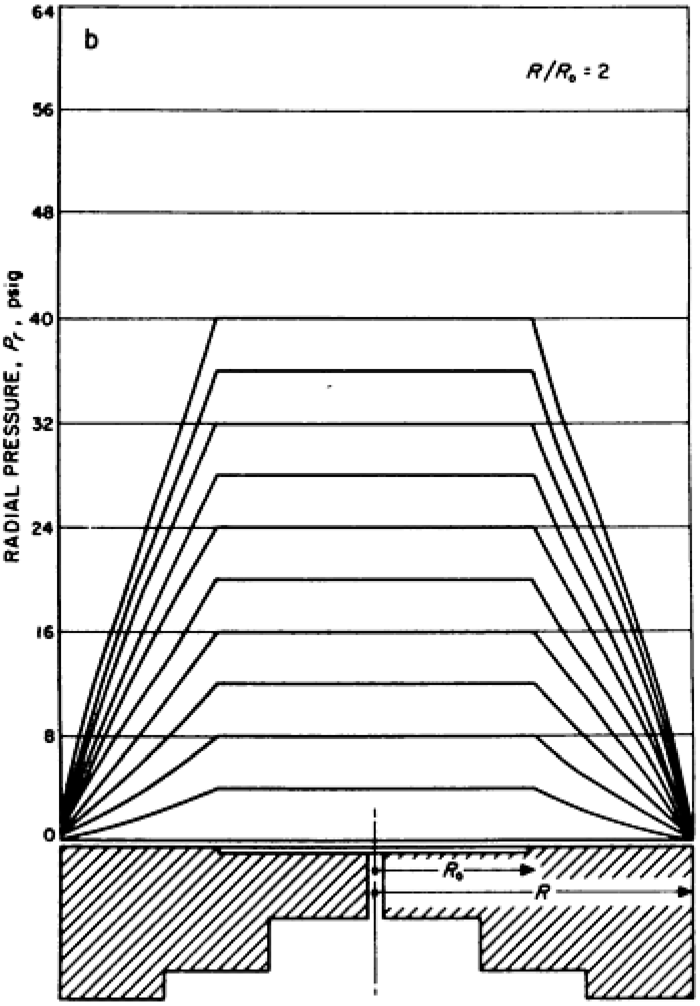

Fig. 28 Pressure profiles in gas-lubricated hydrostatic bearing: Source: Ref 35

As an example of the need to include the compressibility effect in flow prediction, consider the hydrostatic step bearing shown in Fig. 29. For liquids (incompressible), the supply pressure, P_0 and the ambient pressure, P_1, are gage pressures, R_0 is the radius of the recess, and R is the radius of the shaft. The derivation for the flow of lubricant in such a bearing is given in Ref 9 as:

$$Q = \frac{P_0 \pi h_0^3}{6\mu \ln (R/R_0)} \quad \textbf{(Eq 8)}$$

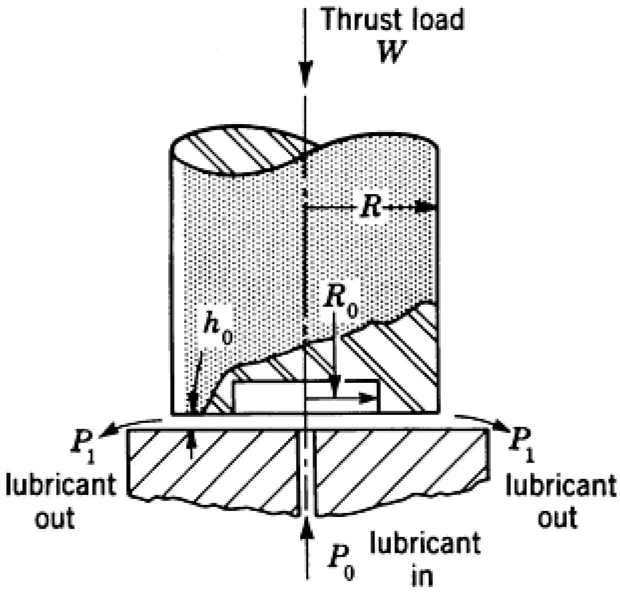

Fig. 29 Schematic diagram of a step bearing

However, when compressibility effects are included, the equation for flow volume becomes (Ref 9):

$$V_0 = \frac{\pi h_0^3}{6\mu \ln \frac{R}{R_0}} \left[\frac{P_0^2 - P_1^2}{2P_0} \right] \quad \textbf{(Eq 9)}$$

where P_0 and P_1 are in this case absolute pressures, and V_0 is the flow volume at the supply pressure P_0.

Pneumatic Hammer

The most troublesome characteristic of the externally pressurized air bearing is instability. During test programs, the phenomenon of self-excited vibration is often encountered, characterized violent fluctuations of pressure in the recess and amplitudes of vibration many times greater than the gap width at the equilibrium point. This phenomenon is often called pneumatic hammer.

Licht, Fuller, and Sternlicht (Ref 36) used a simplified lumped-parameter analysis to examine this problem. The gas film density in an oscillating thrust bearing is time dependent, and, in general, the mass inflow does not equal the mass outflow. As a consequence of film compressibility, energy from the film may be periodically added to the system in phase with the motion so that instability develops. The vibration is independent of system resonances.

The general stability analysis reveals the following:

- For a constant supply pressure, p_s, stability is enhanced by increasing the recess pressure p_0--that is, minimizing the pressure drop through the supply restrictor so that p_s - p_0 is a minimum. This of course reduces the stiffness of the bearing
- A recess depth comparable to the film thickness would be the ideal
- Maximizing the size of the inlet supply orifice will increase stability because capillary restriction is more likely to be unstable than orifice restriction
- Incompressible films are always stable

Multiple-Pressure Sources

To avoid pneumatic instability, it is clear that the high-pressure recess should be very shallow. The limit would be a recess of zero depth or no recess at all. However, that would reduce the load capacity of the bearing. A frequently used alternative is a ring or other appropriate pattern of multiple supply orifices that acts to develop an equivalent high-pressure area with the same depth as the film itself. Figure 30 shows a simple thrust bearing modified in this manner.

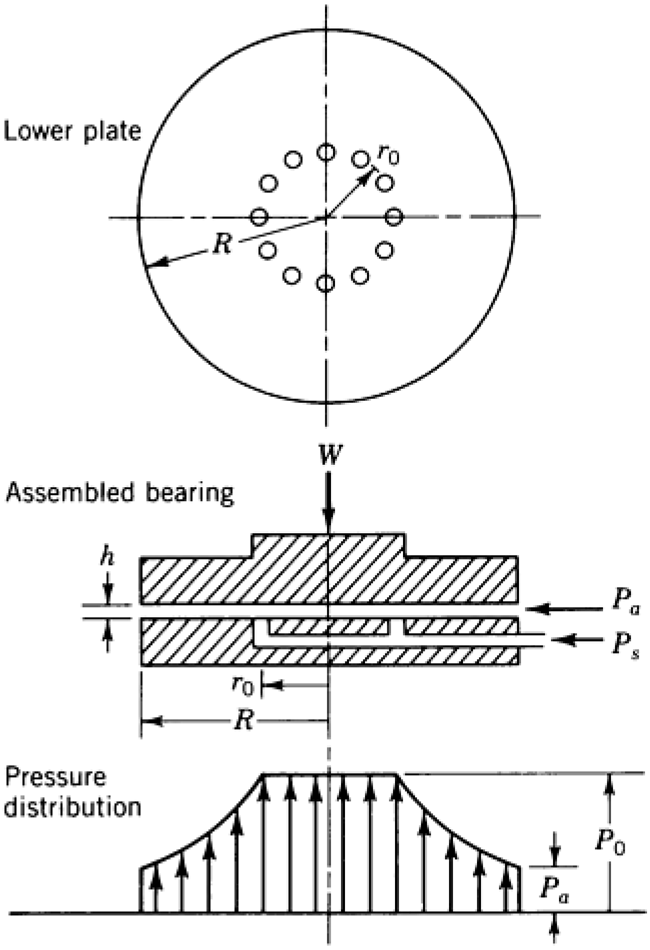

Fig. 30 Multiple-source feed for thrust bearing

In this bearing, the orifices are located on a circle of radius r_0. All orifices feed air to the interface at the same pressure P_0. Because there is no pressure gradient between the orifices, there is no flow between the orifices, and the entire circle of radius r_0 acts as a high-pressure recess. The same concept has also been successfully applied to journal bearings by Laub (Ref 35).

Porous Bearings

An alternate means for reducing the size and depth of a pressurized recess, other than using a finite number of multiple orifices as just described, is to feed the bearing through a section of porous material. Gas is admitted to the bearing interface through the pores of the material, resulting in a very large number of feeding restrictors in parallel. Again, the recess has been eliminated and stability enhanced. Many porous bearings have been made in both flat thrust and cylindrical journal bearing configurations. Sneck (Ref 37) provides an excellent survey of the many applications that have been made of this type of bearing, plus a very complete list of references.

Figure 31 is typical of a circular thrust bearing with pressurization through a porous annulus.Frequently, a porous carbon graphite is used so that antiscuff protection is provided by the material when in solid contact. A reasonable range of

permeability is available in these commercial products, and they have proven to be satisfactory. Clean air is essential to keep the pores from clogging with dust.

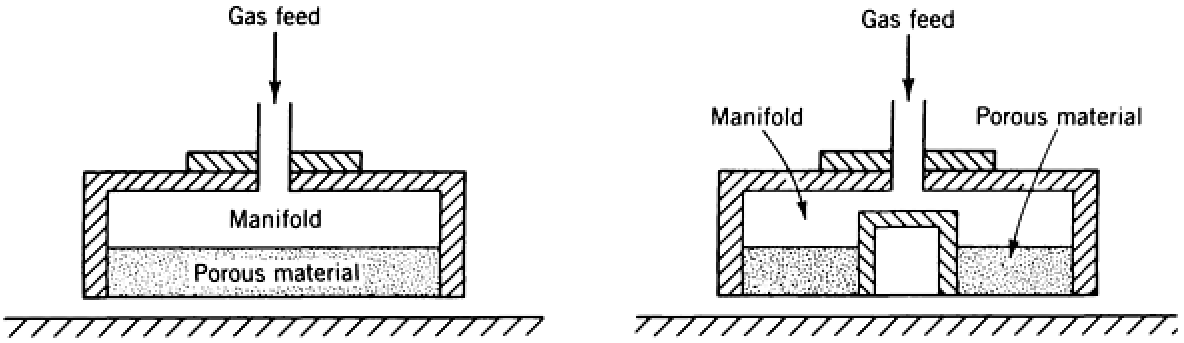

Fig. 31 Typical configurations for externally pressurized porous gas-lubricated thrust bearings. Source: Ref 9

Typically, pressurized porous bearings can be used anywhere classical orifice-compensated bearings are used. Design charts have been prepared by Gargiulo and Gilmour (Ref 38) to assist in a more exact analysis of these bearings.

However, it must be expected that the actual permeability of the material will be subject to some variation, even when cut from the same block. Vohr (Ref 4) discusses many additional design details involved in the use of porous materials in externally pressurized gas-lubricated bearings. These bearings can be extremely useful and are an attractive option for applications that call for a hydrostatic gas bearing.

Compliant-Surface Bearings

Compliant-surface bearings have been mentioned before in this article. They can use elastomers as the bearing material; in this form they have remarkable low-speed fluid-film capabilities. Foil bearings fall into this category as well. Compliant-surface bearings can be used as flexible membrane bearings.

The advantages of compliant-surface bearings include:

- Freedom from precision machining and maintenance of close tolerances
- Ability to accept misalignment
- Tolerance of dirt and particulates
- Accommodation of surface roughness with low surface speeds

The foil bearing (Fig. 32) is the most widely used form of compliant-surface bearing. It was first introduced, in simple form, by Blok and Van Rossum (Ref 39).

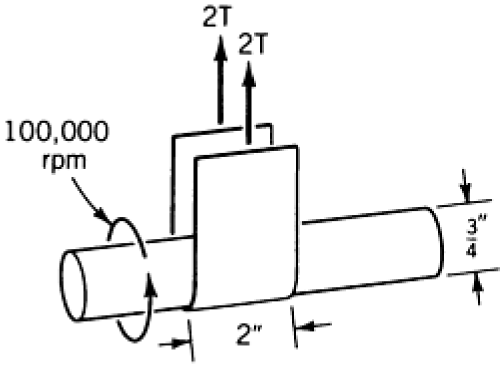

Fig. 32 Schematic diagram of a foil bearing. Source: Ref 27

The bearing can consist of a thin strip of flexible material (such as a plastic tape or thin metallic foil) partially wrapped around simple journal like the saddle belly band on a horse. As the journal spins, a reasonably large force can be supported by the self-acting hydrodynamic film in the contact area between the tape and the journal.

The simple foil bearing was further analyzed by Patel and Cameron (Ref 40) in 1957. It was utilized in the United States as an air bearing for applying load to a rotating shaft as early as 1956 by Fischer, Cherubim, and Fuller (Ref 27). By far, the greatest value of this simple concept is in tape transport for high-speed magnetic tape recorders. In this application, the journal is stationary and contains the recording head for the read-out components, while the tape glides past. Foil bearing analysis and design are reviewed extensively in Ref 4 and 41.

Developments of the original foil bearing concept of Blok and Van Rossum have now reached the stage of commercial application. Their advantages are many. If a metallic foil is used, the bearing can operate at high temperatures, especially when lubricated with air or some other gas. There is no problem with the possible loss of clearance due to differential thermal expansion between shaft and bearing, as is often the case with rigid surface units. The foil bearing establishes its own operating film thickness at all times.

It can also tolerate misalignment. In manufacturing, the foil bearing greatly reduces the need for holding expensive dimensional tolerances. An additional benefit is its stability in conjunction with high-speed rotor applications. The foil bearing is often used just for this reason, because it effectively reduces the possibility of self-excited fractional-frequency whirl (Ref 42).

Three distinct commercial varieties of foil bearings are available:

- Tension-dominated foil bearings (Fig. 33a)
- Bending-dominated segmented foil bearings (Fig. 33b)
- Bending-dominated continuous foil bearings (Fig. 33c)

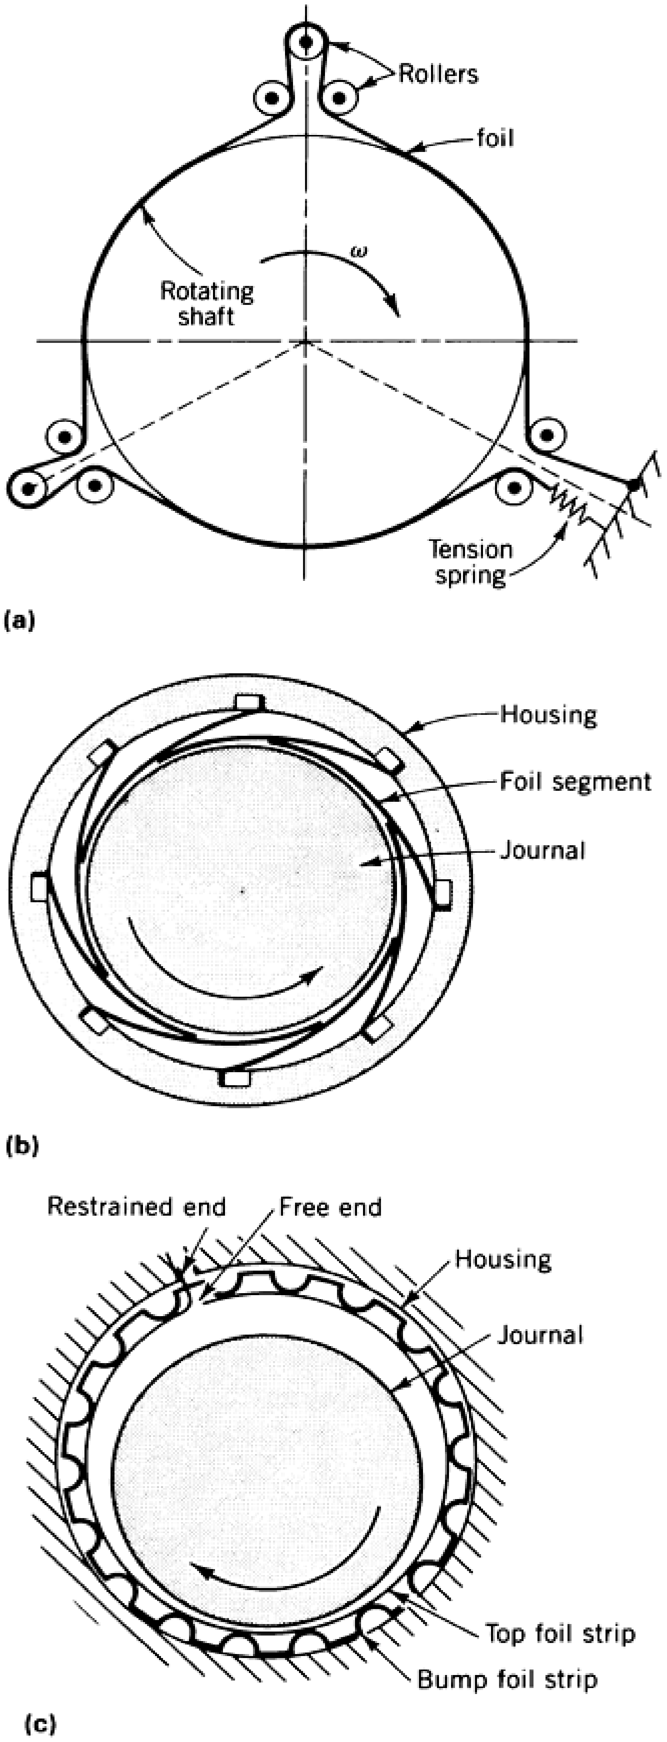

Fig. 33 Foil bearing designs. (a) Tension-dominated foil bearing. (b) Bending-dominated segmented foil bearing. Source: Ref 9. (c) Bending-dominated continuous foil bearing. Source: Ref 9

Tension-dominated foil bearings (Fig. 33a) have been used in data-processing equipment, where they provide support for magnetic tape traveling over guides, heads, and vacuum columns in tape transport. Recent developments have concentrated on adapting these bearings to the support of high-speed rotors for turbomachinery (Ref 43).

Bending-dominated segmented foil bearings of the type shown in Fig. 33(b) are widely used in both commercial and military aircraft applications. One example is the air-cycle refrigeration compressor used on many commercial transports for cabin cooling. Operating speeds can easily be 100,000 rpm, yet the compressor exhibits a high degree of reliability and freedom from rotor whirl instabilities. These bearings are being developed for cryogenic compressors at working temperatures near absolute zero.

A great deal of research and development work is being devoted to extending these bearings to high-temperature applications. With support from the Air Force Aero Propulsion Center and the Naval Air Propulsion Center, research programs are underway to develop a foil bearing capable of operating at high speed in a 650 °C (1200 °F) ambient. The potential application is for high-temperature gas turbines (Ref 44). Thrust bearing configurations are also used.

Bending Dominated Continuous Foil Bearings. This configuration has a single top foil strip that is restrained at one end and supported by a resilient corrugated foil strip called the bump foil strip (Fig. 33c). This piece elastically supports the top foil and controls the stiffness of the bearing. The deflection of the bump foil tolerates load fluctuations, and its elastic behavior provides resilience. Friction damping is also introduced with its beneficial stabilizing effects on the dynamics of the rotor.

Significant accomplishments have been recorded for bending-dominated continuous foil bearings, including:

- Three years of operation in automotive-type gas turbines at 60,000 rpm and 260 °C (500 °F)
- 120,000 rpm in product hardware
- Bearing shock resistance to 25 g at 100,000 rpm
- Tests at 650 °C (1200 °F)
- Unit bearing pressures for hydrodynamic air operation up to 345 kPa (50 psi), based on projected area under laboratory conditions

Modified Bending-Dominated Continuous Foil Bearings. This type of bearing is a modification of the design shown in Fig. 33(c). Although only limited applications have been made, it does appear to have excellent performance characteristics.

Design Analysis. There is no significant design analysis available, in the public domain, for the foil bearings described above. The design procedures are essentially proprietary. However, if a proposed application involves light starting loads ($\leq$7 to 14 kPa, or 1 to 2 psi) and when up to speed (>20,000 rpm) the unit loads do not exceed 70 to 100 kPa (10 to 15 psi), it appears that some type of foil bearing would be an excellent choice.

Pressurized-membrane bearings are bearings with a flexible membrane pressurized from the center through port holes (Fig. 34). At equilibrium conditions, the air escapes from under the inflated membrane through the minimum air gap. Levy and Coogan (Ref 45) first developed the analysis for such a device.

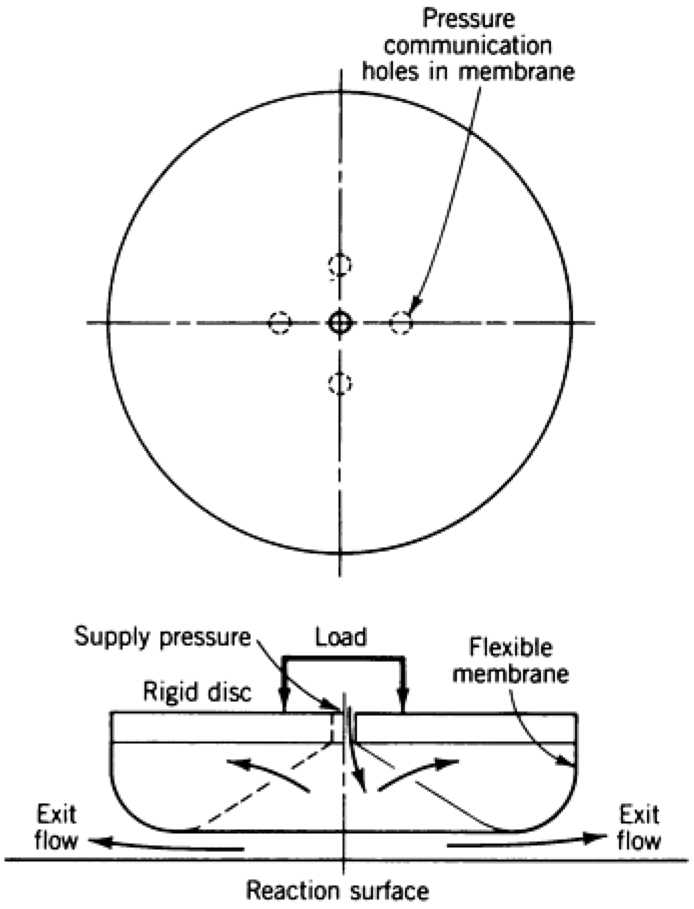

Fig. 34 Compliant-surface membrane bearing. Source: Ref 45

These bearings find wide use in areas where large loads must be lifted and transported over surfaces that may not be perfectly smooth, such as the floors in warehouses and factories. The flexibility of the membrane accommodates itself to the undulations that may exist, and motion proceeds smoothly with almost no friction. When the desired location or position is attained, the air supply is shut off and the object is set down. These devices are now available commercially.

A spectacular application of this type of hydrostatic membrane bearing is the Mile High Stadium in Denver, Colorado. The stadium was designed so that it would be suitable for both football and baseball. Accordingly, the entire side section of the grandstand, weighing 4080 Mg (4500 tons) and including 21,000 seats, is mounted at 46 points on water-lubricated hydrostatic rubber pads. Each pad is 1.2 m (4 ft) in diameter and made of fabric-reinforced synthetic rubber.

When pressurized, the entire section of the grandstand floats on a film of water and is moved back a distance of 44 m (145 ft) with very little effort. It is then set down in place, producing an arena suitable for playing baseball (Fig. 35). Although water was the pressurized lubricant of choice in this application, air could have been used.

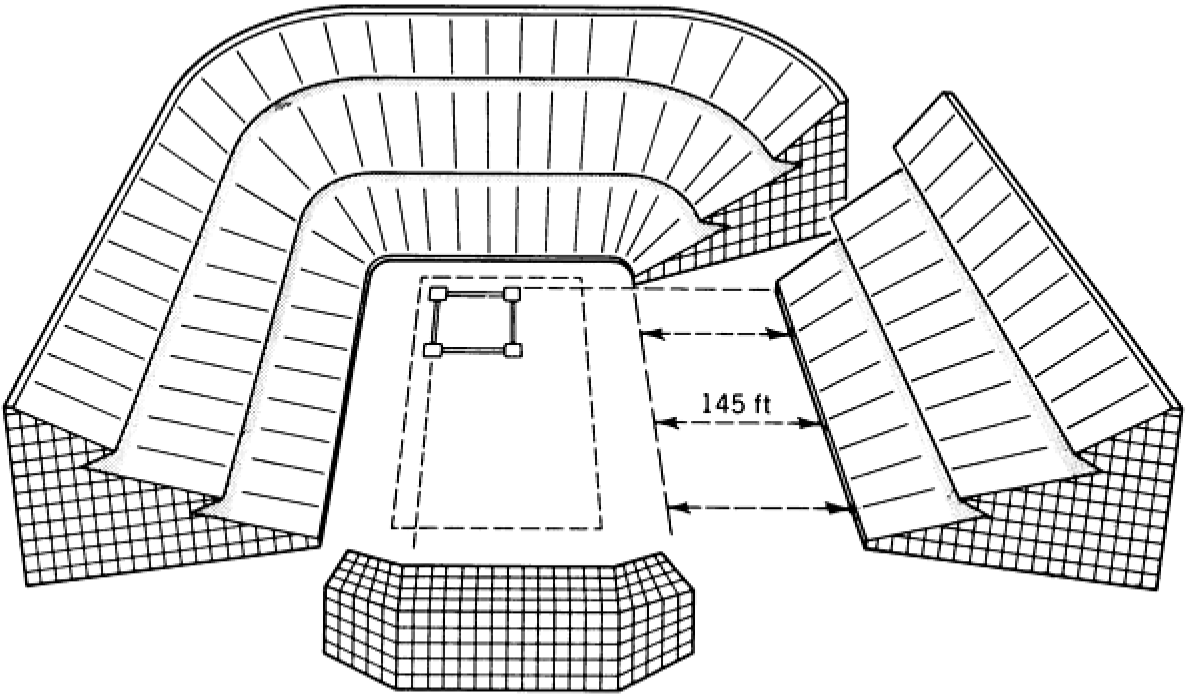

Fig. 35 Use of pressurized membrane bearings in Denver Mile High Stadium

It is surprising how little pressure is needed to support a large load. An available circular commercial unit 430 mm (17 in.) in diameter, with a pressure of about 21 kPa (3 psig) can carry a load of 270 kg (600 lb) with a flow of about 57 L/min (2 standard ft^3/min). The same unit at only 70 kPa (10 psig) can carry 900 kg (2000 lb) with, of course, a greater flow.

A novel application was made recently by a company in England that refurbishes full-size passenger railroad cars. A cradle platform was built to hold the four-wheel trucks at each end of the car. Then the platforms were floated on air-pressurized membrane bearings. Once this was done, the railroad car could be easily moved to any location on the factory floor without being encumbered by rails.

A few years ago, this type of hydrostatic compliant pad was offered as an option on a well-known brand of domestic refrigerator. By reversing the hose connection on a standard vacuum cleaner, the discharge pressure could be directed to the pads under the refrigerator and cause it to float in a film of air. It could then be moved very easily away from the wall, even when fully loaded, to allow for cleaning and maintenance.

Hydrostatic Journal Bearings

Externally pressurized journal bearings may be used when it is necessary to maintain a precise shaft position, with negligible friction, when rotational speed is insufficient to establish a hydrodynamic film. External pressurization is also used in combination with a hydrodynamic-type bearing to increase film stiffness, reduce the attitude angle, and raise the threshold of instability. The combination of these two actions produces what is known as a "hybrid bearing" (Fig. 36).

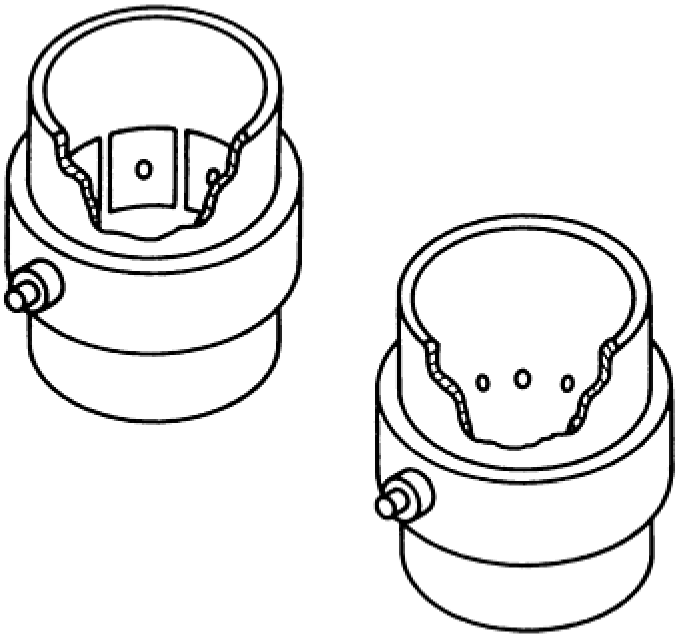

Fig. 36 Typical hybrid journal bearing designs. Source: Ref 9

The mutual contribution of each type of lubrication is of course of design decision. The rotor may be started or stopped without solid contact. Bearings for high-speed dental drills (500,000 rpm) are of the hybrid variety (Ref 46).

Externally pressurized journal bearings are affected by a great many combinations of parameters, so their design is relatively complex. Lund (Ref 47) has combined first-order self-acting and externally pressurized perturbation solutions for small eccentricity ratios. The results are found to be satisfactory and in good agreement with experimental results for small eccentricity ratios.

As with thrust bearings, the recesses must be kept as small as possible to avoid pneumatic instability. Multiple feed orifices or porous sections may be an answer to the problem. With multiple feeds, the assumption is usually made that the discrete points be considered as a continuous line source of pressure.

Comprehensive design charts for externally pressurized journal bearings are presented in Ref 48. Shapiro (Ref 49) has evaluated a three-sector hybrid journal bearing for both steady-state and dynamic behavior. He has published the results for this gas bearing, which uses orifice compensation, in tabular and graphical forms.

Many applications of externally pressurized gas bearings have been made to instruments, with remarkable increases in precision. Wunch, in Ref 45, describes the revolution that gas bearings have produced in the field of metrology. The surprising conclusion is that even though the components of the air bearing have been produced with normal manufacturing tolerances on dimensions and surface finishes, the rotational accuracy of the final instrument itself is of the order 0.075 to 0.125 μm. The explanation assumes the pressurized film has an averaging effect, and the small surface undulations of the bushing (surface roughness) are not transmitted to the shaft. This is similar to the smooth motion of a row boat on the surface of a pond; the boat is not influenced by the roughness of the bottom of the pond.

In machine tool applications, Lewis (Ref 50) has shown that grinder spindles, shapers, and gear cutters will actually show run-outs measured in microinches using externally pressurized journal bearings.

Materials for Gas-Lubricated Bearings

Engineers have been forced to search for materials that, when operated under extremely adverse conditions, will deliver acceptable life expectancy and reasonably low friction. These adverse conditions may be associated with high

temperature, with the use of lubricants with low viscosity and little or no natural oiliness (like gas), or with dry operation where no lubricants are present at all.

Experimentation has led in the direction of harder and harder materials, such as refractory materials and ceramics (Ref 51, 52, 53). These materials are usually brittle, so impact must be avoided. When they are used as rigid bearings with gas lubrication, the geometry must be precise and true because there is little possibility of conformability with such materials (as there could be with tin or lead-based babbitt, for example). Rigid designs, relatively light loads, and elimination of thermal or elastic deformations are necessary.

Investigations of gas-lubricated rigid thrust bearings and journal bearings operating under high temperature and high-speed conditions have shown favorable performance with the use of hard ceramic materials. Materials that might be considered for such applications include boron carbide, chromium carbide, silicon carbide, titanium carbide, alumina, silicon nitride, tungsten carbide, and chromium oxide.

Ceramics and cermets exhibit superior wear resistance. Cermets are ceramics that have been bonded with metals to improve their ability to handle impact and shock loading. The results, of course, vary with the ceramic and its bonding material. Cobalt is often used as a binder.

Hinkle and Fuller (Ref 54) conducted a study of the friction and wear of various materials for gas-lubricated rigid journal bearings under conditions of start-stop and high-speed whirl-induced rubbing. The tests were performed with a variety of imposed loads, temperatures, and ambient atmospheric conditions. Of the 36 combinations of materials investigated, by far the best performance was exhibited by aluminum oxide (alumina) against itself. The best specimens showed no visible evidence of wear even after extended testing.

Surprisingly, of the four different types of aluminum oxide used, one was far superior to the other three. The binder, the density, and the grain size are apparently strong variables. It might be advisable to get guarantees of friction and wear characteristics from a prospective vendor before selecting a particular grade of aluminum oxide.

Ceramics do provide low wear, but they also have relatively high friction. This may be a problem in some applications. In instrument gyroscopes, the electric motor drive is very small and light and has a low starting torque. Consequently, unless the friction of the bearing material is low enough, the motor will stall and not start. Much current research in gyro bearings is directed toward the reduction of friction in ceramic bearings through the introduction of some form of boundary lubrication.

Research carried out at the University of Rhode Island has determined that if final grinding of the ceramic is done in a bath of a prescribed boundary lubricant, a surface modification is achieved that provides lower friction. For silicon nitride, octadecanoic armide is recommended. For glass ceramics such as Pyroceram, the use of dioctedecyl disulfide is indicated.

In England, the British Royal Navy Scientific Service frequently uses silicon nitride against silicon nitride for gyro air bearings. They have been successful with small built-in graphite brushes that spread a thin film of solid graphite on the running surfaces. This technique not only reduces wear and lowers friction, but it also burnishes the surfaces to a high gloss while running. An alternative technique is burnishing the surfaces before installation with either molybdenum disulfide (MoS_2) or Teflon. Reducing friction with ceramics is an active research field.

Surface Coatings. High-density ultrahard coatings can be applied to the surfaces of ordinary commercial machine elements and provide them with a highly wear-resistant capability. Typical applications include parts for use in jet aircraft and in the chemical, textile, steel, and data processing industries. New coating technologies for tribological applications are described in Ref 55. Many different techniques can be used in making these surface depositions, depending on the end results desired.

Surface coating is a specialized field in which dramatic developments have been made within the last decade. For example, the metallic foil compliant-surface bearings, described earlier, have been coated with wear- and friction-resistant materials for use in various applications. Commercially bonded MoS_2, aluminum oxide, chromium oxide, and a three-component commercial blend of aluminum oxide, silicon oxide, and chromium oxide have all been used successfully for coating these bearings.

Friction, Lubrication, and Wear of Gears

Robert Errichello, GEARTECH

Introduction

BECAUSE GEARS are such common machine components, they may be taken for granted. It is not generally appreciated that they are complex systems requiring knowledge from all the engineering disciplines for their successful design. Gear design is a process of synthesis in which gear geometry, materials, heat treatment, manufacturing methods, and lubrication are selected to meet the requirements of a given application. The designer must design the gearset with adequate strength, wear resistance, and scuffing resistance. To do this, he or she must consider gear tribology. The choice of lubricant and its application method is as important as the choice of steel alloy and heat treatment. The interrelationship of the following factors must be considered:

- Gear tooth geometry
- Gear tooth motion (kinematics)
- Gear tooth forces (static and dynamic)
- Gear tooth material and surface characteristics (physical and chemical)
- Lubricant characteristics (physical and chemical)
- Environmental characteristics (physical and chemical)

Advantages and Disadvantages

The advantages of gas-lubricated bearings over liquid-lubricated fluid-film bearings are now well understood. These include:

- Cleanliness. Elimination of contamination caused by more traditional lubricants
- Reduction (often elimination) of the need for bearing seals
- Stability of lubricant. No vaporization, cavitation, solidification, decomposition, or phase change over extreme ranges of temperature, from cryogenic (-270 °C, or -450 °F) up to approximately 1650 °C (3000 °F). Operation at these extremes of temperature is a current research goal
- Low friction and heating with little or no cooling generally required. Permits practical attainment of high speeds (700,000 rpm)

Disadvantages of gas-lubricated bearings are recognized as resulting from the relatively low viscosity and damping of gas films. Thus, gas-lubricated bearings have a reduced load-carrying capacity compared to liquid-lubricated bearings, especially with self-acting or hydrodynamic bearings. For acceptable application, therefore, the bearings are necessarily larger and operate with thinner hydrodynamic films than their liquid-lubricated counterparts.

Thinner films demand closer control of manufacturing tolerances, surface finishes, and possible thermal and elastic distortions and alignments, to prevent rubbing contact. With compliant surface bearings, as with foil bearings and membrane bearings, rigid specifications regarding design and manufacture can be dramatically relaxed. The membrane bearing, for example, operates very satisfactorily over a typical factory floor.

The low damping of the gas film makes it necessary to carefully analyze the dynamic characteristics of the mechanical system employing the gas bearing, since if a critical speed or instability is encountered, there may not be enough damping

to suppress it or control it. With liquid-lubricated bearings these instabilities might not have been suppressed or passed over unnoticed because of the greater damping action that inherently exists with liquids. Much recent research has been devoted to the dynamics of gas bearings and their associated mechanical systems.

Gas-lubricated bearings have been characterized as being less forgiving than oil-lubricated bearings. This is certainly true for self-acting or hydrodynamic bearings. They are less forgiving of errors in estimating loads, of deviations from specifications during manufacture and installation, and of distortions and dirt that may afflict the rotor.

Compressibility Numbers

Gas is, of course, compressible and this effect must be included in the derivations for various forms of bearings--whether hydrodynamic (self-acting) or hydrostatic (externally pressurized). The extent of compressibility (represented by the compressibility number, Λ) is determined by a dimensionless group of parameters that actually evolves from the mathematical analysis. It takes on several forms depending on the geometry of the bearing.

For journal bearings (Fig. 1), the value of Λ is:

$$\Lambda = \frac{6\mu\omega}{p_a}\left(\frac{r}{c}\right)^2 \qquad \textbf{(Eq 1)}$$

where c is the machined-in radial clearance, p_a is the absolute ambient pressure, ω is the angular velocity of the journal (rad/s), μ is the absolute viscosity, and r is the radius of the shaft.

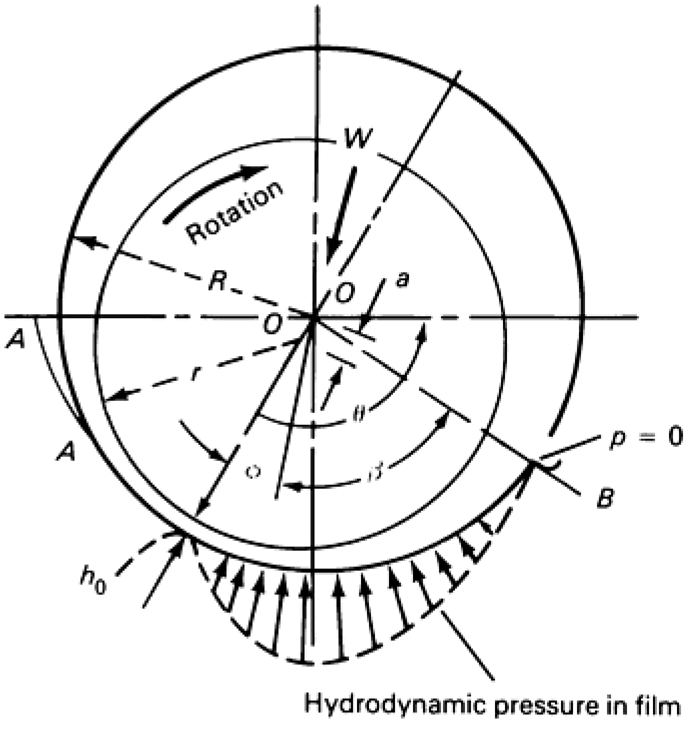

Fig. 1 Journal in full 360° bearing

For a tilting-pad thrust bearing (Fig. 2), the value of Λ is:

$$\Lambda = \frac{6\mu ul}{h_2^2 p_a} \qquad \textbf{(Eq 2)}$$

where l is the length of the pad in the direction of sliding (sometimes designated as L), and h_2 is the minimum film thickness (sometimes referred to as h_0), and u is the velocity of the runner past the shoe.

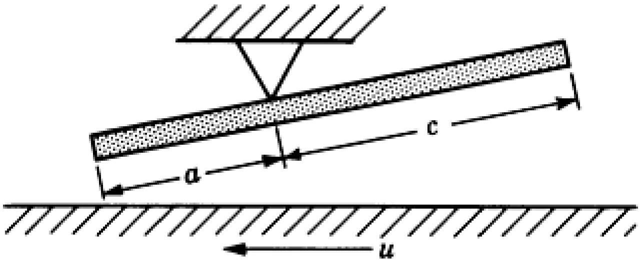

Fig. 2 Representation of pivoted shoe

For a Rayleigh step bearing (Fig. 3), the value of Λ is:

$$\Lambda = \frac{6\mu U l}{h_2^2 p_a} \qquad \textbf{(Eq 3)}$$

where l is the length of the pad in the direction of sliding, U is the velocity of the runner past the pad, and h_2 is the minimum film thickness.

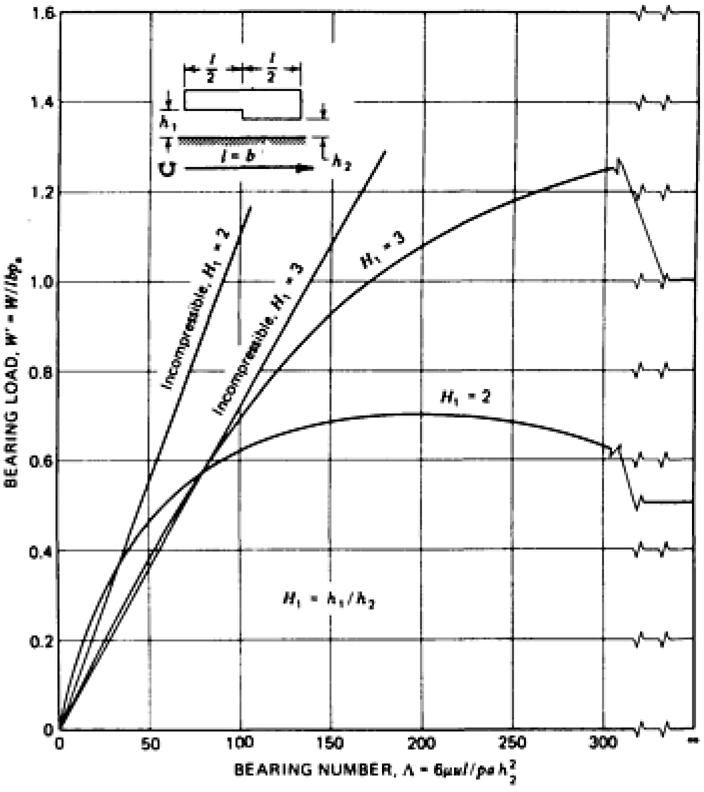

Fig. 3 Effect of bearing number on isothermal load for square-step slider bearings with film thickness ratios h_1/h_2 = 2 and 3. Source: Ref 4

When Λ approaches 0, operation of the gas-lubricated bearing approaches that of the liquid-lubricated (incompressible) case. As a Λ gets larger, as with lower ambient pressure or higher speed, the compressibility effects become very significant and must be included. For example, with journal bearings it can be shown that the equations for determining the load-carrying capacity for liquids and gases are essentially the same up to a value of Λ= 1 (Fig. 4). For tilting-pad bearings, the identity remain up to a value of about 15 (Fig. 5).

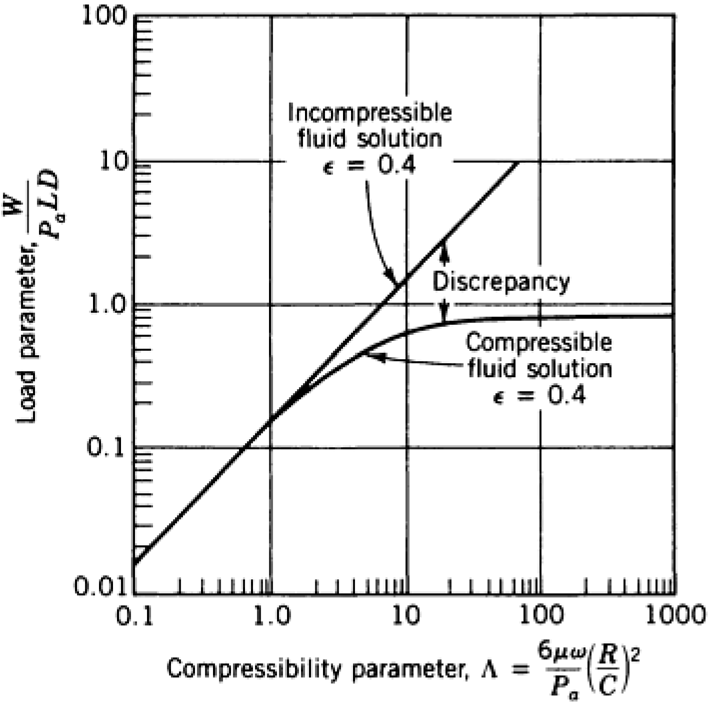

Fig. 4 Discrepancy in load capacity between results based on incompressible and compressible lubricants. Source: Ref 5

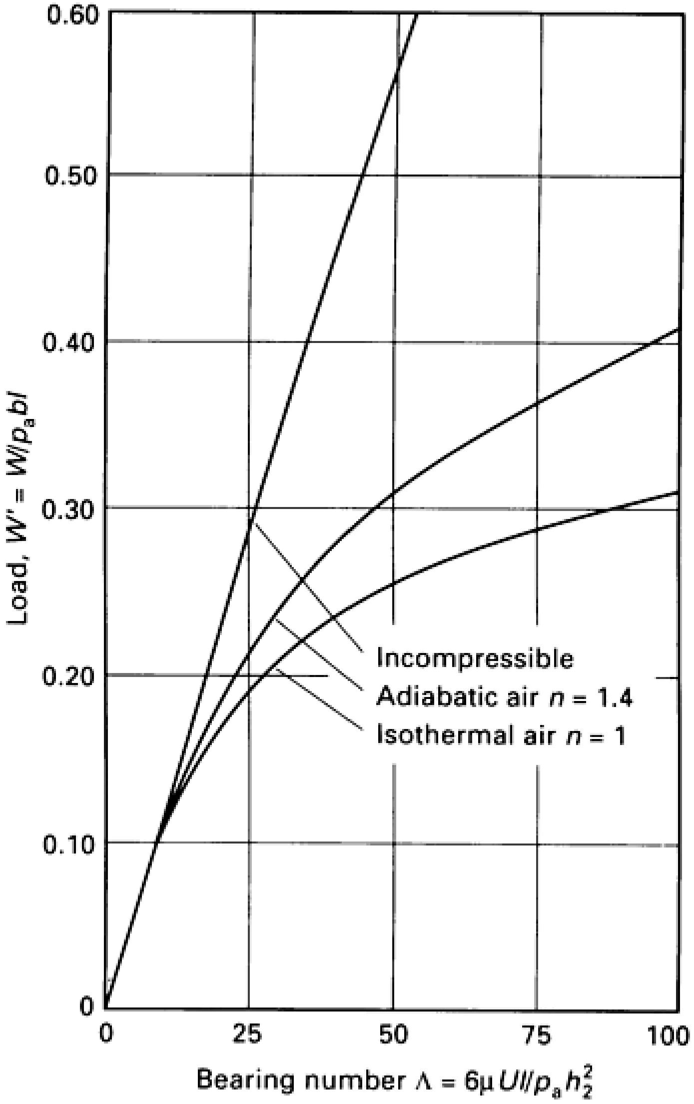

Fig. 5 Effect of bearing number on isothermal and adiabatic load for plane slider bearing operating in air with film thickness ratio h_1/h_2 = 2. Length-to-breadth ratio l/b = 1. Source: Ref 6

An interesting experimental demonstration is illustrated in Fig. 6, which shows the relationship between load-carrying capacity, *W*, and Λ for a hydrodynamic gas-lubricated journal bearing. Speed, viscosity, and eccentricity ratio were held constant while the ambient pressure was reduced, thus producing higher values of Λ. Notice that when the ambient pressure was reduced to 9% of atmospheric, the load-carrying capacity was lowered by 40%.

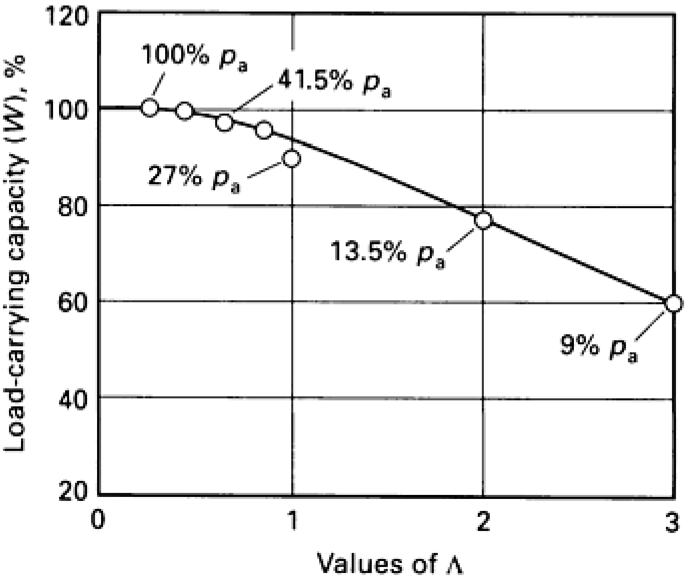

Fig. 6 Example of relationship between load-carrying capacity, *W,* and Λ for self-acting gas-lubricated journal bearing. Speed, viscosity, and eccentricity ratio held constant. Ambient pressure varied. Source: Ref 7

Definitions of Eccentricity Ratio and Clearance Modulus

In Fig. 1, *O* represents the center of the bearing and *O*' the center of the shaft. The distance *O*-*O*' is also designated as *a;* for light loads and high operating speeds, the center of the shaft and bearing coincide, and *a* approaches zero. The ratio of the distance *a* for any given operating condition to the machined-in radial clearance *c* of the bearing is called the eccentricity ratio, ϵ.

For heavy loads or extremes of operation, such as low speed or very low viscosity, the journal becomes more eccentric in the bearing and the distance *a* increases. The limit is where the journal just begins to make solid contact with the bearing, or the distance *a* equals the radial clearance. The eccentricity ratio is then 1. The radial clearance in the journal bearing is often designated as *mr,* where *m* is the clearance modulus of the bearing and *r* is the radius of the shaft or journal. The value of *m* will usually range between 0.0005 and 0.003 mm/mm, with typical industrial-type bearings running between 0.001 and 0.0025 mm/mm.

In the analysis of fluid-film bearings using incompressible lubricants, the continuity relationship was satisfied by saying that the volume of lubricant leaving the bearing was the same as the volume entering. With gas, of course, the volume changes, so that continuity must be based on equality of mass. Thus the mass of lubricant leaving equals the mass entering.

The basic Reynolds equation then becomes (Ref 8):

$$\frac{\partial}{\partial x}\left[\frac{\rho h^3}{\mu}\frac{\partial p}{\partial x}\right]+\frac{\partial}{\partial z}\left[\frac{\rho h^3}{\mu}\frac{\partial p}{\partial z}\right]=6U\frac{\partial \rho h}{\partial x} \quad \textbf{(Eq 4)}$$

where ρ is the mass density, *x* is the coordinate along the film in the direction of motion, *z* is the coordinate along the bearing dimension perpendicular to the direction of motion (sometimes called the length of the bearing, *l,* or the width of the bearing, *b*), *p* is the differential pressure, and *h* is the local differential film thickness.

Except for a few restricted solutions with no side flow in the *z* direction, solutions are only possible through extended iterative computer solutions. The order of magnitude of the solutions, however, can often be checked by reference to results for incompressible lubricants, especially for cases of low Λ(Ref 9).

Tilting-Pad Bearings

Some marked differences in behavior exist between tilting-pad gas-lubricated bearings (Fig. 2) and liquid-lubricated bearings. The expected pressure is somewhat modified, as shown comparatively in Fig. 7. The peak pressure is shifted toward the trailing edge of the shoe. This means that the pivot position for a gas-lubricated bearing is not the same as for a liquid-lubricated bearing. Figure 8 shows quantitative values for a tilting-pad gas-lubricated bearing for various values of Λ(Eq 2). In this case, $\Lambda$was reduced by lowering the ambient pressure.

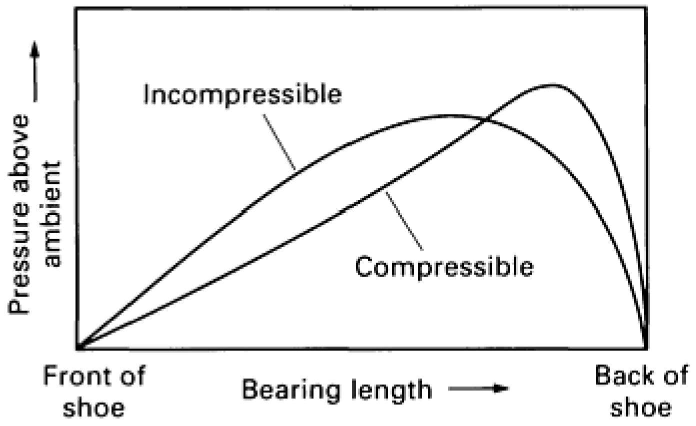

Fig. 7 Comparative pressure distribution for compressible and incompressible lubrication. Source: Ref 6

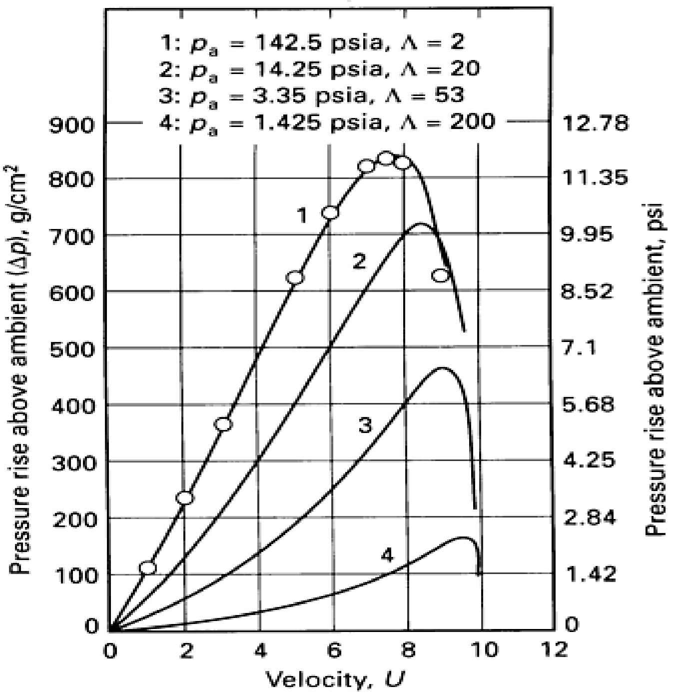

Fig. 8 Gas pressure distribution in flat tilting-pad bearing. Note open circles (data points) for theoretical liquid case. Source: Ref 7

Notice that for high values of Λ, the center of pressure moves toward the trailing edge or the back of the pad. For each designated operating condition, the pivot should be located at the center of pressure. Thus, if the ambient pressure, the speed, or the load is subject to change, a fixed pivot position will be optimum for only one set of operating conditions. This is a disadvantage.

In contrast, with incompressible lubricants, the tilting pad will react to a change in load or speed so that the ratio of inlet-to-outlet film thickness remains constant, even with the minimum film thickness getting smaller with increasing load. Thus, with liquid lubricants, once the pivot position is chosen, it will remain optimized for all changes of load, speed, or viscosity.

With gas-lubricated tilting-pad bearings, yet another complication arises. As the load increases, the minimum film thickness decreases, but since the pivot location is fixed, the pad angle of inclination begins to get smaller and eventually becomes parallel to the runner. An unstable condition will result, and the bearing will be unable to support the load and will collapse completely.

Collapse of the gas film will not occur for a convex curved surface on a tilting pad (Fig. 9). Because of the geometry, neglecting the influence of surface roughness asperities, a wedge must always be developed no matter how thin the film. An experimental study by Brunner *et al.* (Ref 12) shows that for a pad 19 mm ($\frac{3}{4}$ in.) wide by about 13 mm ($\frac{1}{2}$ in.) long in the direction of motion, even a crown height, δ, of as little as 0.25 μm will prevent collapse of the film and produce a load-carrying characteristic that continues to rise as the film reduces. Experience has shown that crown heights for optimum load-carrying capacity are approximately equal to the minimum film thickness, or about 7.5 to 10 μm.

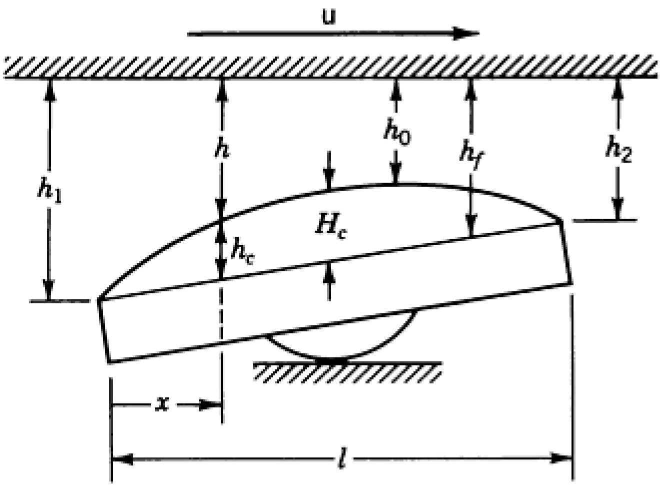

Fig. 9 Nomenclature for crowned tilting-pad bearing. Source: Ref 11

A thorough analysis of optimum crown heights and pivot positions can be found in Ref 4. Experimental verification of the theory has been especially good. Figure 10 shows values of the dimensionless load-carrying function as a function of the compressibility number for shoes having cylindrical crowns. The pivot position is not identified, but a value of about 0.6 is typical. That means, in Fig. 2, *c* is 0.6 of the length in the direction of motion and *a* is 0.4 of the length. The pivot is always between the midpoint and the trailing edge.

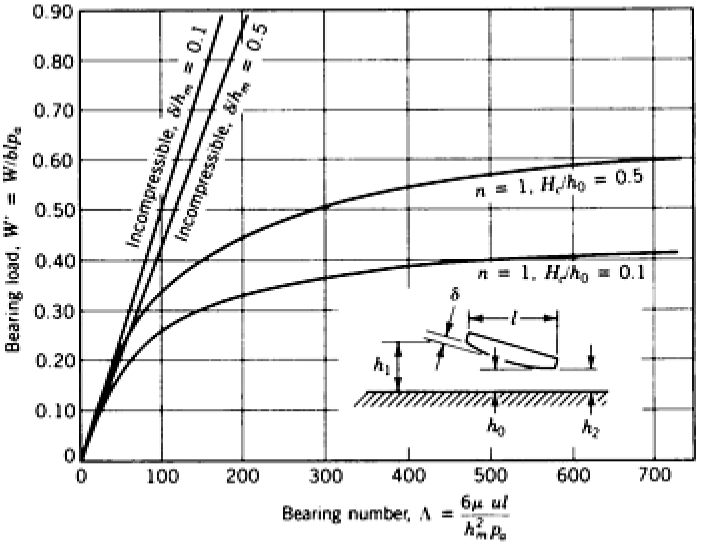

Fig. 10 Effect of bearing number on isothermal load for cylindrically crowned slider bearing, $b/l = 1$, $h_1/h_m = 2$, and $H_c/h_0 = 0.1$ and 0.5. Source: Ref 4

Effect of Mean Free Path

When gas films become very thin, as for example, when operating in a partial vacuum, the gas may no longer be considered as a continuous fluid, having the bulk viscosity of that fluid. Effects take place that can no longer be explained by continuous theory. Slip occurs at the boundary between the bearing surface and the gas and must be introduced into the calculation.

The measure of this slip condition is determined by the Knudsen number (K_n). This is the ratio of the mean free path of the gas (λ) to the film thickness in the bearing (h). Thus, $K_n = \lambda/h$. When K_n is less than 0.01, the gas flow can be treated as a continuum and slip flow ignored. When K_n is in the range of 0.01 to 1.5, slip flow increases and should be considered. When K_n is greater than 1.5, slip flow becomes significant and fully developed molecular flow results.

Typical values of mean free path at atmospheric conditions are:

Gas	Typical mean free path value	
	in. × 10^{-6}	**μm**
Hydrogen	4.43	0.1125
Helium	7.32	0.186
Air	2.52	0.064
Neon	5.20	0.132

Thus, with an air-film thickness of 2.5 μm (0.0001 in.), the value of K_n would be $2.52 \times 10^{-6}/100 \times 10^{-6}$, or 0.025. The slip effect would be small but not negligible.

Many tilting-pad-type thrust bearings with air lubrication are used in magnetic storage devices for computers, where they "fly" at film thicknesses of about 0.5 μm (20 μin.). At these very small film thicknesses, surface roughness can become a significant factor because no surfaces are perfectly smooth. This effect can be analyzed and included in predicting load-carrying capacity.

Rayleigh Step Bearings

This type of bearing is shown in Fig. 3. Analytical results for a square-step bearing (width equals length) are shown in Fig. 11 for lubrication with gas. A dimensionless load function *W*' is plotted against the compressibility number established for step bearings (see Eq 3).

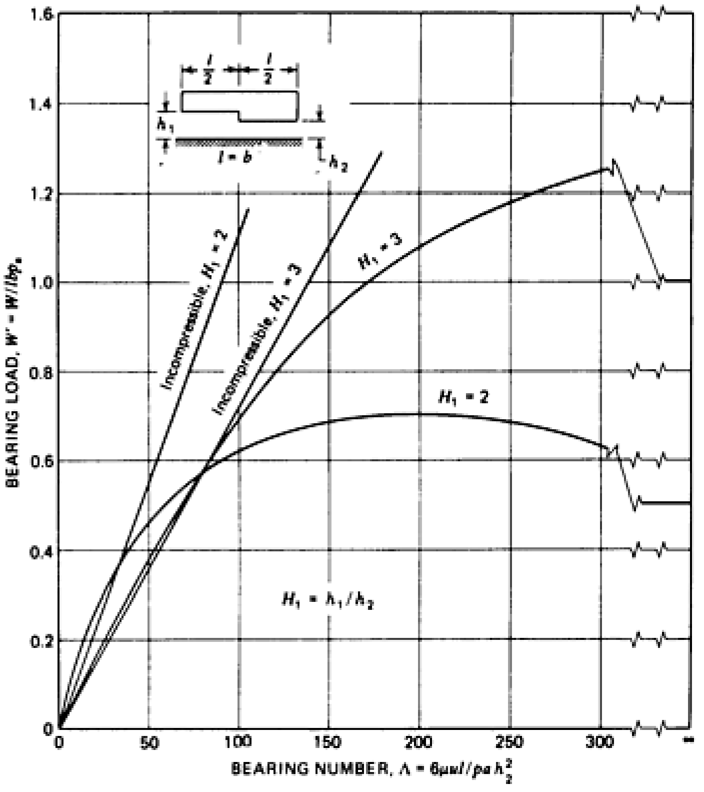

Fig. 11 Effect of bearing number on isothermal load for square-step slider bearings with film thickness ratios h_1/h_2 = 2 and 3. Source: Ref 4

Journal Bearings

This was the geometry first used to demonstrate true load-bearing ability by Kingsbury in 1897 (Ref 13). The same concept was used by Brubach (Ref 14) in utilizing inexpensive hypodermic syringes as air bearings. These are precision-made plungers in closely fitting barrels that perform remarkably well as hydrodynamic journal bearings.

Brubach has used these syringes as bearings for small centrifugal blowers running at 6000 rpm (Fig. 12). Perhaps his most important application has been in the measurement of gas leaks at very low pressures. Figure 13 shows the apparatus used for this purpose. The plunger of the syringe is caused to rotate by air impinging on the Scotch tape vanes. Due to this rotation, the plunger acts as an air bearing and is separated from the barrel by a hydrodynamic air film. Because the surfaces are separated from the barrel by a thin air film, the force required to move the plunger along the axis of the barrel actually approaches zero.

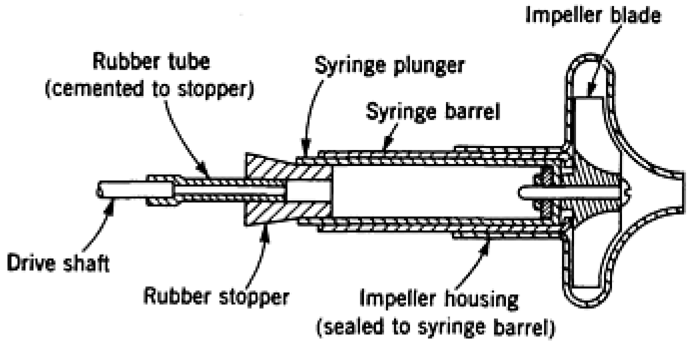

Fig. 12 Centrifugal blower using hypodermic syringe as air-lubricant bearing. Source: Ref 14

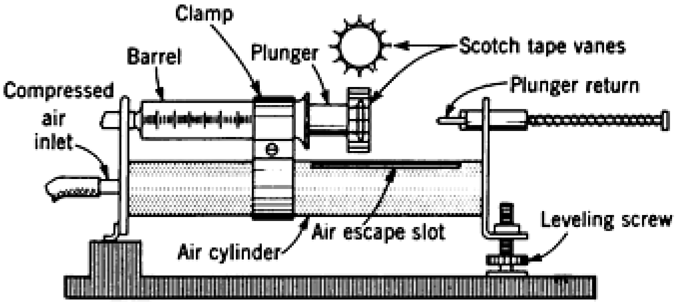

Fig. 13 Sensitive pressure-measuring apparatus using hypodermic syringe as air-lubricated bearing. Source: Ref 14

As an illustration of the sensitivity of this apparatus, it was connected to a tank of 100 L (26 gal) capacity. Then 0.1 mL (0.06 in.^{3}) of air was introduced into the tank. Immediately the plunger moved a corresponding 0.1 mL (0.06 in.^{3}). The theoretical pressure increase resulting from the injection of 0.1 mL (0.06 in.^{3}) into 100 L (26 gal) is about 0.01 mm (0.0004 in.) of water, and yet the low friction of the rotating plunger permitted it to respond instantly to this exceedingly small pressure differential.

Journal bearings are also influenced by compressibility of the gaseous lubricant. The value of Λ was given in Eq 1. Ford, Harris, and Pantall (Ref 7) show experimental correlation of the load-carrying parameter W' plotted against Λ (Fig. 14). For values of Λ greater than 1, the relationship is no longer linear. The deviation from a straight line indicates the point at which the compressibility effects make their influence felt.

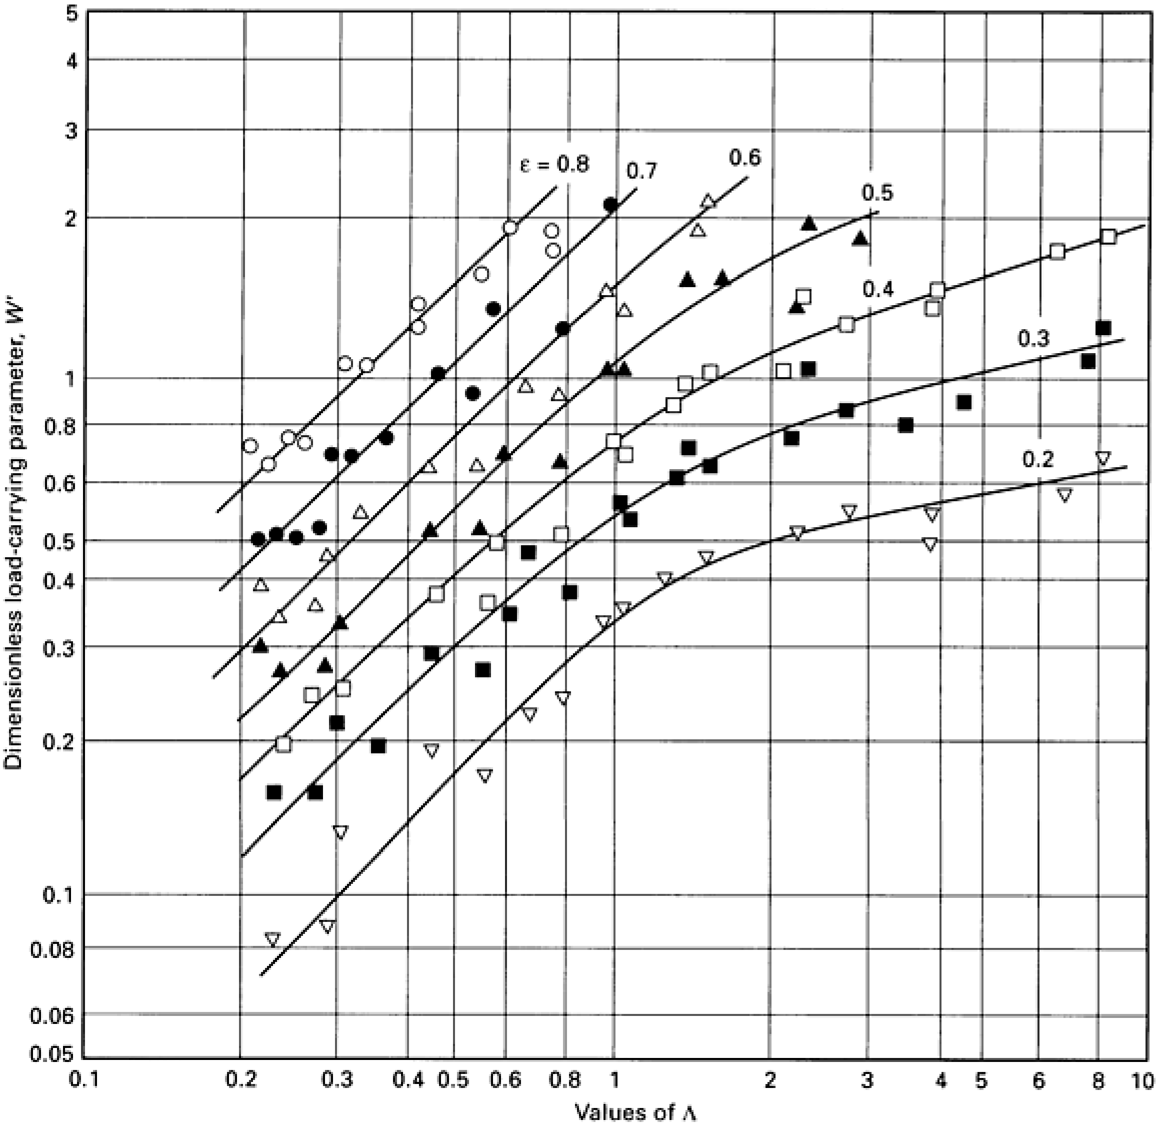

Fig. 14 Load parameter *W*' evaluated in terms of $\Lambda$and ϵ. Source: Ref 7

Another important variable in journal bearing analysis, especially stability analysis, is the attitude angle. In Fig. 1 this angle is shown as the angle, ϕ, between the line of load action, *W*, and the line of centers of the bearing, *O*-*O*'. The attitude angle will vary with load, speed, and other operating conditions, and also will depend on the geometrical configuration of the bearing itself. In general, if the attitude angle is small, the bearing is more stable against self-excited whirl. If the attitude is large, the bearing will be less stable against self-excited whirl.

For load-carrying capacity, the accumulated results of Gross (Ref 4), Elrod and Malanoski (Ref 15, 16), Elrod and Burgdorfer (Ref 17), and Raimondi (Ref 18) can be used as a general design approach for complete (360°) journal bearings. Figures 15, 16, and 17 show typical results from these analytical evaluations.

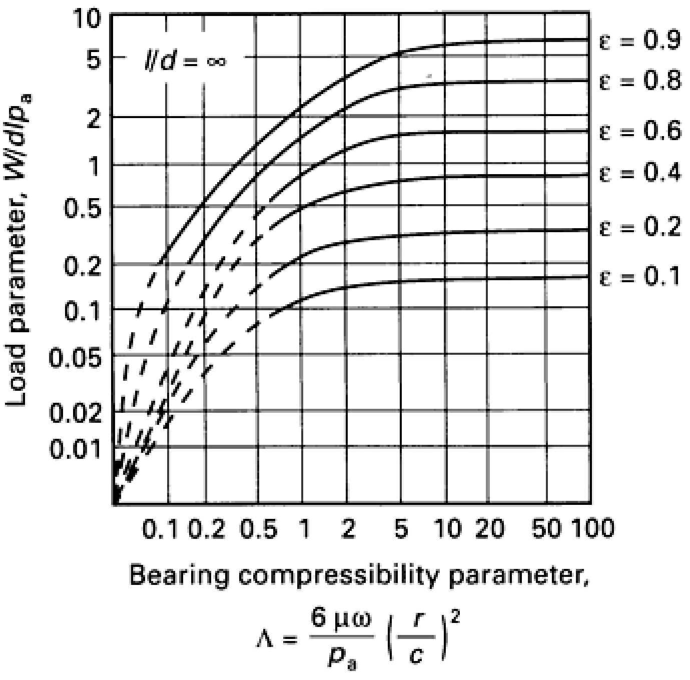

Fig. 15 Theoretical load-carrying parameter versus compressibility number for full journal bearing with *l*/*d* = ∞

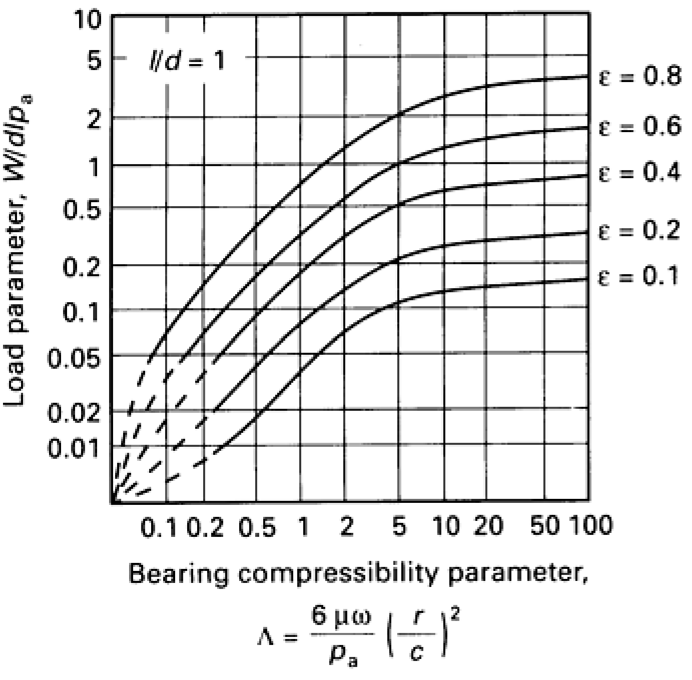

Fig. 16 Theoretical load-carrying parameter versus compressibility number for full journal bearing with *l*/*d* = 1

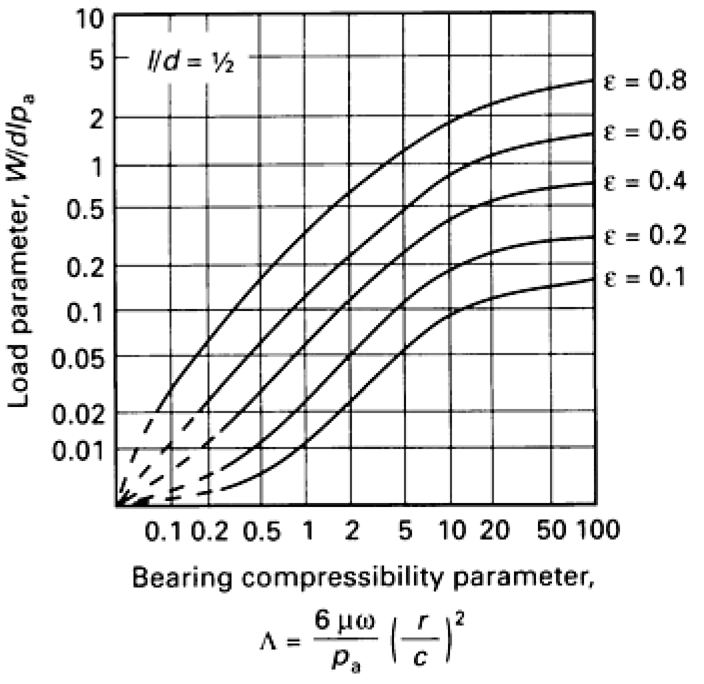

Fig. 17 Theoretical load-carrying parameter versus compressibility number for full journal bearing with *l/d* = $\frac{1}{2}$

Friction in Gas-Lubricated Journal Bearings

Of interest in some design applications is the power loss in the bearing due to friction resulting from viscous drag effects of the gas. Raimondi (Ref 18) has graphs of friction factors applicable to four *l*/*d* ratios, namely ∞, 2, 1, and $\frac{1}{2}$ for values of ϵ.

Specifically, the dimensionless friction factor for a plain journal bearing of ∞ length is defined as:

$$C_f^{\infty} = \frac{M_J}{2\pi\mu U r^2 l/c} \quad \text{(Eq 5)}$$

where,in English units, M_J is the frictional moment on the journal (in. · lbf). Figure 18 shows the friction factor plotted against the compressibility parameter.

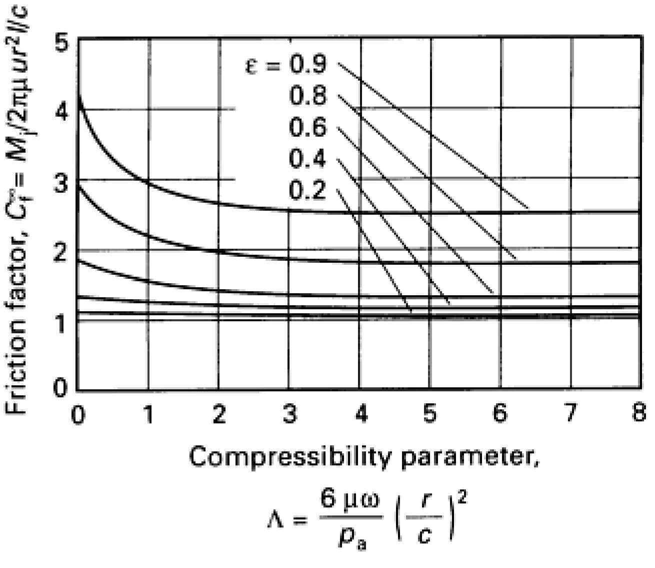

Fig. 18 Friction factor for full bearing of infinite length. Source: Ref 16

It can be seen from Fig. 18 that the friction loss is quite independent of Λ up to values of ϵ about 0.5. This means that for many bearings with low ϵ, values of friction can be reasonably estimated by using only simple Newtonian viscous shear. That would be shown by:

$$M_J = \mu A r \frac{v}{h} \quad \textbf{(Eq 6)}$$

where *A* is the swept area, which equals 2 πrl; *v* is the linear surface velocity; and *h* is the radial clearance, which equals *c*.

Synchronous Whirl

Synchronous whirl is a term used to describe a vibration condition in a fluid-film bearing where the mass of the rotor, combined with the spring stiffness of the bearing fluid film, can result in a natural frequency of vibration that is troublesome. If this natural frequency is the same as the rotational speed of the shaft, very large motions may be produced, resulting in possible bearing failure. If this natural frequency is below the operating speed, then it is necessary to pass through this resonant condition when approaching bearing speed.

Synchronous whirl can take the form of a translatory whirl, where the center line of the shaft describes the locus of a cylinder, or synchronous whirl can be conical. The conical mode form would resemble a bow tie, where there is no displacement at the center, only at the ends of the rotor. The displacement at the ends of the rotor would be out phase with each other.

If the bearing housing itself is elastically supported, it may also be capable of vibrating in either translatory or conical modes of vibration. These phenomena are analyzed in considerable detail in Ref 9.

A generally satisfactory approach is to estimate the quasi-static stiffness of the bearing film and then, in conjunction with the mass of the rotor, evaluate the natural frequency of vibration. It is a method that has proven its value over dozens of applications; Ref 9 provides examples of analyses that demonstrate the procedure.

Half-Frequency Whirl

One of the most serious forms of instability encountered in journal bearing operation is known as half-frequency whirl. This phenomenon is one of self-excited vibration and is characterized by having the center of the shaft orbit around the

center of the bearing (within the clearance circle) at a frequency of one-half of the spinning or rotational speed of the shaft (the speed may be little less than one-half in some applications).

Under these conditions, Hagg (Ref 19) has shown that the capacity of the bearing to support radial loads falls to zero. The shaft system may be stable as the speed is increased until this threshold is reached. Crossing this threshold with further increase in speed will bring the system into a region of instability. Unlike an ordinary critical speed, the shaft cannot pass through this one and attain a region of stability on the other side at a higher speed as with synchronous resonant whirl.

A typical instance would be a bearing running smoothly without any difficulty at 40,000 rpm, but seizing and falling completely at 43,000 rpm. Failure in most instances is instantaneous and complete as the amplitude of vibration becomes equal to the radial clearance in the bearing. This is especially true of rigid gas-lubricated bearings because of their inherent low damping.

This type of instability is not specific to gas bearings, but is a serious and continuing problem with high-speed, lightly loaded, rigid, liquid-lubricated bearings as well (Ref 9).

The compressibility of the gas has significant impact on the threshold of instability in gas-lubricated bearings, and must of course be included in the analysis. One of the more convenient procedures is due to Castelli and Elrod (Ref 20) and deals with translatory half-frequency shaft whirl in infinitely long, cylindrical bearings.

Although the procedure applies particularly to bearings of infinite length, it appears to have adequate accuracy in predicting the stability threshold for shaft in very long bearings--for example, where *l*/*d* values are 2.5, 3, or greater.

It also appears to be conservative for all 360° bearings of finite length, provided that the eccentricity ratio for static loads, ϵ_0, is calculated for an equivalent bearing of infinite length. This can be done using Fig. 15, with a unit load on the bearing (lb/in.) corresponding to that of the finite length bearing of interest.

The procedure is to use Fig. 19 from Ref 20, showing the relationship between ω^*_1, and $\Lambda$for several values of ϵ_0. These curves represent the threshold of instability for the bearing of interest. The value of ϵ_0 is computed on a static load basis:

$$\omega^*_1 = \omega \sqrt{\frac{cM_1}{w}} \qquad \textbf{(Eq 7)}$$

where $\omega$is the shaft speed (rad/s), *c* is the radial clearance (in.), M_1 is mass per unit length (lb · s^2/$in.^2$), and *w* is load per unit of length (lb/in.). Individual curves are drawn for ϵ_0, the value of eccentricity ratio for a bearing of infinite length but with the same unit loading (lb/in.) as the bearing being examined.

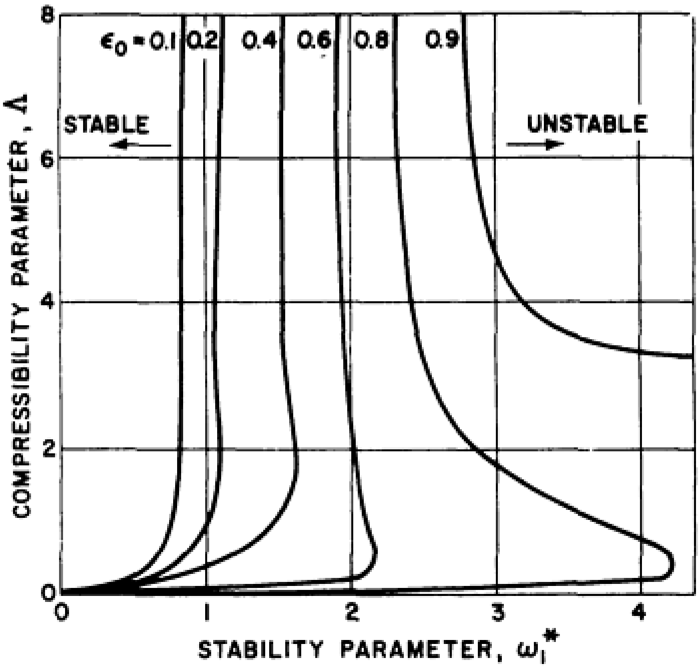

Fig. 19 Plot of half-frequency whirl threshold for infinite-length 360° journal bearing. Source: Ref 20

If the intersection of ω^*_1 and Λ falls to the left of the curve for the operating value of ϵ_0, the bearing should be stable. If it falls to the right, the bearing should be unstable.

Tilting-Pad Journal Bearings

One favored bearing design to achieve rotor stability is to use tilting-pad journal bearings. Considerable analytical and experimental work has been devoted to these bearings, both in the liquid- and gas-lubricated forms. These bearings also offer circumferential and axial misalignment capabilities.

Placing a resilient support (like a spring) under one pad of a three-pad bearing permits accommodation of centrifugal growth of the shaft at high speed or thermal or elastic dimensional changes in both shaft and bearing housing. When properly designed, this bearing is very forgiving. Many succesful applications have been made.

When using gas as the lubricant, some designs will include an auxiliary hydrostatic lift for starting (Fig. 20), which will reduce initial solid contact friction and protect the surfaces. The complete design is quite complex and an area of great specialization. Design guides for gas-lubricated journal and thrust bearings can be found in Ref 21, 22, 23, 24, and 25.

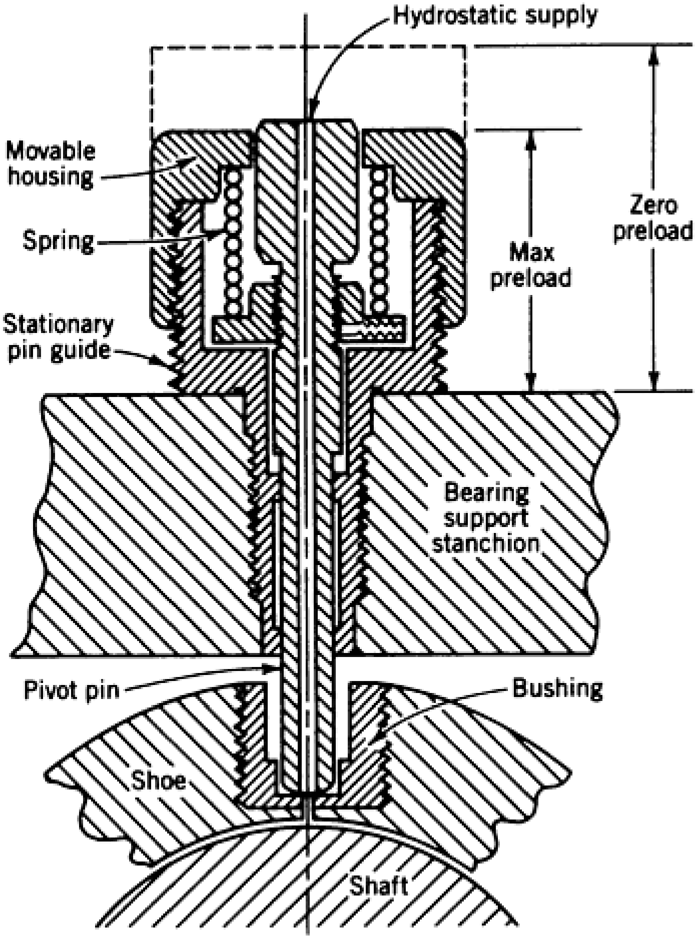

Fig. 20 Cross-sectional view of a spring-mounted pivot assembly. Source: Ref 21

A few fundamental concepts are critical in the design of a tilting-pad journal bearing. Of primary importance are yaw stability, pivot circle clearance, and pivot design. Other design features--such as film stiffness of combined bearing, minimization of bearing friction, the effect of clearance on minimum film thickness, shoe pitching frequency, and rotor critical speeds--are examined in the referenced design manual (Ref 21).

Yaw Stability. A pivoted shoe (or pad) has three degrees of freedom. It can pitch and roll like a ship, and it can yaw. To yaw is to act like a boat rotating about a vertical axis through its center of gravity. Any such rotation will lead to film rupture at the outer corners of th pad, with resulting solid contact. To provide for yaw stiffness in the bearing pad, the angle of wrap of the shoes should be no less than 90° of circumferential arc. With shorter arcs, the pad rapidly loses its ability to provide a resisting moment.

Pivot Circle Clearance. One of the crucial parameters governing the operation of the bearing is the setting of the pivot circle clearance (C' in Fig. 21). If the shaft always remained in the central concentric position, then C' could equal the actual clearance in the bearing, designated by C. That is to say, the radius of curvature of the shoe equals the radius of curvature of the shaft, R, plus the clearance C. The radius of curvature of the shoe is thus greater than the radius of curvature of the shaft. This produces the same phenomenon as having a crowned tilting pad. The load-carrying film cannot collapse even if the film becomes very thin.

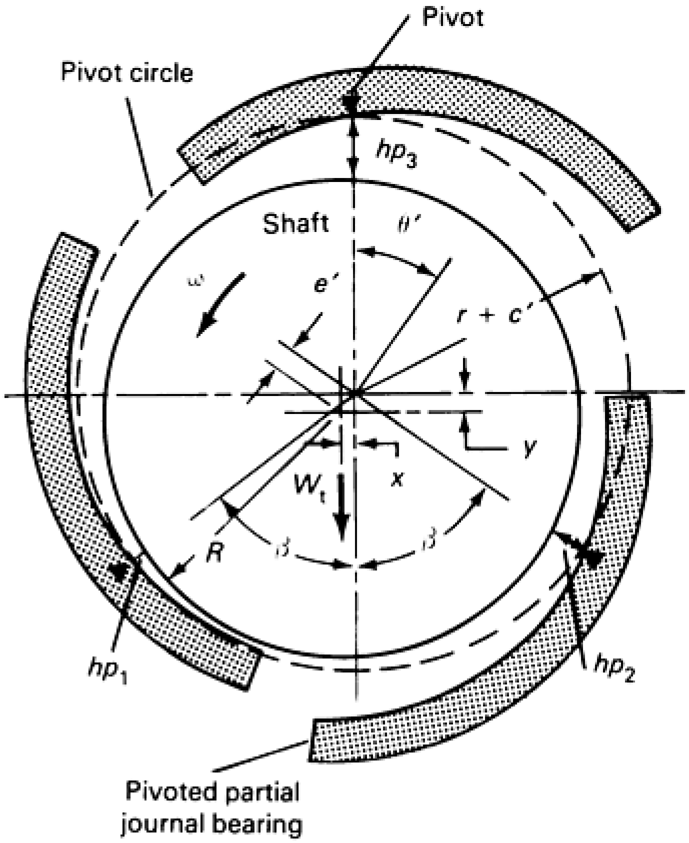

Fig. 21 Pivoted-pad journal bearing with three shoes. Source: Ref 21

However, with the journal bearing under load, and with low speeds, the eccentricity of the shaft can become great enough so that it moves away from the top (unloaded) tilting pad, so that the pad will lose its converging wedge and become unstable. To avoid this possibility, the shaft is preloaded by squeezing the pads radially inward, making *C*′ less than *C*. The measure of this is the ratio *C*′/*C*, which should be less than 1. This is a design parameter and depends on the expected range of eccentricity ratios to be encountered.

Pivot Design. The third important concept is the design of the actual pivot. A ball and socket joint will not be satisfactory because of the frictional resistance to sliding. As the pad assumes its equilibrium position, its righting capacity goes to zero. Any residual friction in the pivot will prevent the pad from ever reaching its equilibrium design inclination. Figure 22 shows a recommended configuration utilizing rolling friction rather than sliding friction. Incidentally, the surfaces should be smooth and very hard to prevent fretting corrosion.

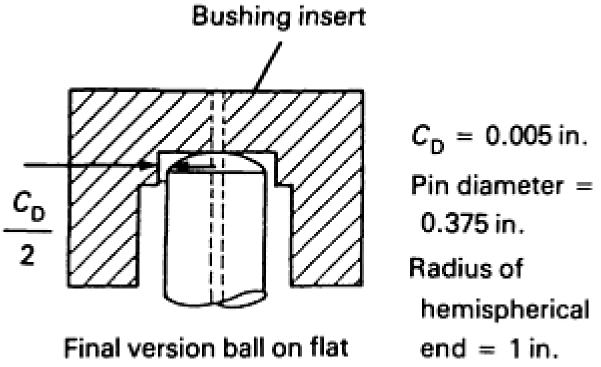

Fig. 22 Bushing insert for pivoted-pad hydrostatic journal bearing. Source: Ref 21

Three-Sector Journal Bearing

This journal bearing, with three equally spaced axial grooves, has shown some degree of stability against self-excited whirl. Castelli and Pirvics (Ref 26) have presented comprehensive numerically computed performance characteristics for three- and four-axial grooved gas-lubricated journal bearings. Angular extent of each groove is considered to be 5°. Thus for a three-sector bearing, the arc length of a sector would be 120 - 5 = 115°.

Figure 23 lists results in terms of the dimensionless load capacity parameter $W' = W/p_a\ rl$ plotted against the bearing compressibility number Λ. Note that the value of Λ used here is actually the same as in Eq 1. The applied load is directed toward the center of one sector. Evaluating W' and Λ will determine the eccentricity ratio and thus the minimum film thickness.

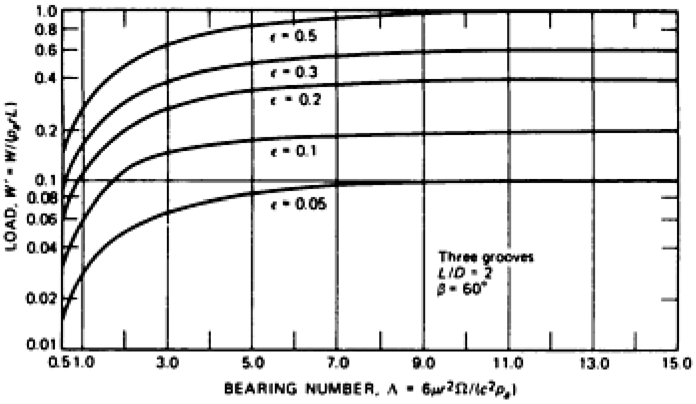

Fig. 23 Load function *W'* versus Λ for three-groove journal bearing. Source: Ref 26

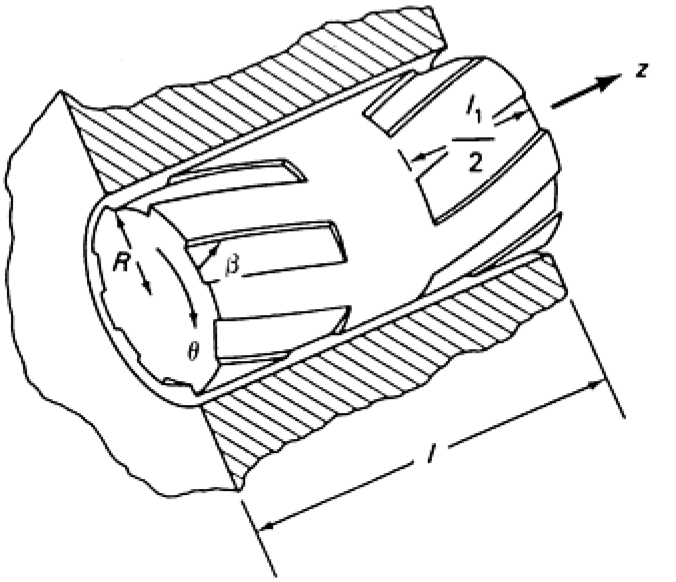
Information on many other sizes, load directions, and attitude angles can be found in Ref 26 and 27.

Helical-Grooved Journal Bearings

The helical grooving in this type of journal bearing enhances stability by reducing the attitude angle below that obtained from a plain cylindrical journal bearing. These bearings are known for their stability and are often used as a possible substitute for tilting-pad journal bearings.

Castelli and Vohr (Ref 28) solved the appropriate equations numerically for load capacity and attitude angle for the case of l/d = 1.0, with various values of Λ. Figure 24 lists the geometric parameters for the spiral-grooved bearing as used in Ref 28. Figure 25 lists the results showing the load parameter $W' = Wp_a$ as a function of Λ with the eccentricity ratio ϵ as the third variable. Malanoski (Ref 29) shows good comparison between the theoretical predictions of Castelli and Vohr and his own measured results for helical-grooved journal bearings.



$$\alpha = \frac{a_g}{a_g + a_r} \qquad \bar{z} = \frac{l_1}{l} \qquad \Gamma = \frac{h_g}{h_r}$$

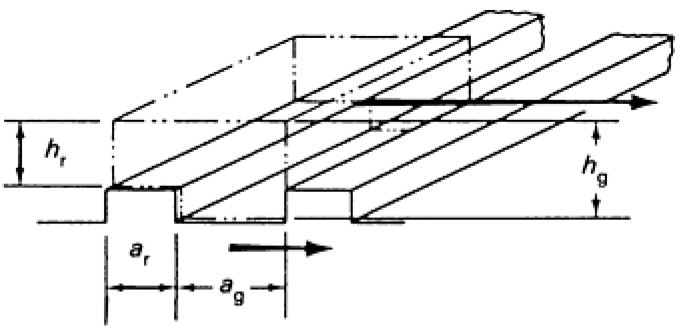


Fig. 24 Geometry of spiral-groove bearing, using notation of Castelli and Vohr (Ref 28)

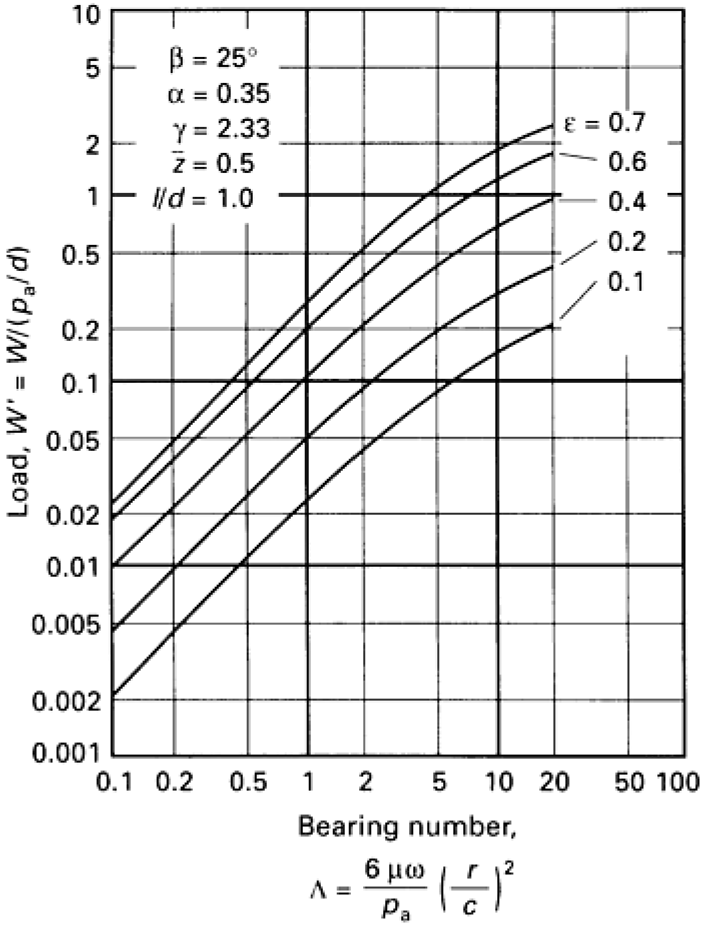

Fig. 25 Load capacity of spiral-groove journal bearing as a function of bearing number and eccentricity ratio. Source: Ref 28

Hydrostatic Gas-Lubricated Bearings

The many advantages of externally pressurized bearings are well known (Ref 9). With gas they have the added benefit of extreme cleanliness, and the use of gas enables them to operate over a wide range of temperatures.

However, analytical and design complications arise because of the compressibility of the gas. At low supply pressures (gage) equal to or less than ambient pressure (absolute), the system can be very simple; for example, supply pressure 70 kPa (10 psig) with an ambient pressure of 100 kPa (14.7 psia).

With high feed pressure, the gas flow in the entrance section is extremely complicated and may involve choked flow, shock waves, vortex formation, and boundary layer growth. Many comprehensive studies have been made of supersonic pressure depression in the feeding region of externally pressurized bearings (Ref 30, 31, 32, 33, 34).

These bearings do not involve a constant volume of flow as is the case with many liquid-lubricated hydrostatic bearings. Therefore, in order to achieve stiffness, they must have some kind of upstream restrictor in the feed line (Fig. 26). The flow restrictor can be an orifice or a capillary, and the bearing is then described as being restrictor compensated; the orifice restrictor area is equal to $\pi d_0^2/4$ (Fig. 26).

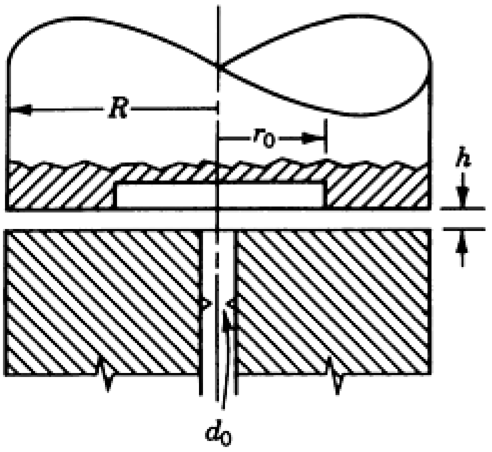

Fig. 26 Flow-restricted hydrostatic gas-lubricated bearing

Sometimes, the resistance to flow at the entrance to the film itself may dominate. In that case the bearing is identified as having inherent compensation. Many bearings are of this type. The inherent restrictor area would then be the circumferential annulus $\pi r_0 h$ at the entrance to the film (Fig. 26).

A typical pressure profile is shown in Fig. 27 for a simple circular thrust bearing with a central feed source. With a supply pressure of 480 kPa (70 psig) and a film thickness on the "sill" of *h* = 0.05 mm (0.002 in.), the effect of sonic velocity is seen. The minimum pressure measured on the sill (p_s) is 76 kPa (11.01 psia), indicating a partial vacuum. The maximum recovery pressure on the sill is 101 kPa (14.6 psig).

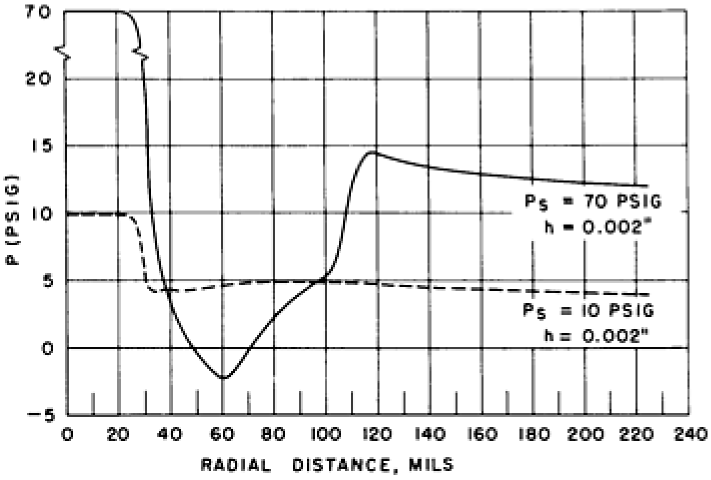

Fig. 27 Experimental pressure profiles for simple area 2 πr_0 *h* externally pressurized thrust bearing

However, notice in Fig. 27 that the radial distances are measured in mils (0.001 in. = 0.025 mm), so that all of this "micro-aerodynamic" activity has taken place within a radius of 120 mils, or about 3.2 mm. The remainder of the bearing area can thus be treated as laminar isothermal gas flow and analyzed accordingly.

The dashed line in Fig. 27 shows the pressure profile when the bearing feed pressure was 70 kPa (10 psig). There is no sonic flow. Allowing for the pressure drop in the restrictor, either external or inherent, the bearing characteristics can be obtained in a relatively simple manner.

Figure 28 is a sample of the excellent program conducted by Laub (Ref 35) on thrust bearings and journal bearings intended for metrology applications. The pressure profiles show no indication of significant flow restriction and localized pressure loss because of bearing geometry and low pressure levels that were used. Flow evaluation, however, must include compressibility effects.

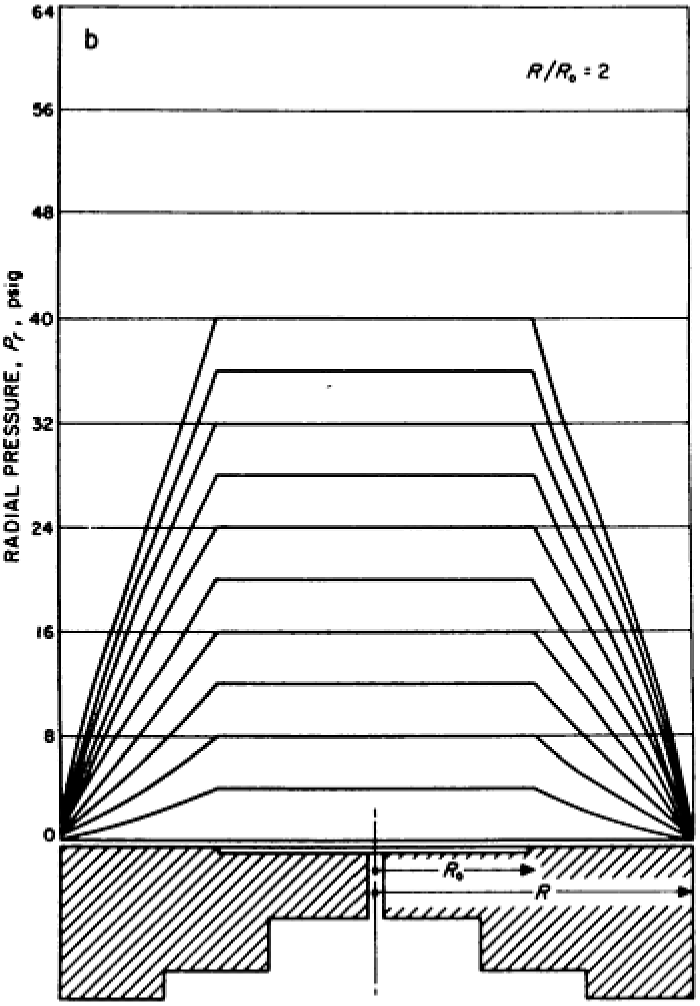

Fig. 28 Pressure profiles in gas-lubricated hydrostatic bearing: Source: Ref 35

As an example of the need to include the compressibility effect in flow prediction, consider the hydrostatic step bearing shown in Fig. 29. For liquids (incompressible), the supply pressure, P_0 and the ambient pressure, P_1, are gage pressures, R_0 is the radius of the recess, and R is the radius of the shaft. The derivation for the flow of lubricant in such a bearing is given in Ref 9 as:

$$Q = \frac{P_0 \pi h_0^3}{6\mu \ln (R/R_0)} \quad \textbf{(Eq 8)}$$

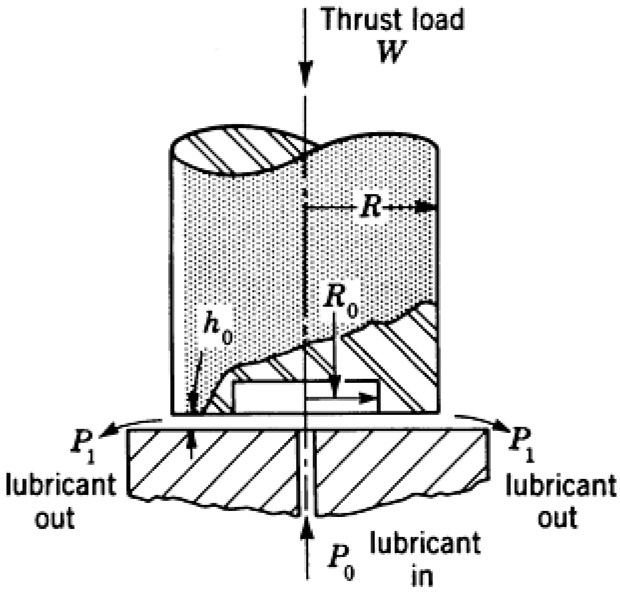

Fig. 29 Schematic diagram of a step bearing

However, when compressibility effects are included, the equation for flow volume becomes (Ref 9):

$$V_0 = \frac{\pi h_0^3}{6\mu \ln \dfrac{R}{R_0}} \left[\frac{P_0^2 - P_1^2}{2P_0} \right] \qquad \textbf{(Eq 9)}$$

where P_0 and P_1 are in this case absolute pressures, and V_0 is the flow volume at the supply pressure P_0.

Pneumatic Hammer

The most troublesome characteristic of the externally pressurized air bearing is instability. During test programs, the phenomenon of self-excited vibration is often encountered, characterized violent fluctuations of pressure in the recess and amplitudes of vibration many times greater than the gap width at the equilibrium point. This phenomenon is often called pneumatic hammer.

Licht, Fuller, and Sternlicht (Ref 36) used a simplified lumped-parameter analysis to examine this problem. The gas film density in an oscillating thrust bearing is time dependent, and, in general, the mass inflow does not equal the mass outflow. As a consequence of film compressibility, energy from the film may be periodically added to the system in phase with the motion so that instability develops. The vibration is independent of system resonances.

The general stability analysis reveals the following:

- For a constant supply pressure, p_s, stability is enhanced by increasing the recess pressure p_0--that is, minimizing the pressure drop through the supply restrictor so that p_s - p_0 is a minimum. This of course reduces the stiffness of the bearing
- A recess depth comparable to the film thickness would be the ideal
- Maximizing the size of the inlet supply orifice will increase stability because capillary restriction is more likely to be unstable than orifice restriction
- Incompressible films are always stable

Multiple-Pressure Sources

To avoid pneumatic instability, it is clear that the high-pressure recess should be very shallow. The limit would be a recess of zero depth or no recess at all. However, that would reduce the load capacity of the bearing. A frequently used alternative is a ring or other appropriate pattern of multiple supply orifices that acts to develop an equivalent high-pressure area with the same depth as the film itself. Figure 30 shows a simple thrust bearing modified in this manner.

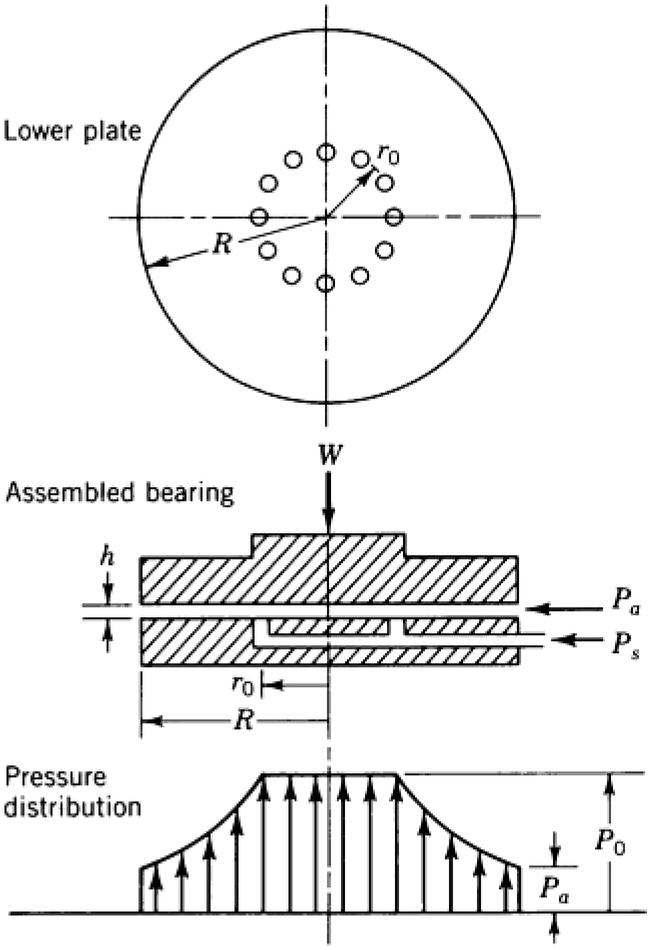

Fig. 30 Multiple-source feed for thrust bearing

In this bearing, the orifices are located on a circle of radius r_0. All orifices feed air to the interface at the same pressure P_0. Because there is no pressure gradient between the orifices, there is no flow between the orifices, and the entire circle of radius r_0 acts as a high-pressure recess. The same concept has also been successfully applied to journal bearings by Laub (Ref 35).

Porous Bearings

An alternate means for reducing the size and depth of a pressurized recess, other than using a finite number of multiple orifices as just described, is to feed the bearing through a section of porous material. Gas is admitted to the bearing interface through the pores of the material, resulting in a very large number of feeding restrictors in parallel. Again, the recess has been eliminated and stability enhanced. Many porous bearings have been made in both flat thrust and cylindrical journal bearing configurations. Sneck (Ref 37) provides an excellent survey of the many applications that have been made of this type of bearing, plus a very complete list of references.

Figure 31 is typical of a circular thrust bearing with pressurization through a porous annulus.Frequently, a porous carbon graphite is used so that antiscuff protection is provided by the material when in solid contact. A reasonable range of

permeability is available in these commercial products, and they have proven to be satisfactory. Clean air is essential to keep the pores from clogging with dust.

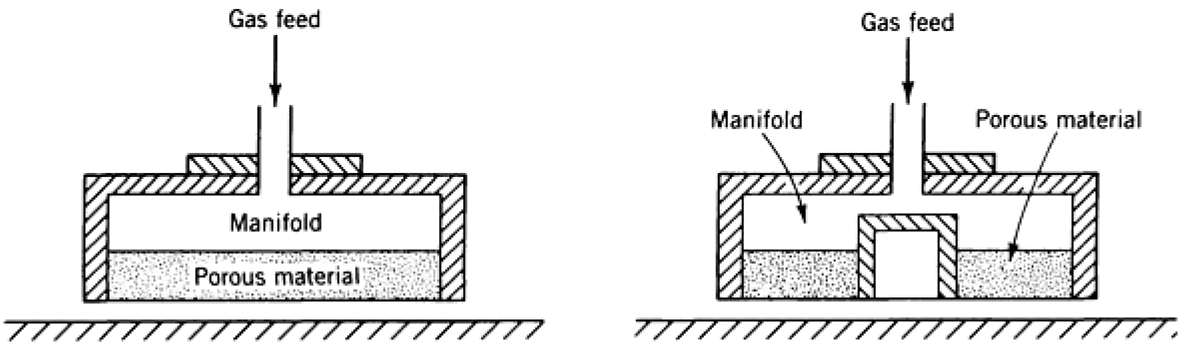

Fig. 31 Typical configurations for externally pressurized porous gas-lubricated thrust bearings. Source: Ref 9

Typically, pressurized porous bearings can be used anywhere classical orifice-compensated bearings are used. Design charts have been prepared by Gargiulo and Gilmour (Ref 38) to assist in a more exact analysis of these bearings.

However, it must be expected that the actual permeability of the material will be subject to some variation, even when cut from the same block. Vohr (Ref 4) discusses many additional design details involved in the use of porous materials in externally pressurized gas-lubricated bearings. These bearings can be extremely useful and are an attractive option for applications that call for a hydrostatic gas bearing.

Compliant-Surface Bearings

Compliant-surface bearings have been mentioned before in this article. They can use elastomers as the bearing material; in this form they have remarkable low-speed fluid-film capabilities. Foil bearings fall into this category as well. Compliant-surface bearings can be used as flexible membrane bearings.

The advantages of compliant-surface bearings include:

- Freedom from precision machining and maintenance of close tolerances
- Ability to accept misalignment
- Tolerance of dirt and particulates
- Accommodation of surface roughness with low surface speeds

The foil bearing (Fig. 32) is the most widely used form of compliant-surface bearing. It was first introduced, in simple form, by Blok and Van Rossum (Ref 39).

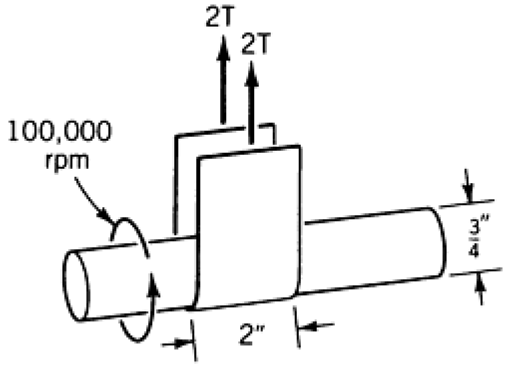

Fig. 32 Schematic diagram of a foil bearing. Source: Ref 27

The bearing can consist of a thin strip of flexible material (such as a plastic tape or thin metallic foil) partially wrapped around simple journal like the saddle belly band on a horse. As the journal spins, a reasonably large force can be supported by the self-acting hydrodynamic film in the contact area between the tape and the journal.

The simple foil bearing was further analyzed by Patel and Cameron (Ref 40) in 1957. It was utilized in the United States as an air bearing for applying load to a rotating shaft as early as 1956 by Fischer, Cherubim, and Fuller (Ref 27). By far, the greatest value of this simple concept is in tape transport for high-speed magnetic tape recorders. In this application, the journal is stationary and contains the recording head for the read-out components, while the tape glides past. Foil bearing analysis and design are reviewed extensively in Ref 4 and 41.

Developments of the original foil bearing concept of Blok and Van Rossum have now reached the stage of commercial application. Their advantages are many. If a metallic foil is used, the bearing can operate at high temperatures, especially when lubricated with air or some other gas. There is no problem with the possible loss of clearance due to differential thermal expansion between shaft and bearing, as is often the case with rigid surface units. The foil bearing establishes its own operating film thickness at all times.

It can also tolerate misalignment. In manufacturing, the foil bearing greatly reduces the need for holding expensive dimensional tolerances. An additional benefit is its stability in conjunction with high-speed rotor applications. The foil bearing is often used just for this reason, because it effectively reduces the possibility of self-excited fractional-frequency whirl (Ref 42).

Three distinct commercial varieties of foil bearings are available:

- Tension-dominated foil bearings (Fig. 33a)
- Bending-dominated segmented foil bearings (Fig. 33b)
- Bending-dominated continuous foil bearings (Fig. 33c)

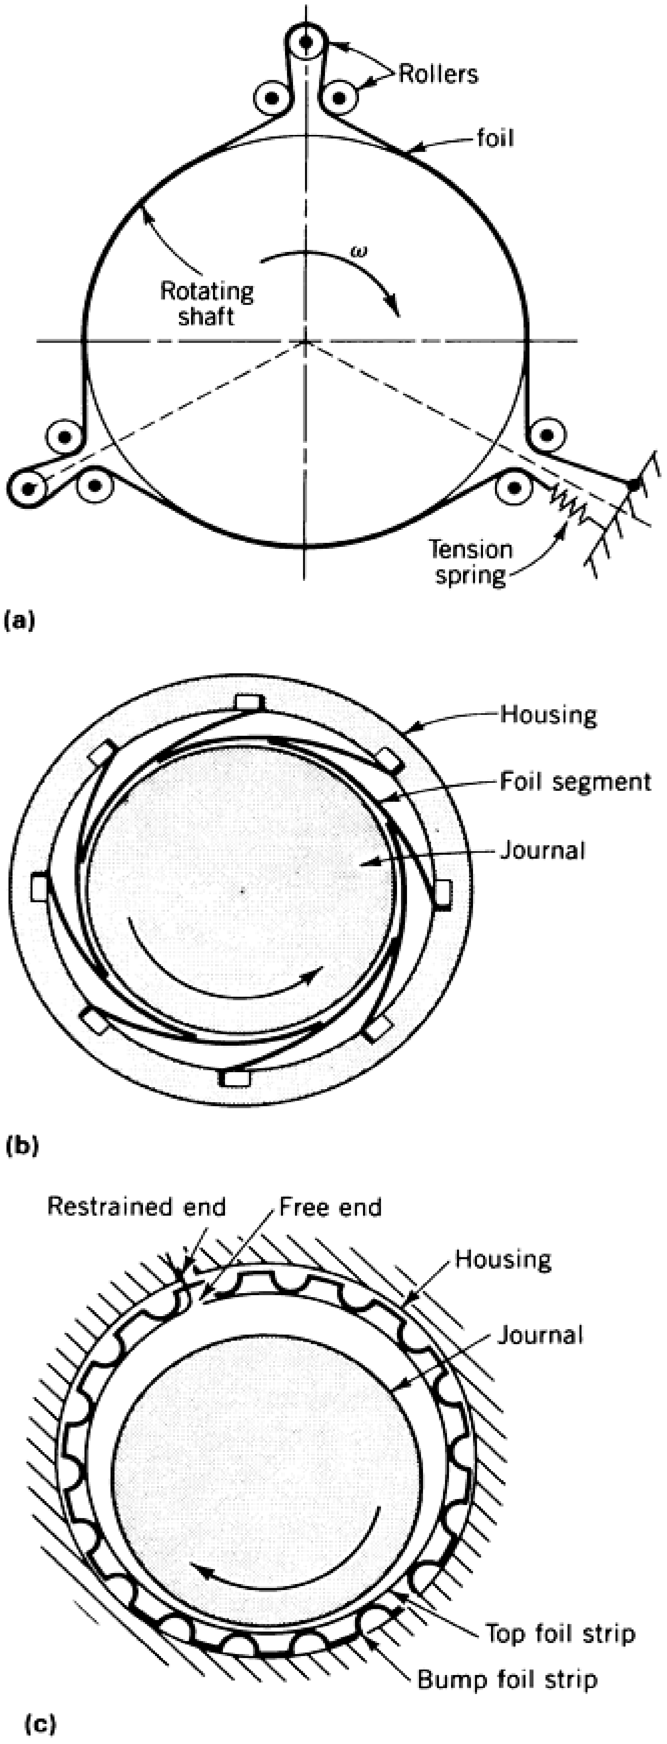

Fig. 33 Foil bearing designs. (a) Tension-dominated foil bearing. (b) Bending-dominated segmented foil bearing. Source: Ref 9. (c) Bending-dominated continuous foil bearing. Source: Ref 9

Tension-dominated foil bearings (Fig. 33a) have been used in data-processing equipment, where they provide support for magnetic tape traveling over guides, heads, and vacuum columns in tape transport. Recent developments have concentrated on adapting these bearings to the support of high-speed rotors for turbomachinery (Ref 43).

Bending-dominated segmented foil bearings of the type shown in Fig. 33(b) are widely used in both commercial and military aircraft applications. One example is the air-cycle refrigeration compressor used on many commercial transports for cabin cooling. Operating speeds can easily be 100,000 rpm, yet the compressor exhibits a high degree of reliability and freedom from rotor whirl instabilities. These bearings are being developed for cryogenic compressors at working temperatures near absolute zero.

A great deal of research and development work is being devoted to extending these bearings to high-temperature applications. With support from the Air Force Aero Propulsion Center and the Naval Air Propulsion Center, research programs are underway to develop a foil bearing capable of operating at high speed in a 650 °C (1200 °F) ambient. The potential application is for high-temperature gas turbines (Ref 44). Thrust bearing configurations are also used.

Bending Dominated Continuous Foil Bearings. This configuration has a single top foil strip that is restrained at one end and supported by a resilient corrugated foil strip called the bump foil strip (Fig. 33c). This piece elastically supports the top foil and controls the stiffness of the bearing. The deflection of the bump foil tolerates load fluctuations, and its elastic behavior provides resilience. Friction damping is also introduced with its beneficial stabilizing effects on the dynamics of the rotor.

Significant accomplishments have been recorded for bending-dominated continuous foil bearings, including:

- Three years of operation in automotive-type gas turbines at 60,000 rpm and 260 °C (500 °F)
- 120,000 rpm in product hardware
- Bearing shock resistance to 25 g at 100,000 rpm
- Tests at 650 °C (1200 °F)
- Unit bearing pressures for hydrodynamic air operation up to 345 kPa (50 psi), based on projected area under laboratory conditions

Modified Bending-Dominated Continuous Foil Bearings. This type of bearing is a modification of the design shown in Fig. 33(c). Although only limited applications have been made, it does appear to have excellent performance characteristics.

Design Analysis. There is no significant design analysis available, in the public domain, for the foil bearings described above. The design procedures are essentially proprietary. However, if a proposed application involves light starting loads ($\leq$7 to 14 kPa, or 1 to 2 psi) and when up to speed (>20,000 rpm) the unit loads do not exceed 70 to 100 kPa (10 to 15 psi), it appears that some type of foil bearing would be an excellent choice.

Pressurized-membrane bearings are bearings with a flexible membrane pressurized from the center through port holes (Fig. 34). At equilibrium conditions, the air escapes from under the inflated membrane through the minimum air gap. Levy and Coogan (Ref 45) first developed the analysis for such a device.

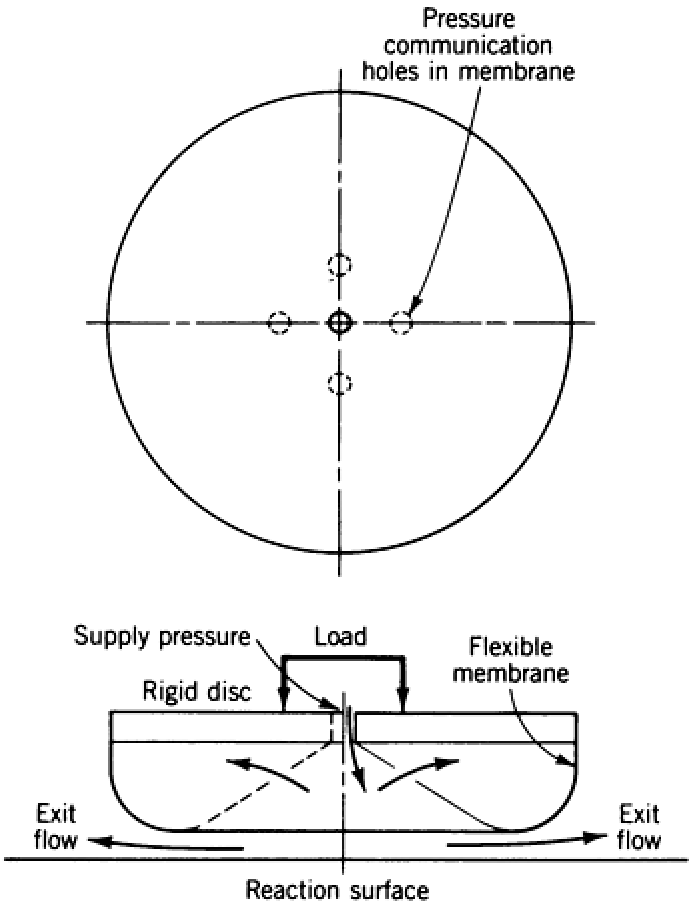

Fig. 34 Compliant-surface membrane bearing. Source: Ref 45

These bearings find wide use in areas where large loads must be lifted and transported over surfaces that may not be perfectly smooth, such as the floors in warehouses and factories. The flexibility of the membrane accommodates itself to the undulations that may exist, and motion proceeds smoothly with almost no friction. When the desired location or position is attained, the air supply is shut off and the object is set down. These devices are now available commercially.

A spectacular application of this type of hydrostatic membrane bearing is the Mile High Stadium in Denver, Colorado. The stadium was designed so that it would be suitable for both football and baseball. Accordingly, the entire side section of the grandstand, weighing 4080 Mg (4500 tons) and including 21,000 seats, is mounted at 46 points on water-lubricated hydrostatic rubber pads. Each pad is 1.2 m (4 ft) in diameter and made of fabric-reinforced synthetic rubber.

When pressurized, the entire section of the grandstand floats on a film of water and is moved back a distance of 44 m (145 ft) with very little effort. It is then set down in place, producing an arena suitable for playing baseball (Fig. 35). Although water was the pressurized lubricant of choice in this application, air could have been used.

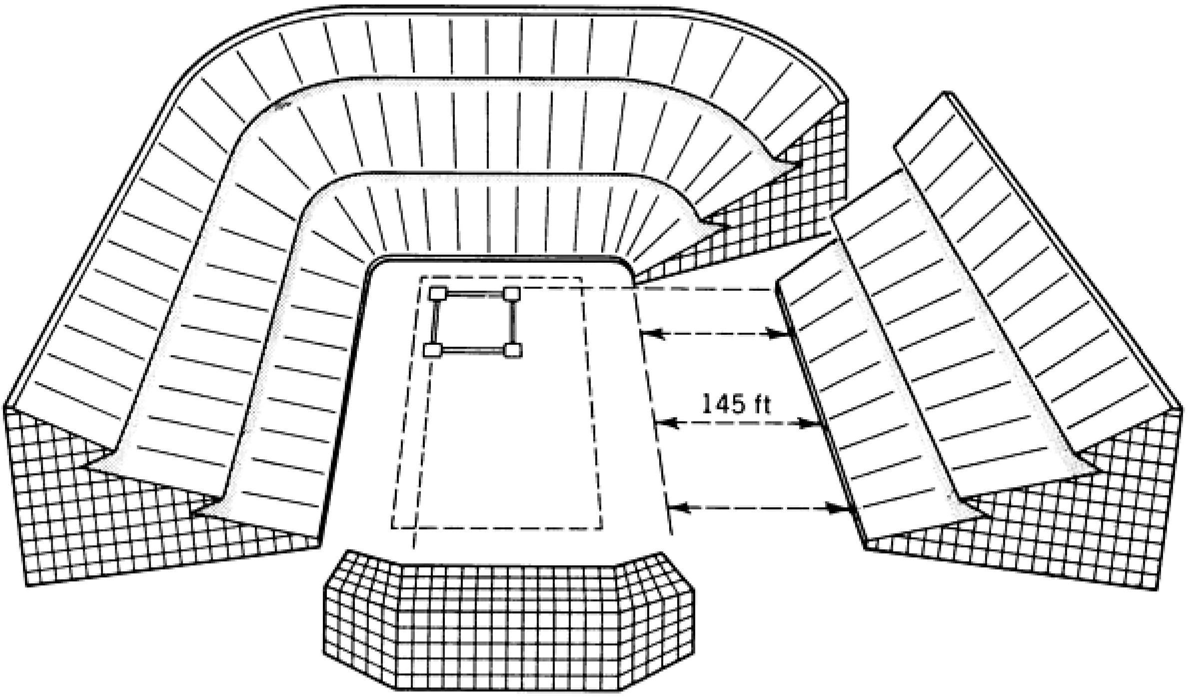

Fig. 35 Use of pressurized membrane bearings in Denver Mile High Stadium

It is surprising how little pressure is needed to support a large load. An available circular commercial unit 430 mm (17 in.) in diameter, with a pressure of about 21 kPa (3 psig) can carry a load of 270 kg (600 lb) with a flow of about 57 L/min (2 standard ft^3/min). The same unit at only 70 kPa (10 psig) can carry 900 kg (2000 lb) with, of course, a greater flow.

A novel application was made recently by a company in England that refurbishes full-size passenger railroad cars. A cradle platform was built to hold the four-wheel trucks at each end of the car. Then the platforms were floated on air-pressurized membrane bearings. Once this was done, the railroad car could be easily moved to any location on the factory floor without being encumbered by rails.

A few years ago, this type of hydrostatic compliant pad was offered as an option on a well-known brand of domestic refrigerator. By reversing the hose connection on a standard vacuum cleaner, the discharge pressure could be directed to the pads under the refrigerator and cause it to float in a film of air. It could then be moved very easily away from the wall, even when fully loaded, to allow for cleaning and maintenance.

Hydrostatic Journal Bearings

Externally pressurized journal bearings may be used when it is necessary to maintain a precise shaft position, with negligible friction, when rotational speed is insufficient to establish a hydrodynamic film. External pressurization is also used in combination with a hydrodynamic-type bearing to increase film stiffness, reduce the attitude angle, and raise the threshold of instability. The combination of these two actions produces what is known as a "hybrid bearing" (Fig. 36).

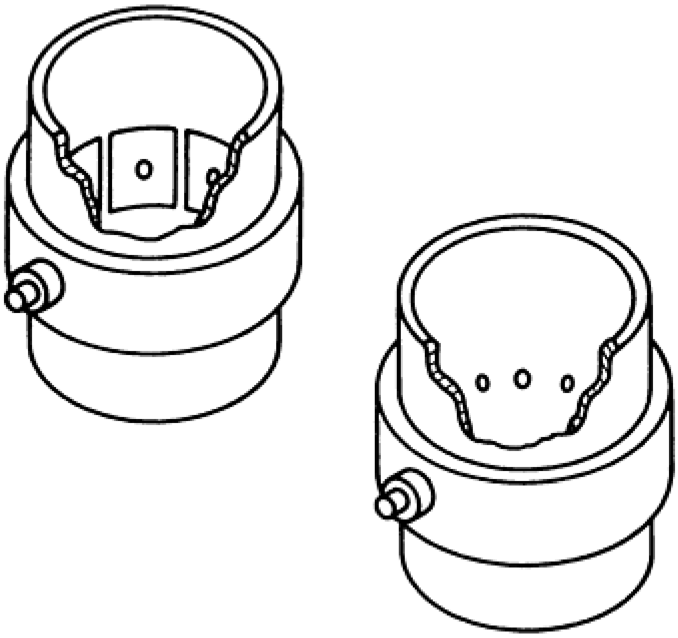

Fig. 36 Typical hybrid journal bearing designs. Source: Ref 9

The mutual contribution of each type of lubrication is of course of design decision. The rotor may be started or stopped without solid contact. Bearings for high-speed dental drills (500,000 rpm) are of the hybrid variety (Ref 46).

Externally pressurized journal bearings are affected by a great many combinations of parameters, so their design is relatively complex. Lund (Ref 47) has combined first-order self-acting and externally pressurized perturbation solutions for small eccentricity ratios. The results are found to be satisfactory and in good agreement with experimental results for small eccentricity ratios.

As with thrust bearings, the recesses must be kept as small as possible to avoid pneumatic instability. Multiple feed orifices or porous sections may be an answer to the problem. With multiple feeds, the assumption is usually made that the discrete points be considered as a continuous line source of pressure.

Comprehensive design charts for externally pressurized journal bearings are presented in Ref 48. Shapiro (Ref 49) has evaluated a three-sector hybrid journal bearing for both steady-state and dynamic behavior. He has published the results for this gas bearing, which uses orifice compensation, in tabular and graphical forms.

Many applications of externally pressurized gas bearings have been made to instruments, with remarkable increases in precision. Wunch, in Ref 45, describes the revolution that gas bearings have produced in the field of metrology. The surprising conclusion is that even though the components of the air bearing have been produced with normal manufacturing tolerances on dimensions and surface finishes, the rotational accuracy of the final instrument itself is of the order 0.075 to 0.125 μm. The explanation assumes the pressurized film has an averaging effect, and the small surface undulations of the bushing (surface roughness) are not transmitted to the shaft. This is similar to the smooth motion of a row boat on the surface of a pond; the boat is not influenced by the roughness of the bottom of the pond.

In machine tool applications, Lewis (Ref 50) has shown that grinder spindles, shapers, and gear cutters will actually show run-outs measured in microinches using externally pressurized journal bearings.

Materials for Gas-Lubricated Bearings

Engineers have been forced to search for materials that, when operated under extremely adverse conditions, will deliver acceptable life expectancy and reasonably low friction. These adverse conditions may be associated with high

temperature, with the use of lubricants with low viscosity and little or no natural oiliness (like gas), or with dry operation where no lubricants are present at all.

Experimentation has led in the direction of harder and harder materials, such as refractory materials and ceramics (Ref 51, 52, 53). These materials are usually brittle, so impact must be avoided. When they are used as rigid bearings with gas lubrication, the geometry must be precise and true because there is little possibility of conformability with such materials (as there could be with tin or lead-based babbitt, for example). Rigid designs, relatively light loads, and elimination of thermal or elastic deformations are necessary.

Investigations of gas-lubricated rigid thrust bearings and journal bearings operating under high temperature and high-speed conditions have shown favorable performance with the use of hard ceramic materials. Materials that might be considered for such applications include boron carbide, chromium carbide, silicon carbide, titanium carbide, alumina, silicon nitride, tungsten carbide, and chromium oxide.

Ceramics and cermets exhibit superior wear resistance. Cermets are ceramics that have been bonded with metals to improve their ability to handle impact and shock loading. The results, of course, vary with the ceramic and its bonding material. Cobalt is often used as a binder.

Hinkle and Fuller (Ref 54) conducted a study of the friction and wear of various materials for gas-lubricated rigid journal bearings under conditions of start-stop and high-speed whirl-induced rubbing. The tests were performed with a variety of imposed loads, temperatures, and ambient atmospheric conditions. Of the 36 combinations of materials investigated, by far the best performance was exhibited by aluminum oxide (alumina) against itself. The best specimens showed no visible evidence of wear even after extended testing.

Surprisingly, of the four different types of aluminum oxide used, one was far superior to the other three. The binder, the density, and the grain size are apparently strong variables. It might be advisable to get guarantees of friction and wear characteristics from a prospective vendor before selecting a particular grade of aluminum oxide.

Ceramics do provide low wear, but they also have relatively high friction. This may be a problem in some applications. In instrument gyroscopes, the electric motor drive is very small and light and has a low starting torque. Consequently, unless the friction of the bearing material is low enough, the motor will stall and not start. Much current research in gyro bearings is directed toward the reduction of friction in ceramic bearings through the introduction of some form of boundary lubrication.

Research carried out at the University of Rhode Island has determined that if final grinding of the ceramic is done in a bath of a prescribed boundary lubricant, a surface modification is achieved that provides lower friction. For silicon nitride, octadecanoic armide is recommended. For glass ceramics such as Pyroceram, the use of dioctedecyl disulfide is indicated.

In England, the British Royal Navy Scientific Service frequently uses silicon nitride against silicon nitride for gyro air bearings. They have been successful with small built-in graphite brushes that spread a thin film of solid graphite on the running surfaces. This technique not only reduces wear and lowers friction, but it also burnishes the surfaces to a high gloss while running. An alternative technique is burnishing the surfaces before installation with either molybdenum disulfide (MoS_2) or Teflon. Reducing friction with ceramics is an active research field.

Surface Coatings. High-density ultrahard coatings can be applied to the surfaces of ordinary commercial machine elements and provide them with a highly wear-resistant capability. Typical applications include parts for use in jet aircraft and in the chemical, textile, steel, and data processing industries. New coating technologies for tribological applications are described in Ref 55. Many different techniques can be used in making these surface depositions, depending on the end results desired.

Surface coating is a specialized field in which dramatic developments have been made within the last decade. For example, the metallic foil compliant-surface bearings, described earlier, have been coated with wear- and friction-resistant materials for use in various applications. Commercially bonded MoS_2, aluminum oxide, chromium oxide, and a three-component commercial blend of aluminum oxide, silicon oxide, and chromium oxide have all been used successfully for coating these bearings.

Friction, Lubrication, and Wear of Gears

Robert Errichello, GEARTECH

Introduction

BECAUSE GEARS are such common machine components, they may be taken for granted. It is not generally appreciated that they are complex systems requiring knowledge from all the engineering disciplines for their successful design. Gear design is a process of synthesis in which gear geometry, materials, heat treatment, manufacturing methods, and lubrication are selected to meet the requirements of a given application. The designer must design the gearset with adequate strength, wear resistance, and scuffing resistance. To do this, he or she must consider gear tribology. The choice of lubricant and its application method is as important as the choice of steel alloy and heat treatment. The interrelationship of the following factors must be considered:

- Gear tooth geometry
- Gear tooth motion (kinematics)
- Gear tooth forces (static and dynamic)
- Gear tooth material and surface characteristics (physical and chemical)
- Lubricant characteristics (physical and chemical)
- Environmental characteristics (physical and chemical)

Gear Tooth Failure Modes

To obtain optimum minimum-weight gearsets, the gear designer must be aware of the intricate details of many competing modes of failure. In its nomenclature publication (Ref 1), the American Gear Manufacturers Association (AGMA) has classified 20 modes of gear failure under the broad categories of wear, surface fatigue, plastic flow, breakage, and associated gear failures. References 2, 3, 4, 5, 6 also give gear failure modes. For our purposes, the basic categories are overload, bending fatigue, Hertzian fatigue, wear, and scuffing (Table 1).

Table 1 Basic failure modes of gear teeth

Nonlubrication-related failures

Overload
Brittle fracture
Ductile fracture
Plastic deformation
    Cold flow
    Hot flow
    Indentation
        Rolling
        Bruising
        Peening
        Brinelling
    Rippling (fish scaling)
    Ridging
    Bending (yielding)
    Tip-to-root interference

Bending fatigue **Low-cycle fatigue ($\leq$1000 cycles to failure)** **High-cycle fatigue (>1000 cycles to failure)**

Lubrication-related failures

Hertzian fatigue
Pitting
    Initial
    Superficial
    Destructive
    Spalling
Micropitting
    Frosting
    Gray staining
    Peeling
Subcase fatigue (case crushing)

Wear
Adhesion
    Normal
    Running-in
    Mild
    Moderate
    Severe
    Excessive
Abrasion
    Scoring
    Scratching
    Plowing
    Cutting
    Gouging
Corrosion
Fretting corrosion
Cavitation
Electrical discharge damage
Polishing (burnishing)

Scuffing **Scoring**

Galling **Seizing** **Welding** **Smearing** **Initial** **Moderate** **Destructive**

Many gear failures are known by several names and qualifying terms, such as initial, moderate, destructive, and so on. The term "scoring" has been used in the past in the United States, while the term "scuffing" is used in Europe to describe the severe form of adhesive wear that involves the welding and tearing of the surfaces of gear teeth. To agree with current usage, the term scuffing will be used in this article when referring to this failure mode. The term scoring implies scratching, and it will be used to describe abrasive wear rather than scuffing.

Lubrication-Related Failure Modes

This article is concerned with gear tooth failures that are influenced by friction, lubrication, and wear. Pitting or scuffing may cause the gear teeth to deteriorate and generate dynamic forces, which in turn cause the gear teeth to fail by bending fatigue. In these cases, the bending failure is secondary and not directly related to lubrication, whereas pitting or scuffing are the primary failure modes, and both are definitely influenced by lubrication. The failure analyst must discern and difference between primary and secondary failure modes because the wrong corrective action is likely to be recommended if a secondary failure mode is mistaken for the primary failure mode. For example, increasing the size of the gear teeth to prevent reoccurrence of the above-mentioned bending failure would only make the situation worse by lowering the pitting and scuffing resistance. Godfrey (Ref 7) gives a good description of lubrication-related failure modes.

On the basis of the above considerations, overload and bending fatigue are judged to be unrelated to lubrication and are eliminated from further discussion together with another category, subcase Hertzian fatigue. Although corrosion, fretting-corrosion, cavitation, and electrical discharge damage are influenced by lubrication, they will not be discussed in this article because these failure modes occur relatively rarely in gear teeth. Hence, only the following failure modes are discussed in this article:

- Hertzian fatigue (including pitting and micropitting)
- Wear (including adhesion, abrasion, and polishing)
- Scuffing

Hertzian Fatigue. Pitting and micropitting are two lubrication-related gear tooth failure modes caused by Hertzian fatigue.

Pitting is a common failure mode for gear teeth because they are subjected to high Hertzian contact stresses and many stress cycles. For example, through-hardened gears are typically designed to withstand contact stresses of approximately 700 MPa (100 ksi), while the contact stresses can carburized gears may reach 2100 MPa (300 ksi). In addition, a given tooth on a pinion that is revolving at 3600 rev/min accumulates over 5×10^6 stress cycles every 24 h.

Pitting is a fatigue phenomenon (Ref 8) that occurs when a fatigue crack initiates either at the surface of the gear tooth or at a small depth below the surface. The crack usually propagates for a short distance in a direction roughly parallel to the tooth surface before turning or branching to the surface. When the cracks have grown to the extent that they separate a piece of the surface material, a pit is formed. If several pits grow together, the resulting larger pit is often referred to as a "spall." There is no endurance limit for Hertzian fatigue, and pitting occurs even at low stresses if the gears are operated long enough. Because there is no endurance limit, gear teeth must be designed for a suitable finite lifetime.

To extend the pitting life of a gearset, the designer must keep the contact stress low and the material strength and lubricant specific film thickness high. There are several geometric variables, such as diameter, face width, number of teeth, pressure angle, and so on, that can be optimized to lower the contact stress. Material alloys and heat treatment are selected to obtain hard tooth surfaces with high strength. Maximum pitting resistance is obtained with carburized gear teeth because they have hard surfaces, and carburizing induces beneficial compressive residual stresses that effectively lower the load stresses. The drawbacks to using carburized gear teeth are that they are relatively expensive to produce and that they must be finished by grinding. The details for obtaining high lubricant specific film thickness will be explained

later when elastohydrodynamic (EHD) lubrication is discussed (see the section "Elastohydrodynamic Lubrication" in this article), but general recommendations are to use an adequate supply of cool, clean, and dry lubricant that has adequate viscosity and a high pressure-viscosity coefficient.

Pitting may initiate at the surface or at a subsurface defect, such as a nonmetallic inclusion. With gear teeth, pits are most often of the surface-initiated type because the lubricant film thickness is usually low, resulting in relatively high metal-to-metal contact. The interaction between asperities or contacts at defects, such as nicks or furrows, creates surface-initiated, rather than subsurface-initiated cracks. For high-speed gears with smooth surface finishes, the film thickness is greater and subsurface-initiated pitting, rather than surface-initiated, may predominate. In these cases, pitting usually starts at a subsurface inclusion, which acts as a point of stress concentration. Cleaner steels, such as those produced by vacuum melting, prolong the pitting life by reducing the number of inclusions.

Contamination from water in the lubricant is believed to promote pitting through hydrogen embrittlement of the metal, and abrasive particles in the lubricant cause pitting by indenting the tooth surfaces, causing stress concentrations, and disrupting the lubricant film. At present, the influence of lubricant additives on pitting is unresolved.

The following recommendations serve as guidelines for preventing the onset of pitting in gearsets:

- Reduce contact stresses by reducing loads or optimizing gear geometry
- Use clean steel, properly heat treated to high hardness, preferably by carburizing
- Use smooth tooth surfaces produced by careful grinding or honing
- Use an adequate amount of cool, clean, and dry lubricant of adequate viscosity

Micropitting. On relatively soft gear tooth surfaces, such as those of through-hardened gears, Hertzian fatigue forms large pits with dimensions on the order of millimeters. With surface-hardened gears (for example, carburized, nitrided, induction hardened, and flame hardened), pitting may occur on a much smaller scale, typically only 10 μm (400 μin.) deep. To the naked eye, the areas where micropitting has occurred appear frosted, and "frosting" is a popular term for micropitting. Japanese researchers (Ref 9) have referred to the failure mode as "gray staining" because the light-scattering properties of micropitting give the gear teeth a gray appearance. With scanning electron microscopy (SEM), it is immediately evident that micropitting proceeds by the same fatigue process as classical pitting, except the pits are extremely small.

In many cases, micropitting is not destructive to the gear tooth surface. It sometimes occurs only in patches and may stop after the tribological conditions have been improved by running-in. The micropits may actually be removed by mild polishing wear during running-in, in which case the micropitting is said to "heal." However, there have been examples (Ref 9, 10, 11) where micropitting has escalated into full-scale pitting, leading to the destruction of the gear teeth.

The specific film thickness is the most important parameter that influences micropitting. Damage seems to occur most readily on gear teeth with rough surfaces, especially when they are lubricated with low-viscosity lubricants. Gears finished with special grinding wheels to a mirrorlike finish (Ref 12) have effectively eliminated micropitting. Slow-speed gears are prone to micropitting because their film thickness is low.

The prevent micropitting, the specific film thickness should be maximized by using smooth gear tooth surfaces, high-viscosity lubricants, and high speeds. Experiments (Ref 10) have shown that flame-hardened and induction-hardened gears have less resistance to micropitting than carburized gears of the same hardness. This is probably due to the lower carbon content of the surface layers of the flame-hardened and induction-hardened gears.

The following recommendations serve as guidelines for preventing the onset of micropitting in gearsets:

- Use smooth tooth surfaces produced by careful grinding or honing
- Use an adequate amount of cool, clean, and dry lubricant of the highest viscosity permissible
- Use high speeds if possible
- Use carburized steel with proper carbon content in the surface layers

Wear. Gearsets are susceptible to wear caused by adhesion, abrasion, and polishing.

Adhesion. Adhesive wear is classified as "mild" if it is confined to the oxide layers of the gear tooth surfaces. If, however, the oxide layers are disrupted and bare metal is exposed, the transition to severe adhesive wear usually occurs. Severe adhesive wear is termed scuffing and will be discussed in the section "Scuffing" in this article. Here we assume that scuffing has been avoided through proper design of the gears, selection of the lubricant, and control of the running-in process.

When new gear units are first operated, the contact between the gear teeth is not optimum because of unavoidable manufacturing inaccuracies. If the tribological conditions are favorable, mild adhesive wear occurs during running-in and usually subsides with time, resulting in a satisfactory lifetime for the gears. The wear that occurs during running-in is beneficial if it smooths the tooth surfaces (thereby increasing the specific film thickness) and if it increases the area of contact by removing minor imperfections through local wear. To ensure that the wear rate remains under control, new gearsets should be run-in by being operated for at least the first ten hours at one-half load.

The amount of wear considered tolerable depends on the expected lifetime for the gears and requirements for control of noise and vibration. Wear is considered excessive when the tooth profiles wear to the extent that high dynamic loads occur or the tooth thickness is reduced to the extent that bending fatigue becomes possible.

Many gears, because of practical limits on lubricant viscosity, speed, and temperature, must operate under boundary-lubricated conditions in which some wear is inevitable. Highly loaded, slow speed (<30 m/min, or 100 ft/min), boundary-lubricated gears are especially prone to excessive wear. Tests with slow-speed gears (Ref 10) have shown that nitrided gears have good wear resistance, whereas carburized and through-hardened gears have similar but lower wear resistance. Winter and Weiss (Ref 10) concluded that lubricant viscosity has the greatest effect on slow-speed adhesive wear, and that high-viscosity lubricants reduce the wear rate significantly. Winter and Weiss (Ref 10) also found that sulfur-phosphorus additives can be detrimental with slow-speed (<3 m/min, or 10 ft/min) gears, giving very high wear rates.

A few gear units operate under ideal conditions with smooth tooth surfaces, high pitch line speed, and high lubricant film thickness. For example, turbine gears that operated almost continuously at 9000 m/min (30,000 ft/min) pitch line speed still had the original machining marks on their teeth, even after operating for 20 years. Most gears, however, operate between the boundary and full-film lubrication regimes, under EHD conditions. In the EHD regime, with the proper type and viscosity of lubricant, the wear rate usually reduces during running-in and adhesive wear virtually ceases once running-in is completed. If the lubricant is properly maintained (cool, clean, and dry), the gearset should not suffer an adhesive wear failure.

The following recommendations serve as guidelines for preventing the onset of adhesive wear in gearsets:

- Use smooth tooth surfaces
- If possible, run-in new gearsets by operating the first 10 hours at one-half load
- Use high speeds if possible. Otherwise, recognize that highly loaded slow-speed gears are boundary lubricated and are especially prone to excessive wear. For these conditions, specify nitrided gears and the highest permissible lubricant viscosity
- For very slow-speed gears (<3 m/min, or 10 ft/min), avoid using lubricants with sulfur-phosphorus additives
- Use an adequate amount of cool, clean, and dry lubricant of the highest viscosity permissible

Abrasion. Abrasive wear on gear teeth is usually caused by contamination of the lubricant by hard, sharp-edged particles. Contamination enters gearboxes by being built-in, internally generated, ingested through breathers and seals, or inadvertently added during maintenance.

Many gear manufacturers do not fully appreciate the significance of clean assembly; it is not uncommon to find sand, machining chips, grinding dust, weld splatter, or other debris in new gearboxes. To remove built-in contamination, the gearbox lubricant should be drained and flushed before start-up and again after the first 50 h of operation, refilled with the recommended lubricant, and a new oil filter should be installed.

Internally generated particles are usually wear debris from gears or bearings due to Hertzian fatigue pitting or adhesive and abrasive wear. The wear particles are especially abrasive because they become work-hardened when they are trapped between the gear teeth. Internally generated wear debris can be minimized by using accurate surface-hardened gear teeth (with high pitting resistance), smooth surfaces, and high-viscosity lubricants.

Breather vents are used on gearboxes to vent internal pressure, which may occur when air enters through seals, or when air within the gearbox expands (or contracts) during the normal heating and cooling of the gear unit. The breather vent should be located in a clean, nonpressurized area and should have a filter to prevent ingress of airborne contaminants. In especially harsh environments, the gearbox can be completely sealed, and the pressure variation can be accommodated by an expansion chamber with a flexible diaphragm.

All maintenance procedures that involve opening any part of the gearbox or lubrication system must be carefully performed to prevent contamination of the gearbox system.

Abrasive wear due to foreign contaminants, such as sand or internally generated wear debris, is called three-body abrasion and is a common occurrence. Two-body abrasion also occurs when hard particles or asperities on one gear tooth abrade the opposing tooth surface. Unless the tooth surfaces of a surface-hardened gear are smoothly finished, they will act like files if the mating gear is appreciably softer. This is the reason that a worm pinion is polished after grinding before it is run with a bronze worm wheel. Manufacturers of computer disk drives have found that stainless steel pinions mated with anodized aluminum racks have excessively high wear rates. The anodized layer of the aluminum rack is extremely thin and brittle, and it breaks up and impregnates the relatively soft stainless steel pinion. The aluminum oxide particles then act like emery paper and wear the teeth of the rack very quickly.

The lubrication system should be carefully maintained and monitored to ensure that the gears receive an adequate amount of cool, clean, and dry lubricant. For circulating-oil systems, fine filtration removes contamination. Filters as fine as 3 μm (120 μin.) have significantly increased gear life. For oil bath gearboxes, the lubricant should be changed frequently to remove contamination. Under normal operating conditions, the lubricant should be changed at least every 2500 h of operation or every six months, whichever occurs first. For critical gearboxes, a regular program of lubricant monitoring can help prevent gear failures by showing when maintenance is required. The lubricant monitoring should include spectrographic and ferrographic analysis of contamination, along with analysis of acid number, viscosity, and water content.

In summary, the following guidelines should be observed to prevent abrasive wear in gearsets:

- Remove built-in contamination from new gearboxes by draining and flushing the lubricant before start-up and again after the first 50 h of operation. Refill with the recommended lubricant and install a new filter
- Minimize internally generated wear debris by using surface-hardened gear teeth, smooth tooth surfaces, and high-viscosity lubricants
- Minimize ingested contamination by maintaining oil-tight seals and using filtered breather vents located in clean, nonpressurized areas
- Minimize contamination that is added during maintenance by using good housekeeping procedures
- For circulating-oil systems, use fine filtration
- For oil bath systems, change the lubricant at least every 2500 h or every six months
- Monitor the lubricant with spectrographic and ferrographic analysis together with analysis of acid number, viscosity, and water content

Polishing Wear. If the extreme-pressure (EP) antiscuff additives in the lubricant are too chemically reactive, they may cause polishing of the gear tooth surfaces until they attain a bright mirror finish. Although the polished gear teeth may look good, polishing wear is undesirable because it generally reduces gear accuracy by wearing the tooth profiles away from their ideal form. Antiscuff additives used in lubricants to prevent scuffing, such as sulfur and phosphorus, will be covered when scuffing is discussed. They function by forming iron-sulfide and iron-phosphate films on areas of the gear teeth where high temperatures occur. Ideally, the additives should react only at temperatures where there is a danger of welding. If the rate of reaction is too high, and there is a continuous removal of the surface films caused by a very fine abrasives in the lubricant, the polishing wear may be excessive (Ref 13).

Polishing wear can be prevented by using less chemically active additives. As an alternative to sulfur-phosphorus additives, antiscuff lubricants are available with dispersions of potassium borate (Ref 14) that deposit EP films without chemically reacting with the metal. Removing the abrasives in the lubricant by using fine filtration or frequent oil changes is helpful.

In summary, the following guidelines should be observed to prevent polishing wear in gearsets:

- Use less chemically active antiscuff additives (for example, borate)
- Remove abrasives from the lubricant by using fine filtration or frequent oil changes

Scuffing is defined as localized damage caused by solid-phase welding between sliding surfaces. It is accompanied by the transfer of metal from one surface to another due to welding and tearing. It may occur in any sliding and rolling contact where the oil film is not thick enough to separate the surfaces. The symptoms of scuffing are microscopically rough, matte, and torn surfaces. Surface analysis that shows transfer of metal from one surface to the other is proof of scuffing.

Scuffing can occur in gear teeth when they operate in the boundary lubrication regime. If the lubricant film is insufficient to prevent significant metal-to-metal contact, the oxide layers that normally protect the gear tooth surfaces may be broken through, and the bare metal surfaces may weld together. The sliding that occurs between gear teeth results in tearing of the welded junctions, metal transfer, and catastrophic damage.

In contrast to pitting and bending fatigue, which only occur after a period of running time, scuffing may occur immediately upon start-up. In fact, gears are most vulnerable to scuffing when they are new and their tooth surfaces have not yet been smoothed by running-in. For this reason, it is wise to run-in a new gearbox under one-half load for at least 10 h to reduce the surface roughness of the teeth before applying full load. The gear teeth can be coated with iron-manganese phosphate or plated with copper or silver to protect them from scuffing during the critical running-in period.

The basic mechanism of scuffing is not clearly understood, but by general agreement it is believed to be caused by intense frictional heating generated by the combination of high sliding velocity and intense surface pressure. Blok's (Ref 15) critical temperature theory is believed to be the best criterion for predicting scuffing. It states that scuffing will occur in gear teeth that are sliding under boundary-lubricated conditions when the maximum contact temperature of the gear teeth reaches a critical magnitude. For mineral oils without antiscuff/EP additives, each combination of oil and rubbing materials has a critical scuffing temperature that is constant, regardless of the operating conditions (Ref 16). The critical scuffing temperatures are not constant for synthetic lubricants and lubricants with antiscuff additives; they must be determined from tests that closely simulate the operating conditions of the gears.

Today, most antiscuff additives are sulfur-phosphorus compounds, which form boundary-lubricating films by chemically reacting with the metal surfaces of the gear teeth at local points of high temperature. Antiscuff films help prevent scuffing by forming solid films on the gear tooth surfaces and inhibiting true metal-to-metal contact. The films of iron sulfide and iron phosphate have high melting points, allowing them to remain as solids on the gear tooth surfaces even at high contact temperatures. The rate of reaction of the antiscuff additives is greatest where the gear tooth contact temperatures are highest. Because of the rubbing action of the gear teeth, the surface films are repeatedly scraped off and reformed. In effect, scuffing is prevented by substituting mild corrosion in its place. Occasionally, antiscuff additives (for example, sulfur) are too chemically active, causing polishing wear and necessitating a change to less aggressive additives. Lubricants with antiscuff additives of potassium borate do not cause polishing wear because they deposit glasslike boundary films without reacting with the metal.

For mineral oils without antiscuff additives, the critical scuffing temperature increases with increasing viscosity and ranges from 150 to 300 °C (300 to 570 °F). The increased scuffing resistance of high-viscosity lubricants is believed to be due to differences in chemical composition rather than increases in viscosity. However, a viscosity increase also helps to reduce the risk of scuffing by increasing the lubricant film thickness and reducing the contact temperature generated by metal-to-metal contact.

Scuffing is controlled by the total contact temperature, T_c, which consists of the sum of the gear bulk temperature, T_b, and the flash temperature, T_f:

$$T_c = T_b + T_f \qquad \textbf{(Eq 1)}$$

The bulk temperature is the equilibrium temperature of the surface of the gear teeth before they enter the meshing zone. The flash temperature is the local and instantaneous temperature rise that occurs on the gear teeth due to the frictional heating as they pass through the meshing zone.

Anything that reduces either the bulk temperature or the flash temperature will reduce the total contact temperature and lessen the risk of scuffing. Higher viscosity lubricants or smoother tooth surfaces help by increasing the specific film thickness, which in turn reduces the frictional heat and, therefore, the flash temperature. Also, the lubricant performs the important function of removing heat from the gear teeth. The lubricant must be supplied to the gear teeth in such a way that it removes heat rapidly and maintains a low bulk temperature. A heat exchanger can be used with a circulating-oil system to cool the lubricant before it is sprayed at the gears.

The gear designer can maximize scuffing resistance by optimizing the gear geometry so that the gear teeth are as small as possible, consistent with bending strength requirements, to reduce the temperature rise caused by sliding. Figure 1 shows that the rolling velocity of the pinion, V_{r1}, and the rolling velocity of the gear, V_{r2}, linearly increase from zero at the interference points to a maximum at each end of the path of contact. The sliding velocity is represented by the distance between the V_{r1} and V_{r2} lines. The amount of sliding is proportional to the distance from the pitch point, *P*, and is zero when the gear teeth contact at the pitch point, and largest at the ends of the path. Addendum modification can be used to balance and minimize the temperature rise that occurs in the addendum and dedendum of the gear teeth. The temperature rise may also be reduced by modifying the tooth profiles with slight tip and/or root relief to ease the load at the start and end of the engagement path where the sliding velocities are the greatest. Also, the gear teeth must be accurate and held rigidly in good alignment to minimize tooth loading and, therefore, the temperature rise.

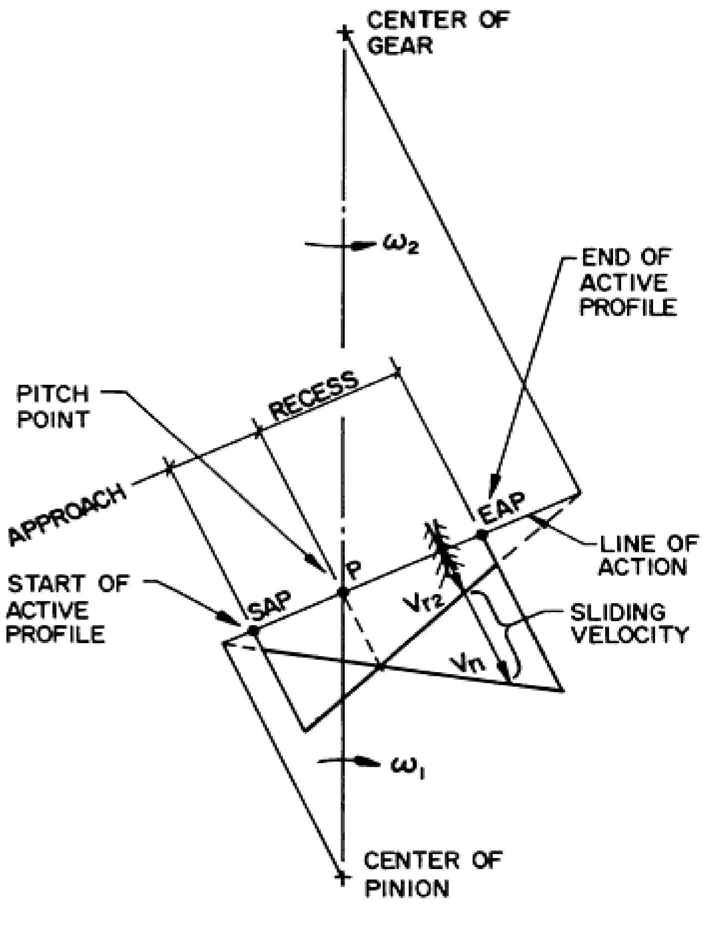

Fig. 1 Graphical representation of rolling velocities of pinion (V_{r1}) and gear (V_{r2}) in relation to sliding velocity

Gear materials should be chosen with their scuffing resistance in mind. Nitrided steels, such as Nitralloy 135M, are generally found to have the highest resistance to scuffing, whereas stainless steels are liable to scuff even under near-zero loads. The thin oxide layer on stainless steel is hard and brittle and breaks up easily under sliding loads, exposing the bare metal and thus promoting scuffing. Like stainless steel, anodized aluminum has a low scuffing resistance. Hardness does not seem to be a reliable indication of scuffing resistance.

In summary, the following guidelines should be observed to prevent scuffing in gearsets:

- Use smooth tooth surfaces produced by careful grinding or honing
- Protect the gear teeth during the critical running-in period by coating them with iron-manganese phosphate or plating them with copper or silver. Run-in new gearsets by operating the first 10 h at one-half load
- Use high-viscosity lubricants with antiscuff additives, such as sulfur, phosphorus, or borate
- Cool the gear teeth by supplying an adequate amount of cool lubricant. For circulating-oil systems, use a heat exchanger to cool the lubricant
- Optimize the gear tooth geometry by using small teeth, addendum modification, and profile modification
- Use accurate gear teeth, rigid gear mountings, and good helix alignment
- Use nitrided steels for maximum scuffing resistance. Do not use stainless steel or aluminum for gears if there is a risk of scuffing

Elastohydrodynamic Lubrication

Gear teeth are subjected to enormous contact pressures on the order of the ultimate tensile strength of hardened steel, yet they are quite successfully lubricated with oil films that are <1 μm (<40 μin.) thick. This is possible because lubricants have a fortuitous property that causes their viscosity to increase dramatically with increased pressure. Figure 2 depicts the region of contact between mating gear teeth. It shows the shape of the elastically deformed teeth and the pressure distribution developed within the contact zone. The molecular adsorption of the lubricant onto the gear tooth surfaces causes it to be dragged into the inlet region of the contact, where its pressure is increased due to the convergence of the tooth surfaces. The viscosity increase of the lubricant caused by the increasing pressure helps to entrain the lubricant into the contact zone. Once it is within the high-pressure Hertzian region of the contact, the lubricant cannot escape because its viscosity has increased to the extent where the lubricant is virtually a rigid solid.

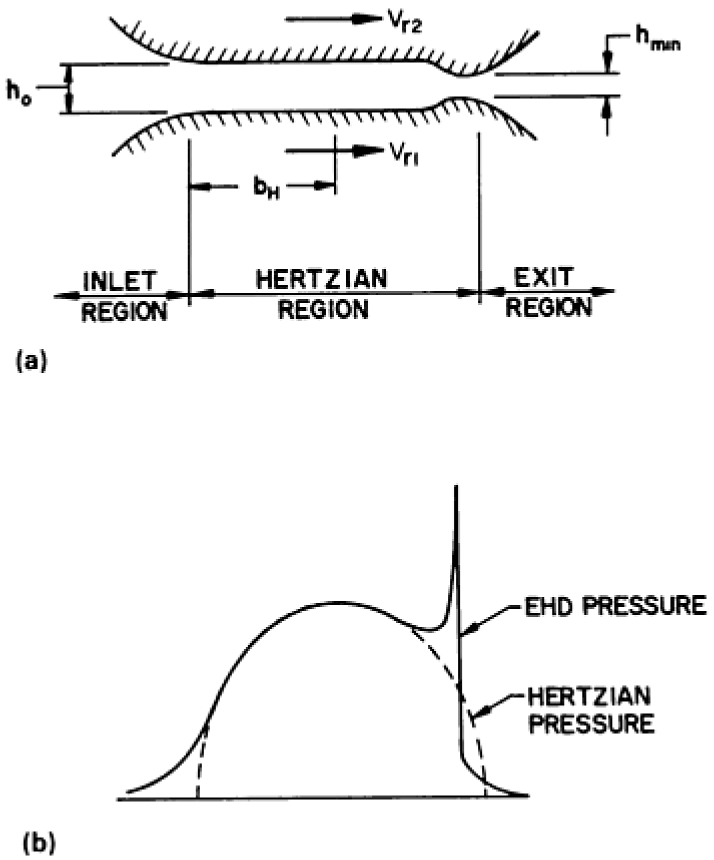

Fig. 2 Regions of elastohydrodynamic contact between the mating gear teeth of a gearset. (a) Schematic showing three distinct regions on pinion and gear tooth surfaces and key parameters determining oil film lubrication. (b) Plot of pressure distribution within contact zone. b_H, semiwidth of Hertzian contact band; h_0, central film thickness; h_{min}, minimum film thickness

The following equation, from Dowson and Higginson (Ref 17) gives the minimum film thickness that occurs near the exit of the contact. The minimum film thickness, h_{min}, is obtained from:

$$h_{min} = \frac{1.63\alpha^{0.54}\,(\mu_0 V_e)^{0.7}\,\rho_n^{0.43}}{(X_\Gamma w_{Nr})^{0.13}\,E_r^{0.03}} \qquad \textbf{(Eq 2)}$$

where α is the pressure-viscosity coefficient (in.^{2}/lbf), μ_0 is the absolute viscosity (reyns, or lbf · s/in.^{2}), and V_e is the entraining velocity, in which:

$$V_e = V_{r1} + V_{r2} \qquad \textbf{(Eq 3)}$$

where V_{r1} and V_{r2} are the rolling velocities of pinion and gear, respectively, given by:

$$V_{r1} = \omega_1\,\rho_2 \qquad \textbf{(Eq 4a)}$$

$$V_{r2} = \omega_1\,\rho_2 \qquad \textbf{(Eq 4b)}$$

in which ω_1 and ω_2 are the angular velocities of pinion and gear, respectively, and ρ_1 and ρ_2 are the transverse radii of curvature of the pinion and gear, respectively.

The normal relative radius of curvature, ρ_n, is given by:

$$\rho_n = \frac{\rho_1 \rho_2}{(\rho_2 \pm \rho_1)\cos \psi_b} \qquad \textbf{(Eq 5)}$$

where ψ_b is the base helix angle, $X\Gamma$ is the load-sharing factor, and ω_{Nr} is the normal unit load given by:

$$w_{Nr} = \frac{W_{Nr}}{L_{min}} \qquad \textbf{(Eq 6)}$$

in which W_{Nr} is the normal operating load and L_{min} is the minimum contact length.

E_r is the reduced modulus of elasticity, given by:

$$E_r = 2\left(\frac{1-\nu_1^2}{E_1} + \frac{1-\nu_2^2}{E_2}\right)^{-1} \qquad \textbf{(Eq 7)}$$

where v_1 is the Poisson's ratio of pinion, v_2 is the Poisson's ratio of gear, E_1 is the modulus of elasticity of pinion, and E_2 is the modulus of elasticity of gear.

Figure 3 gives average values of absolute viscosity, μ_0, versus bulk temperature for typical mineral gear lubricants with a viscosity index of 95.

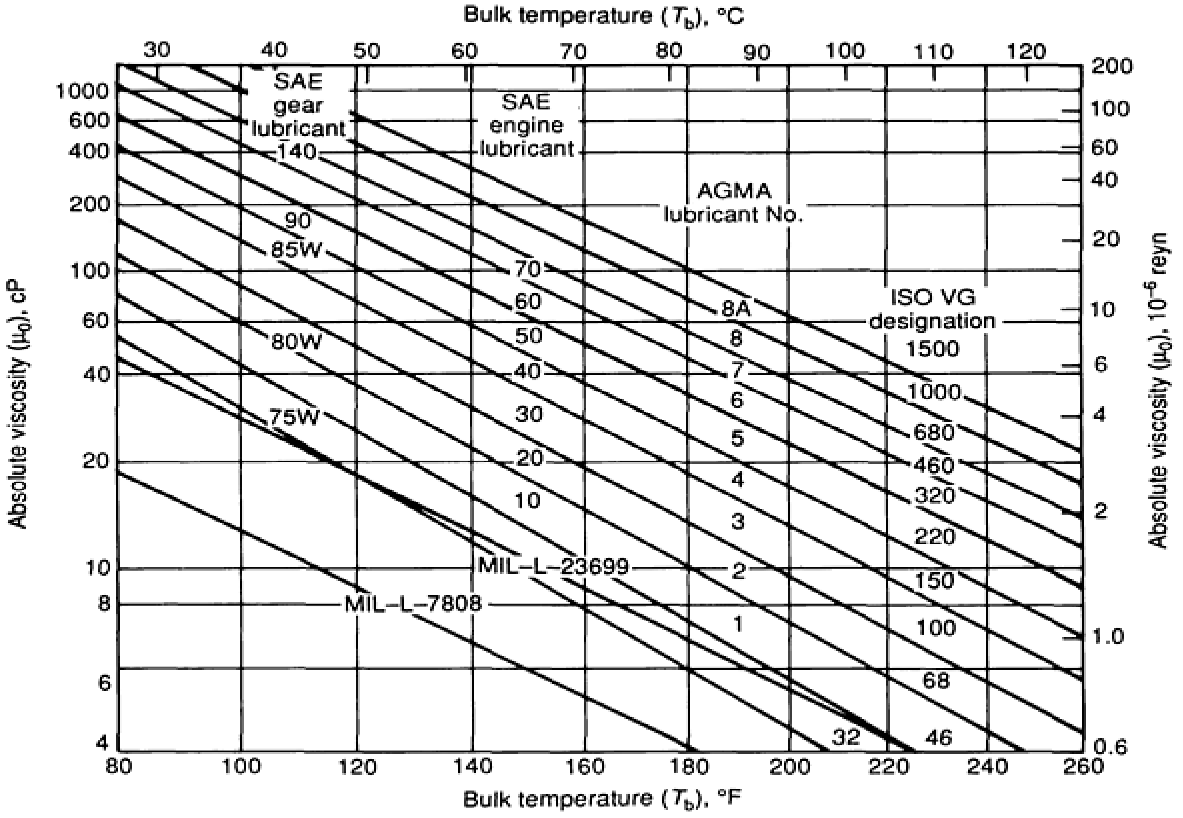

Fig. 3 Plot of absolute viscosity versus bulk temperature for selected mineral oil gear lubricants having a viscosity index of 95

The pressure-viscosity coefficient, α, ranges from 0.5×10^{-4} to 2×10^{-4} in.^{2}/lbf for typical gear lubricants. Data for pressure-viscosity coefficients versus bulk temperature for typical gear lubricants are given in Fig. 4.

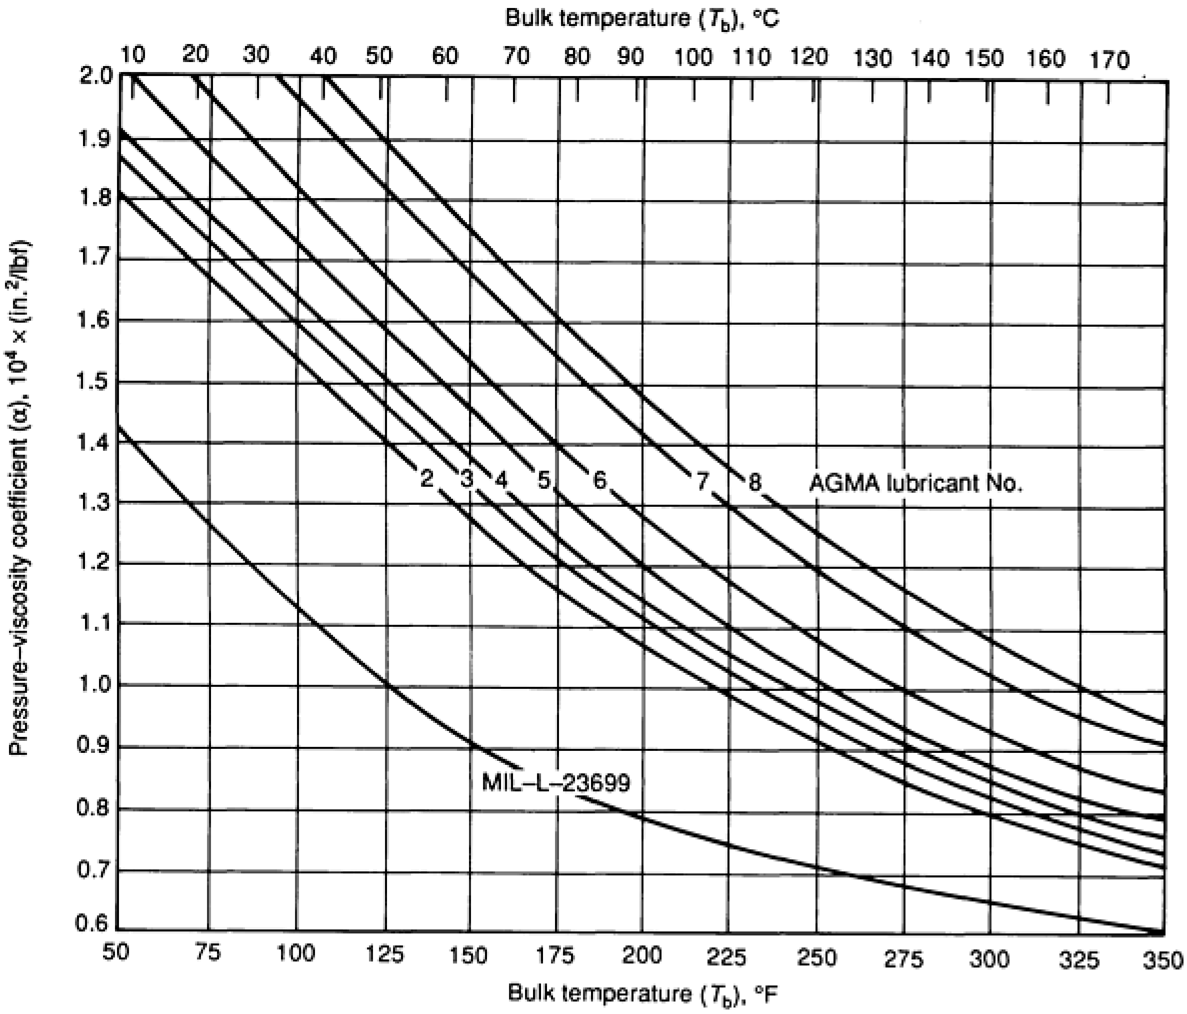

Fig. 4 Plot of pressure-viscosity coefficient versus bulk temperature for selected mineral oil gear lubricants

The specific film thickness, λ, is given by:

$$\lambda = \frac{h_{min}}{\sigma} \quad \textbf{(Eq 8)}$$

where h_{min} is the minimum film thickness and σ is the composite surface roughness given by:

$$\sigma = (\sigma_1^2 + \sigma_2^2)^{1/2} \quad \textbf{(Eq 9)}$$

in which σ_1 is the root-mean-square (rms) surface roughness of the pinion and σ_2 is the rms surface roughness of the gear.

Load-Sharing Factor. The load-sharing factor, $X\Gamma$, accounts for load sharing between succeeding pairs of teeth as affected by profile modification (tip and root relief) and whether the pinion or gear is the driver. Figure 5 gives plots of the load-sharing factors for unmodified and modified tooth profiles.

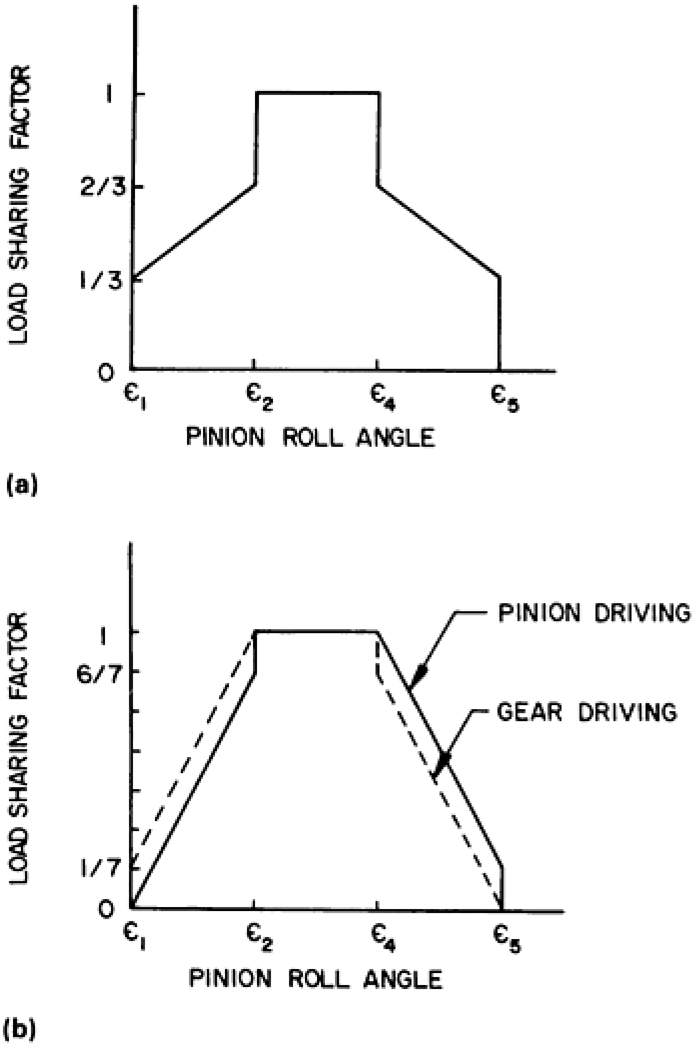

Fig. 5 Plot of load-sharing factor ($X\Gamma$) versus pinion roll angle. (a) Unmodified tooth profiles. (b) Modified tooth profiles.

As shown by the exponents in Eq 2, the film thickness is essentially determined by the entraining velocity, lubricant viscosity, and pressure-viscosity coefficient; the elastic properties of the gear teeth and the load have relatively small influences. In effect, the relatively high stiffness of the oil film makes it insensitive to load, and an increase in load simply increases the elastic deformation of the tooth surfaces and widens the contact area, rather than decreasing the film thickness.

Blok's contact temperature theory (Ref 15) states that scuffing will occur in gear teeth which are sliding under boundary-lubricated conditions when the maximum contact temperature of the gear teeth reaches a critical magnitude. The contact temperature is the sum of two components: the bulk temperature and the flash temperature, as described in Eq 1.

Blok's flash temperature equation as formulated in AGMA 2001-B88, Appendix A (Ref 18) for spur and helical gears is:

$$T_f = \frac{0.8\mu_m X_\Gamma w_{Nr} \left| (V_{r1})^{0.5} - (V_{r2})^{0.5} \right|}{B_M (b_H)^{0.5}} \quad \text{(Eq 10)}$$

where μ_m is the mean coefficient of friction, B_M is the thermal contact coefficient, and b_H is the semiwidth of the Hertzian contact band.

Mean Coefficient of Friction. The following equation gives a typical value of $0.06 < \mu_m < 0.18$ for the mean coefficient of friction for gears operating in the partial EHD regime ($\lambda < 1$). It may give values too low for boundary-lubricated gears, where μ_m may be greater than 0.2, or too high for gears in the full-film regime ($\lambda > 2$), where μ_m may be less than 0.01:

$$\mu_m = 0.06\left(\frac{50}{50 - S}\right) \quad \text{(Eq 11a)}$$

where:

$$\left(\frac{50}{50 - S}\right) \leq 3.0 \quad \text{(Eq 11b)}$$

in which S is the average rms surface roughness given by:

$$S = \frac{\sigma_1 + \sigma_2}{2} \quad \text{(Eq 12)}$$

Thermal Contact Coefficient. The thermal contact coefficient, B_M, is given by:

$$B_M = (\lambda_M \rho_M c_M)^{0.5} \quad \text{(Eq 13)}$$

where λ_M is the heat conductivity, ρ_M is the density, and c_M is the specific heat per unit mass. For typical gear steels, B_M is ~43 lbf/(in. · $s^{0.5}$ · °F).

Semiwidth of the Hertzian Contact Band. The semiwidth of the Hertzian contact band, b_H, is defined as:

$$b_H = \left(\frac{8X_\Gamma w_{Nr} \rho_n}{\pi E_r}\right)^{0.5} \quad \text{(Eq 14)}$$

Bulk Temperature. The gear bulk temperature, T_b, is the equilibrium bulk temperature of the gear teeth before they enter the meshing zone. In some cases, the bulk temperature may be significantly higher than the temperature of the oil supplied to the gear mesh. In a test with ultrahigh-speed gears (Ref 19), the pinion bulk temperature was 135 °C (275 °F), which is 95 °C (171 °F) hotter than the oil inlet temperature. For turbine gears at lower speeds, the bulk temperature rise of the gear teeth over the inlet oil temperature may range from 11 °C (20 °F) at 3700 m/min (1.2×10^4 ft/min) pitch line velocity to 22 °C (40 °F) at 4900 m/min (1.6×10^4 ft/min). At similar speeds, the bulk temperature rise of aircraft gears with less oil flow may range from 22 to 33 °C (40 to 60 °F).

Scuffing Temperature. The scuffing temperature, T_s, is the contact temperature at which scuffing is likely to occur with the chosen combination of lubricant and gear materials.

For mineral oils without antiscuff additives or for mineral oils with low concentrations of antiscuff additives, the scuffing temperature is independent of the operating conditions for a fairly wide range. For these oils, the scuffing temperature may be correlated with the composition of the oil. The viscosity grade is a convenient index of the composition and, thus, of the scuffing temperature.

For nonantiscuff mineral oils, the mean scuffing temperature (50% chance of scuffing) in °F is given by:

$$T_s = 146 + 59 \ln v_{40} \qquad \textbf{(Eq 15)}$$

where v_{40} is the kinematic viscosity at 40 °C (105 °F) in centistokes.

For mineral oils with low concentrations of antiscuff additives, the mean scuffing temperature in °F is given by:

$$T_s = 245 + 59 \ln v_{40} \qquad \textbf{(Eq 16)}$$

The scuffing temperature determined from Forschungsstelle für Zahnräder und Getriebebau (FZG, or Technical Institute for the Study of Gears and Drive Mechanisms) test gears for mineral oils without antiscuff additives or with low concentrations of antiscuff additives may be extended to different gear steels, heat treatments, or surface treatments by introducing an empirical welding factor:

$$T_s = T_{b_{test}} + X_w T_{f_{test}} \qquad \textbf{(Eq 17)}$$

where X_w is the welding factor (see Table 2), $T_{b_{test}}$ is the bulk temperature of the test gears, and $T_{f_{test}}$ is the maximum flash temperature of the test gears.

Table 2 Welding factor for selected gears steels

Material	Welding factor, X_w
Through-hardened steel	1.00
Phosphated steel	1.25
Copper-plated steel	1.50
Nitrided steel	1.50
Carburized steel	
Content of austenite < average	1.15
Content of austenite = average	1.00
Content of austenite > average	0.85
Stainless steel	0.45

Scuffing temperatures for synthetic lubricants typically used with carburized gears in the aerospace industry are shown in Table 3.

Table 3 Mean scuffing temperature for synthetic lubricants typically used for operating carburized gears in aerospace applications

Lubricant	Mean scuffing temperature, T_s	
	°C	**°F**
MIL-L-6081 (grade 1005)	129	264
MIL-L-7808	205	400
MIL-L-23699	220	425
DERD2487	225	440
DERD2497	240	465
DOD-L-85734	260	500
Mobil SHC624	280	540
Dexron II	290	550

Source: Ref 20

For mineral oils with high concentrations of antiscuff additives (for example, hypoid gear oils), research is still needed to determinewhether the scuffing temperature is dependent on the materials and operating conditions. Special attention has to be paid to the correlation between test conditions and actual or design conditions.

Lubricant Selection

The choice of lubricant depends on the type of gearing and enclosure, operating speed and load, ambient temperature, and method of lubricant application. Most gears are lubricated with one of the following types:

- Oil
- Grease
- Adhesive open-gear lubricant
- Solid lubricant

The optimum lubricant for any application is the product that is the least expensive, considering both initial cost and maintenance costs, and meets the requirements.

Oil is the most widely used lubricant because it is readily distributed to gears and bearings and has both good lubricating and cooling properties. In addition, contamination may be readily removed by filtering periodically or draining and replacing the oil. However, it requires an oil-tight enclosure provided with adequate shaft seals.

Synthetic lubricants are used for applications (for example, aircraft gas turbines) where the oil must operate over a wide temperature range and have good oxidation stability at high temperature. Ester and hydrocarbon synthetic lubricants have high viscosity indices, giving them good fluidity or low viscosities at very low temperatures and acceptable viscosities at high temperatures. The volatility of esters is lower than that of mineral oils of the same viscosity, thus reducing oil loss at high temperature. Despite their long service life, the extra cost of synthetic lubricants generally cannot be justified for oil-bath systems unless there are extreme temperatures involved, because the oil must be changed frequently to remove contamination.

Grease is suitable only for low-speed, low-load applications because it does not circulate well, and it is a relatively poor coolant. Grease-lubricated gears are generally boundary lubricated because the grease is either pushed aside or thrown from the gear teeth. Contamination from wear particles or other debris is usually trapped in the grease and requires costly maintenance to eliminate. Grease is often used to avoid leakage from enclosures that are not oil tight. However, if all the factors are considered, it is usually found that an oil lubricant is more economical and reliable than a grease lubricant for gear lubrication.

Open-gear lubricants are viscous adhesive semifluids used on large low-speed open gears, such as those used in iron ore and cement mills, antenna drives, bridge drives, cranes, and so on. Gears in these applications run slowly, and they are therefore boundary lubricated. The lubricant must bond strongly to resist being thrown off the gear teeth. However, the squeezing and sliding action of gear teeth tends to push the lubricant into the roots of the gear teeth where it is relatively ineffective. These lubricants are applied by hand brushing or by automatic systems that deliver an intermittent spray. Some open-gear lubricants are thinned with a quick-evaporating solvent/diluent to make them easier to apply. Open-gear lubricants share the disadvantages of grease lubrication, and they are especially costly (in addition to being messy) to maintain. For these reasons, the trend is away from open gears and toward the use of enclosed oil-lubricated gearboxes whenever possible.

Solid lubricants, usually in the form of bonded dry films, are used when the following conditions are encountered:

- The temperature is too high or too low for an oil or grease
- Leakage cannot be tolerated
- The gears must operate in a vacuum

These lubricants are usually molybdenum disulfide (MoS_2) or graphite in a inorganic binder, which is applied to the gear teeth and cured to form a dry film coating. Polytetrafluoroethylene (PTFE) and tungsten disulfide (WS_2) coatings are also

used. Solid lubricants are expensive to apply and have limited wear lives. However, in many applications, such as spacecraft, they are the only alternative and can provide excellent service.

Oil Lubricant Applications

Of the above-mentioned lubricants, only oil will be discussed in greater detail in this article. Oil should be used as the lubricant unless the operating conditions preclude its use. Generally, the simplest and least expensive lubrication system for gears is a totally enclosed oil bath of mineral oil.

Spur, Helical, and Bevel Gears. The lubrication requirements of spur, helical, straight-bevel, and spiral-bevel gears are essentially the same. For this class of gears, the magnitudes of the loads and sliding speeds are similar, and requirements for viscosity and antiscuff properties are virtually identical. Many industrial spur and helical gear units are lubricated with rust and oxidation inhibited (R & O) mineral oils. The low-viscosity R & O oils, commonly called turbine oils, are used in many high-speed gear units where the gear tooth loads are relatively low. Mineral oils without antiscuff additives are suitable for high-speed lightly loaded gears where the high entraining velocity of the gear teeth develops thick EHD oil films. In these cases, the most important property of the lubricant is viscosity. Antiscuff/EP additives are unnecessary because the gear teeth are separated, eliminating metal-to-metal contact and the scuffing mode of failure. Slower speed gears, especially carburized gears tend to be more heavily loaded. These gears generally require higher viscosity lubricants with antiscuff additives.

Hypoid gears, such as those used for automotive axles, are especially prone to scuffing because they are heavily loaded and have high sliding velocities. For these reasons, hypoid gear oils have the higher concentrations of antiscuff additives.

For critical applications, the contact temperature should be calculated with Blok's equation (see Eq 1) (Ref 15) and compared to the scuffing temperature of the lubricant. This quantitative method is effective for selecting a lubricant with adequate scuffing resistance.

Worm gears have high sliding velocity, which generates significant frictional losses. Fortunately, their tooth loads are relatively light, and they are successfully lubricated with mineral oils that are compounded with lubricity additives. These oils contain 3 to 10% fatty oil or low-acid tallow. The polar molecules of the additive form surface films by physical adsorption or by reaction with the surface oxide to form a metallic soap that acts as a low shear strength film, improving the "lubricity," or friction-reducing property.

Selection of Gear Lubricant Viscosity

The recommendations of AGMA 250.04 (Ref 21) should be followed when selecting lubricants for enclosed gear drives that operate at pitch line velocities $\leq$1500 m/min ($\leq$5000 ft/min). AGMA 421.06 (Ref 22) should be consulted for high-speed drives (>1500 m/min, or 5000 ft/min).

As discussed earlier in the section "Gear Tooth Failure Modes" in this article, viscosity is one of the most important lubricant properties, and the higher the viscosity, the greater the protection against the various gear tooth failures. However, the viscosity must be limited to avoid excessive heat generation and power loss from churning and shearing of the lubricant by high-speed gears or bearings. The operating temperature of the gear drive determines the operating viscosity of the lubricant. If the lubricant is too viscous, excessive heat is generated. The heat raises the lubricant temperature and reduces its viscosity, reaching a point of diminishing returns where increasing the starting viscosity of the lubricant leads to a higher operating temperature and a higher oxidation rate, without a significant gain in operating viscosity.

Gear drives operating in cold climates must have a lubricant that circulates freely and does not cause high starting torques. A candidate gear lubricant should have a pour point at least 5 °C (9 °F) lower than the expected minimum ambient start-up temperature. Typical pour points for mineral gear oils are -7 °C (20 °F), whereas synthetic gear lubricants have significantly lower pour points of about -40 °C (-40 °F). Pour point depressants are used to tailor pour points of mineral lubricants for automotive hypoid gears to be as low as -40 °C (-40 °F).

The pitch line speed of the gears is a good index of the required viscosity. An empirical equation for determining required viscosity is:

$$\nu_{40} = \frac{7000}{(V)^{0.5}} \quad \textbf{(Eq 18)}$$

where ν_{40} is the lubricant kinematic viscosity at 40 °C (105 °F) (in cSt) and V is the operating pitch line velocity (in ft/min) given by:

$$V = 0.262\, d \cdot n \quad \textbf{(Eq 19)}$$

where d is the operating pitch diameter of pinion (in inches) and n is the pinion speed (rev/min).

Caution must be used when using AGMA recommendations for viscosity. The author knows of an application where two gear drives were considered to be high speed. The pinion speed was 3625 rev/min, qualifying the gear units as high-speed gear drives per AGMA 421.06. The gear drives were supplied with oil having the recommended viscosity (per AGMA 421.06) of ISO 68. However, because the pinion was relatively small, its pitch line velocity was only 1000 m/min (3000 ft/min). This qualifies the gear drives as slow speed per AGMA 250.04, which recommends a viscosity of ISO 150. Both gear drives failed within weeks of start-up because of pitting fatigue. The empirical equation (Eq 18) for this application gives:

$$\nu_{40} = \frac{7000}{(3000)^{0.5}} = 128 \text{ cSt} \quad \textbf{(Eq 20)}$$

This indicates that the viscosity per AGMA 421.06 (68 cSt, or 6.8×10^{-5} m^2/s) is much too low, and the viscosity per AGMA 250.04 (150 cSt, or 1.5×10^{-4} m^2/s) is appropriate. Hence, definitions of high-speed versus slow-speed gear drives must be carefully considered, and pitch line velocity is generally a better index than shaft speed. The gear drives were rebuilt with new gearsets and the ISO VG 68 oil was replaced with ISO VG 150. The gear drives now operate without overheating, and the pitting has been eliminated.

For critical applications, the specific film thickness, λ, should be calculated with Dowson and Higginson's equation (see Eq 8) (Ref 16). The specific film thickness is a useful measure of the lubrication regime. It can be used with Fig. 6 as an approximate guide to the probability of wear-related surface distress. Figure 6 is based on the data of Wellauer and Holloway (Ref 23), which were obtained from several hundred laboratory tests and field applications of gear drives.

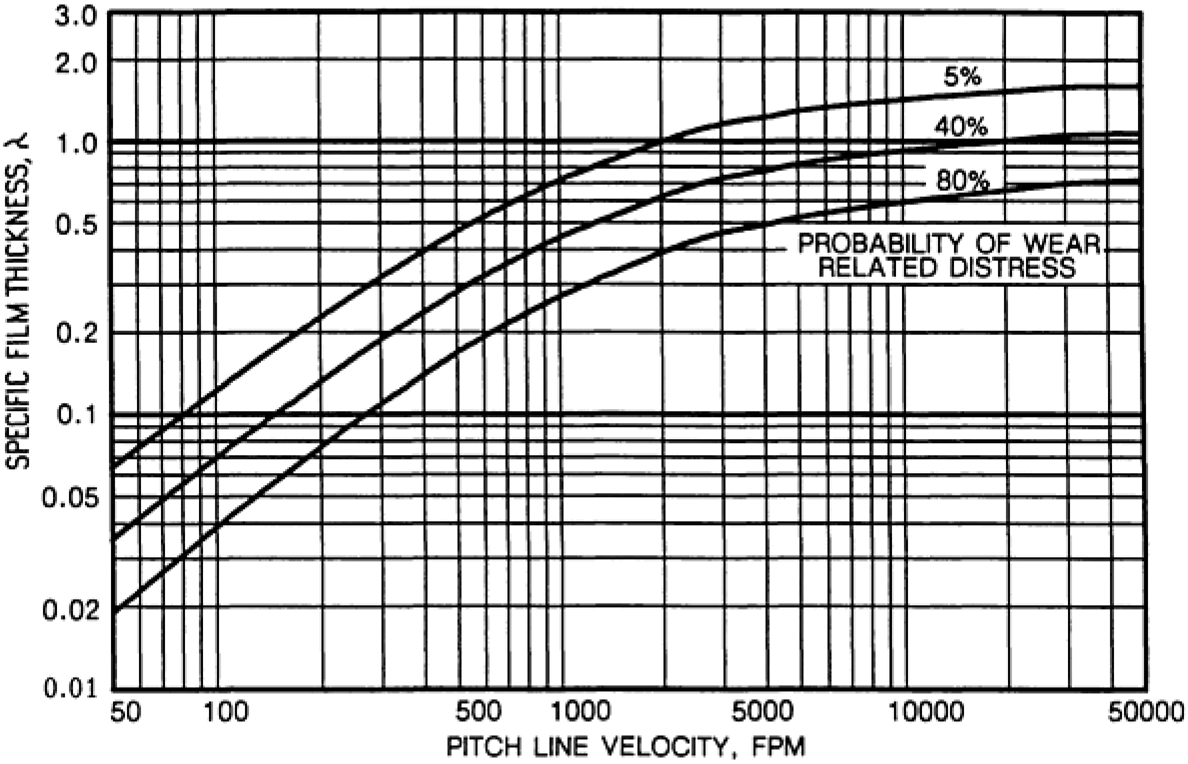

Fig. 6 Probability of wear distress as a function of specific film thickness and pitch line velocity (in ft/min). Source: Ref 18

Application of Gear Lubricants

The method of applying the lubricant to the gear teeth depends primarily on the pitch line velocity.

Splash lubrication systems are the simplest, but they are limited to a pitch line velocity of ~1000 m/min (~3000 ft/min). The gears should dip into the oil bath for about twice the tooth depth to provide adequate splash for pinions and bearings and to reduce losses due to churning. The gear housing should have troughs to capture the oil flowing down the housing walls, channeling it to the bearings.

The range of splash lubrication can be extended to ~1500 m/min (~5000 ft/min) by using baffles and oil pans to reduce churning. However, at velocities >1000 m/min (>3000 ft/min), providing auxiliary cooling with fans and improving heat transfer by adding fins to the housing are usually necessary.

Pressure-Fed Systems. Above 1500 m/min (5000 ft/min), most gears are lubricated by a pressure-fed system. For gearboxes with anti-friction bearings, spraying the oil at the gear mesh only and relying on splash to lubricate the bearings is permissible up to a maximum pitch line velocity of 2100 m/min (7000 ft/min). Above this speed and for gear drives with journal bearings, both the gears and bearings should be pressure-fed.

The oil jets should be placed on the incoming side of the gear mesh for pitch line velocities ≤2600 m/min (≤8000 ft/min). Above 2600 m/min (8000 ft/min), more oil is needed for cooling than for lubricating, and the oil flow removes heat best by being directed at the outgoing side of the gear mesh where the oil jets can strike the hot drive-side of the gear teeth.

For very high-speed gears (Ref 19) (>5300 m/min, or 16,000 ft/min), there is a danger that the amount of oil carried to the incoming side of the gear mesh may be inadequate, and it is prudent to add a supplementary flow at the incoming side of the gear mesh. Generally, about two-thirds of the oil flow should be supplied to the outgoing side of the mesh for cooling,

and one-third of the flow directed at the incoming side for lubrication. The placement of the oil jets is a crucial factor when pitch line velocities are >6100 m/min (>20,000 ft/min). At speeds this high, experiments are required to find the optimum number and location for the oil jets.

In pressure-fed systems, the following parameters must be considered to ensure adequate lubrication and cooling of the gear mesh:

- Quantity of flow
- Jet size
- Feed pressure
- Number of jets

There are general guidelines, based on experience and experimentation, for specifying these parameters, but each application must be evaluated independently based on its particular operating conditions and requirements.

An empirical equation used to calculate the quantity of oil flow, *q,* is:

$$q = P/c \qquad \textbf{(Eq 21)}$$

where q is the oil flow rate (in gal/min), P is the transmitted power (in hp), and c is taken from Table 4.

Table 4 Recommended values of constant *c* based on oil flow and gear mesh specifications

c hp/(gal/min)	Flow conditions	Applications
200	Copious	General industrial
400	Adequate	Typical aviation
800	Lean	Lightweight, high-efficiency aviation
1000	Starved	Only for unusual conditions

For a typical industrial application transmitting 150 kW (200 hp), where weight is not critical, the designer might choose a value of c = 200 hp/(gal/min), resulting in a copious flow of 4 L/min (1 gal/min). On the other hand, for a high-efficiency aviation application transmitting 150 kW (200 hp), where weight is critical, a value of c = 800 hp/(gal/min) might be chosen, resulting in a lean flow of 1 L/min (0.25 gal/min). Some applications may require different flow rates than those given by Table 4. For instance, wide-face, high-speed gearing may require a higher flow rate to ensure uniform cooling and full-face coverage.

The proper jet size, feed pressure, and number of jets must be determined to maintain the proper flow rate, jet velocity, and full-face coverage.

Jet Size. The diameter of a jet can be calculated for a given flow rate and pressure based on the viscosity of the oil at the operating temperature (Ref 24). There are practical limitations on jet size, and the minimum recommended size is 0.8 mm (0.03 in.). If a jet smaller than this is used, contaminants in the oil may clog it. Typical jet diameters range from 0.8 to 3.0 mm (0.03 to 0.12 in.).

Feed Pressure. The feed pressure determines the jet velocity, which in turn determines the amount of oil that penetrates the gear mesh. Typical feed pressures range from 20 to 100 psig. Industrial application feed pressures are typically 30 psig, and high-speed aerospace applications are typically 100 psig. In general, the higher the pressure, the greater the cooling (Ref 25), but the higher the pressure, the smaller the jet diameter. Therefore, pressure is limited by the minimum recommended jet diameter of 0.8 mm (0.03 in.).

Jet Quantity. The number of jets should be sufficient to provide complete lubrication coverage of the face width. More than one jet for each gear mesh is advisable because of the possibility of clogging. The upper limit on the number of jets

is determined by the flow rate and jet diameter; too many jets for a given flow rate will result in a jet diameter less than the minimum recommended.

Example: Friction and Wear in a 24-Unit Speed-Increaser Gearbox.

In an industrial application, 24 speed-increaser gearboxes were used to transmit 258 kW (346 hp) and increase speed from 55 to 375 rev/min. The gears were parallel shaft, single helical, carburized, and ground. The splash lubrication system used a mineral oil without antiscuff additives with ISO 100 viscosity. After about 250 h of operation, two gearboxes failed by bending fatigue. The gear tooth profiles were so badly worn that determining the primary failure mode was impossible. Three other gearboxes with less service were selected for inspection. One had logged 15 h, and the other two had operated for 65 h each. Upon disassembly, no broken teeth were found, but all three gearboxes had scuffed gear teeth. The primary failure mode was scuffing, and the earlier bending fatigue failures were caused by dynamic loads generated by the worn gear teeth. Subsequent inspection of the remaining gearboxes revealed that all had scuffing damage, which probably had occurred immediately upon start-up because the loads were not reduced during run-in.

Fortunately, a prototype gearbox had been run at one-half load for about 50 h. When these gears were inspected, no signs of distress were seen on any of the gear teeth. The tooth profiles were smooth with surface roughness. R_q, estimated to be 0.5 μm (20 μin.), and the contact pattern indicated 100% face contact. This gearbox was reassembled and run under one-half load until its oil sump temperature reached equilibrium at 95 °C (200 °F). For this application, the ambient temperature was in the range of 10 to 50 °C (50 to 125 °F). The center distance of the gears was 405 mm (16 in.) and the pitch line velocity was 120 m/min (400 ft/min). Referring to AGMA 250.04 (Ref 21), the recommended viscosity for these conditions is ISO 150 or ISO 220.

Using the empirical equation (Eq 18), we obtain

$$\nu_{40} = \frac{7000}{(400)^{0.5}} = 350 \text{ cSt} \qquad \textbf{(Eq 22)}$$

Hence, the empirical equation recommends a viscosity close to ISO 320. It is apparent that the viscosity that was originally supplied (ISO VG 100) was too low.

The EHD film thickness was calculated with a special computer program (Ref 26). The gear bulk temperature was assumed to be 110 °C (230 °F), which is 17 °C (30 °F) hotter than the measured oil sump temperature. The following data for the ISO VG 100 lubricant was obtained from Fig. 3 and 4: μ_0 = 6.6 cP = 0.96 × 10^{-6} reyns and α= 1.02 × 10^{-4} in.^{2}/lbf.

Figure 7 shows a plot of the film thickness versus position on the pinion tooth. The minimum film thickness occurs low on the pinion tooth near the lowest point of single-tooth contact (LPSTC), where h_{min} is 0.053 μm (2.1 μin.). The specific film thickness, based on R_q of 0.5 μm (20 μin.) for both profiles, is λ= 0.073. Figure 6 shows that the gears operate in the boundary lubrication regime. The program predicts that the probability of wear is >95%.

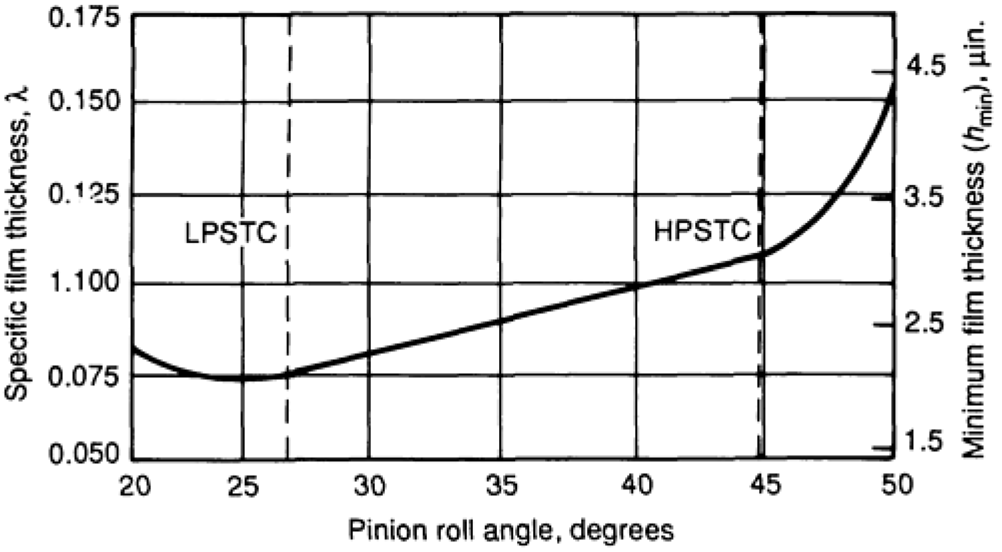

Fig. 7 Plot of film thickness versus pinion roll angle for gear tooth geometry of a scuffed gearset. Minimum specific film thickness, λ_{min}, 0.073; probability of wear, >95%

The contact temperature was also calculated with the program. The scuffing temperature for the ISO VG 100 lubricant was calculated with the equation for nonantiscuff mineral oils:

$$T_s = 146 + 59 \ln (100) = 418 \text{ °F} \quad \textbf{(Eq 23)}$$

Figure 8 shows a plot of the contact temperature versus position on the pinion tooth. The maximum contact temperature occurs high on the pinion tooth near the highest point of single-tooth contact (HPSTC), where T_c is 226 °C (439 °F). The program predicts that the probability of scuffing is 63%. This is considered to be a high risk of scuffing. The relatively high-temperature peak near the tip of the pinion tooth was caused by the geometry of the gears.

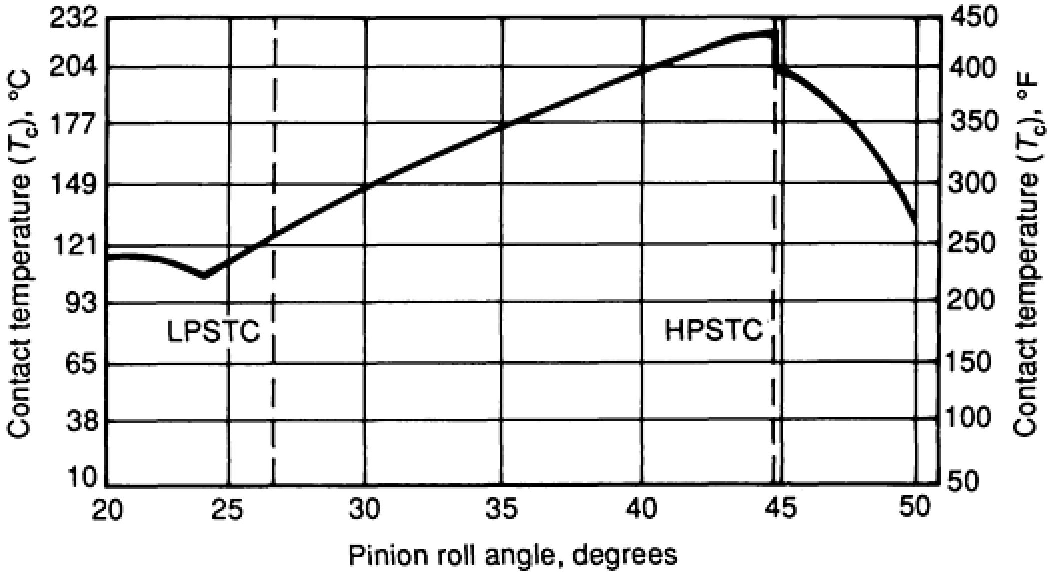

Fig. 8 Plot of contact temperature versus pinion roll angle for gear tooth geometry of scuffed gearset. Maximum T_f, 226 °C (439 °F); scuffing probability, 63%

The designer selected a long-addendum tooth for the pinion. Long-addendum pinions perform well in speed reducers, where they increase the amount of recess action and decrease the amount of approach action of the gear mesh. Because recess action is much smoother than approach action, long-addendum pinions give speed smooth meshing characteristics. When operated as a speed increaser, however, the approach and recess portions of the gear mesh reverse, making a long-addendum pinion rough running and vulnerable to scuffing.

To explore the possibilities for reducing the scuffing risk, new gear tooth geometry was proposed with the pinion and gear addenda designed to minimize the flash temperature rise. The new gearset, analyzed with the program, assumed the lubricant was a mineral oil with antiscuff additives, with a viscosity of ISO 220, and with the following properties: μ_0 = 10 cP = 1.45 × 10^{-6} reyns, α= 1.09 × 10^{-4} in.^{2}/lbf, and

$$T_s = 245 + 59 \ln (220) = 563 \text{ °F} \quad \textbf{(Eq 24)}$$

Figure 9 shows that the film thickness increases to h_{min} of 0.068 μm (2.7 μin.), and the specific film thickness increases to λ= 0.097. Figure 6 shows that the gears still operate in the boundary lubrication regime; however, the probability of wear is reduced to 94%. Figure 10 shows that the optimized gear geometry reduced the maximum contact temperature to a T_c of 150 °C (302 °F). The combination of reduced contact temperature and the increased scuffing resistance provided by the higher viscosity mineral oil with antiscuff additives reduces the scuffing probability to <5%.

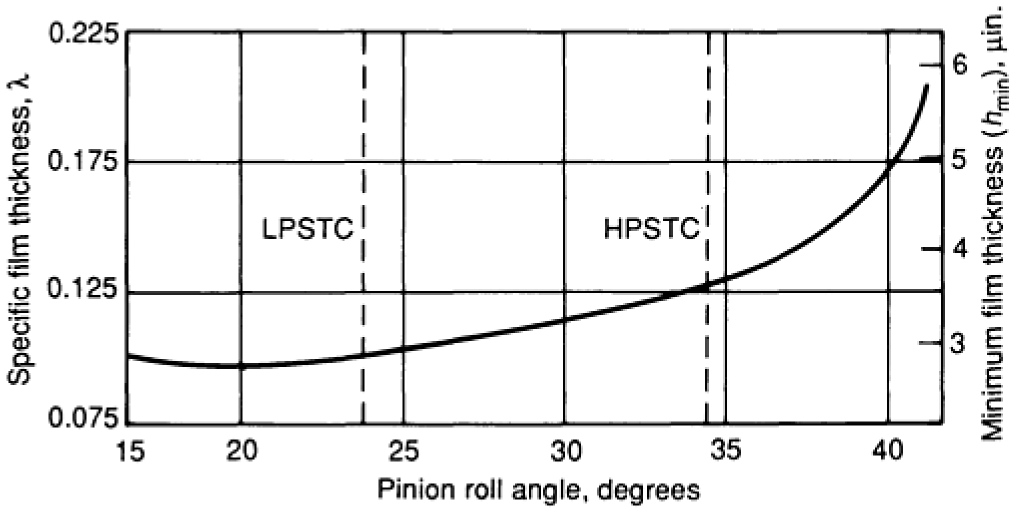

Fig. 9 Plot of film thickness versus pinion roll angle for gear tooth geometry that was optimized for maximum scuffing resistance. λ_{min}, 0.097; probability of wear, 94%

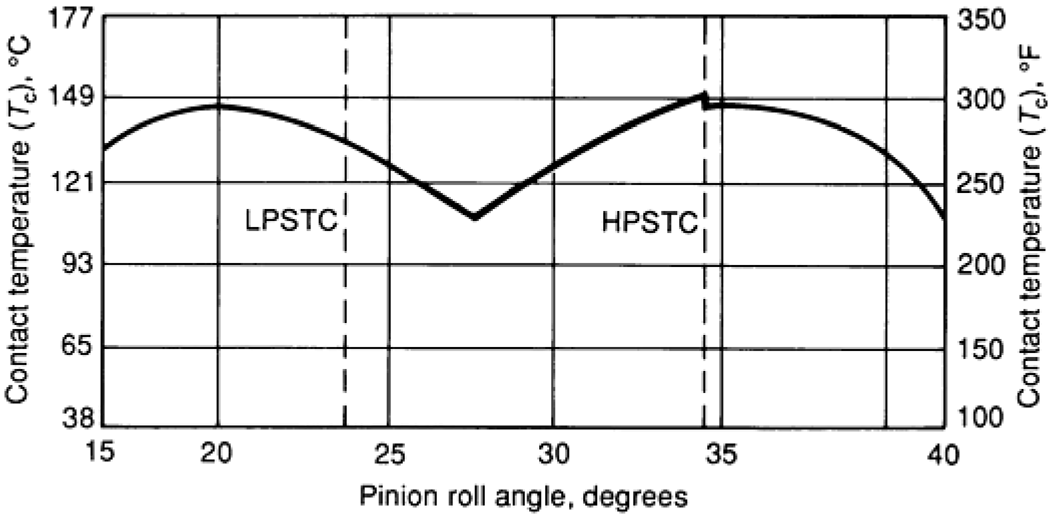

Fig. 10 Plot of contact temperature versus pinion roll angle for gear tooth geometry that was optimized for maximum scuffing resistance. Maximum T_f, 150 °C (302 °F); scuffing probability, <5%

Typical of may gear failures, this example shows that several factors contributed to the failures:

- The lubricant viscosity was too low
- No antiscuff additives were used
- A gearbox designed as a speed reducer was used as a speed increaser
- The gear teeth were not provided with a coating or plating to ease running-in
- The gears were not run-in properly under reduced loads

Gear failures, as exemplified by this case history, can be avoided if designers and operators recognize that the lubricant is an importantcomponent of a gearbox and appreciate that the tribology of gearing requires the consideration and control of many interrelated factors.

Nomenclature

Table 5 lists the parameters used in this article and the units required to calculate Eq 1 through 24.

Table 5 Nomenclature used in friction and wear of gears

Symbol	Description	Units
B_M	Thermal contact coefficient	lbf/(in. · s$^{0.5}$ · °F)
b_H	Semiwidth of Hertzian contact band	in.
c	Constant (see Table 4.)	hp/(gal/min)
c_M	Specific heat per unit mass	lbf · in./[lb · °F]
d	Operating pitch diameter of pinion	in.
E_1	Modulus of elasticity of pinion	lbf/in.^{2}
E_2	Modulus of elasticity of gear	lbf/in.^{2}
E_r	Reduced modulus of elasticity	lbf/in.^{2}
h_{min}	Minimum film thickness	in.
L_{min}	Minimum contact length	in.
n	Pinion speed	rev/min
P	Transmitted power	hp
q	Oil flow rate	gal/min
S	Average root-mean-square (rms) surface roughness	μin.

T_b	Bulk temperature	°F
$T_{b_{test}}$	Bulk temperature of test gears	°F
T_c	Contact temperature	°F
T_f	Flash temperature	°F
$T_{f_{test}}$	Maximum flash temperature of test gears	°F
T_s	Scuffing temperature	°F
V	Operating pitch line velocity	ft/min
V_e	Entraining velocity	in./s
V_{r1}	Rolling velocity of pinion	in./s
V_{r2}	Rolling velocity of gear	in./s
W_{Nr}	Normal operating load	lbf
w_{Nr}	Normal unit load	lbf/in.
X_W	Welding factor	. . .
X_Γ	Load sharing factor	. . .
α	Pressure-viscosity coefficient	in.^{2}/lbf
λ	Specific film thickness	. . .
λ_{min}	Minimum specific film thickness	. . .
λ_M	Heat conductivity	lbf/[s · °F]
μ_m	Mean coefficient of friction	. . .
μ_0	Absolute viscosity	reyns (lbf · s/in.^{2})
v_1	Poisson's ratio of pinion	. . .
v_2	Poisson's ratio of gear	. . .
v_{40}	Kinematic viscosity at 40 °C (105 °F)	cSt
ρ_1	Transverse radius of curvature of pinion	in.
ρ_2	Transverse radius of curvature of gear	in.
ρ_M	Density	lb/in.^{3}
ρ_n	Normal relative radius of curvature	in.
σ	Root-mean-square composite surface roughness	μin.
σ_1	Root-mean-square surface roughness of pinion	μin.
σ_2	Root-mean-square surface roughness of gear	μin.
ψ_b	Base helix angle	degrees
ω_1	Angular velocity of pinion	rad/s
ω_2	Angular velocity of gear rad/s	rad/s

Friction and Wear of Seals

James F. Dray, Mechanical Technology Inc.

Introduction

SEALS are the components in a mechanical system that act as the pressure boundary between other components, such as a piston and cylinder in a hydraulic actuator. A region of high pressure usually exists on one side of the seal, versus low pressure on the other.

In some cases, the role of the seal is to prevent mixing of two incompatible fluids, more so than it is to hold a pressure boundary. The other components can be either stationary or in motion. A diaphragm is an example of a seal that effectively prevents mixing. The fluids being sealed can be either liquids or gases.

Types of Seals

Seals are usually classified as being either static or dynamic, which refers to the motion the seal experiences rather than the presence or absence of pressure fluctuations. A dynamic seal has a surface that is in motion (usually sliding) relative to the contacting surface. This type of seal can experience either rotary or reciprocating motion or a combination of both.

Static seals are available in many variations. The most frequently used static seals are probably O-rings, gaskets, and packing. O-rings (Fig. 1) are also occasionally used as dynamic seals, and are effective as seals when used within their recommended range.

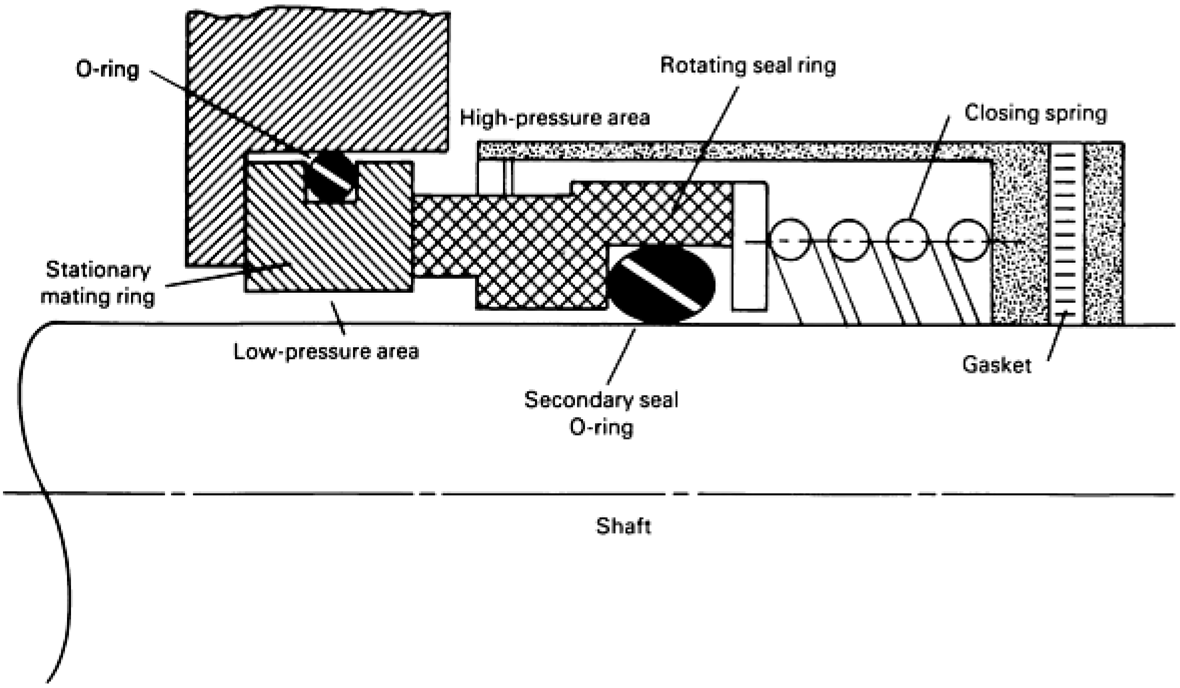

Fig. 1 Mechanical face seal

O-rings are made from a variety of polymer materials, including natural, neoprene, and nitrile rubbers. They are generally limited to a temperature range from 0 to 93 °C (32 to 200 °F), because of their material composition. Chemical compatibility between the seal material and the fluid being sealed is an important design requirement. The surface finishes of the groove containing the O-ring and the mating surface are also significant in determining seal life and effectiveness.

Another design requirement is the amount of compression. The catalogs of O-ring manufacturers provide definitive tables of groove size versus O-ring size and can determine compression, which is generally from 10 to 15%.

Gaskets (Fig. 1) are used as seals between static machine joints and are the least expensive, most effective choice for many applications. They are available in a variety of materials, ranging from cork to metals such as copper. Some, such as room-temperature vulcanizing (RTV) silicone rubber, can be formed in place. Many contain asbestos, which is being phased out because of environmental and health risks.

The material selection and joint design of gaskets are driven by operating temperature range, chemical compatibility, and differential pressure. Typical applications are an engine head to block, steam turbine upper to lower housing, and bearing pillow block housing joints.

Packing is also used for these static applications in place of a gasket because of ready availability, low cost, and simplicity of design and applicability. Another advantage is that it allows intermittent operation of the joint, as is required for ship rudders and submarine periscopes. Packing types have evolved from braided flax, filled with tallow as a lubricant, to modern materials, such as braided polytetrafluoroethylene (PTFE) fiber, impregnated with petrolatum.

Packing is usually square in cross section, and the joint or stuffing box design is controlled by the same parameters that control a gasket (Fig. 2). It can be staged for high-pressure applications, and its compression is controlled by tightening the gland bolts.

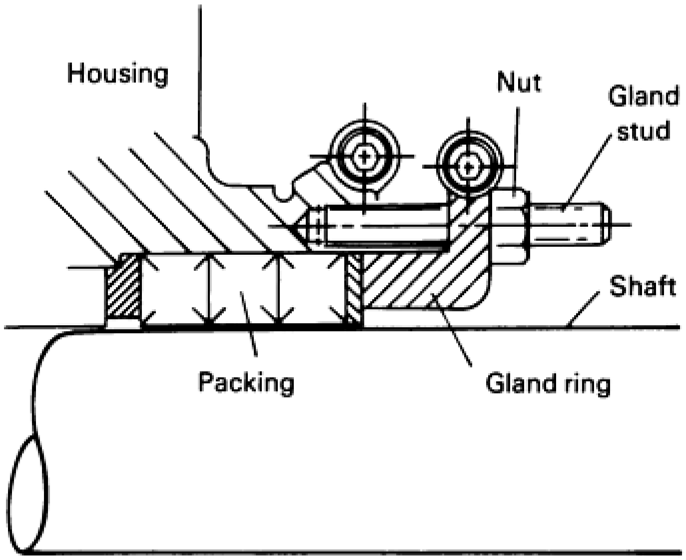

Fig. 2 Packing gland

Dynamic seals can experience either rotary or reciprocating motion or a combination of both. There are a number of different configurations, including lip, face, cap, quad ring, O-ring, and packing, as well as hybrid combinations of these.

Lip seals are widely used to seal low-pressure differentials up to about 137.8 kPa (20 psi) and are limited to relatively small amounts of radial motion between the journal and seal (that is, less than 0.508 mm, or 20 mils). The lips are loaded against the shaft by the pressure differential, or by finger springs molded into the lips, or by a garter spring wrapped around the lip (Fig. 3). When relative velocities and lip loads are high, a considerable amount of heat is generated and the lip may either groove or cut the shaft unless some form of lubrication is provided (Ref 1). Materials such as nitrile rubber must be lubricated with oil or grease, whereas self-lubricating materials such as PTFE provide their own lubrication. Many of these materials also have their lubricity enhanced by the addition of a dispersion of such natural lubricants as graphite or molydisulfide.

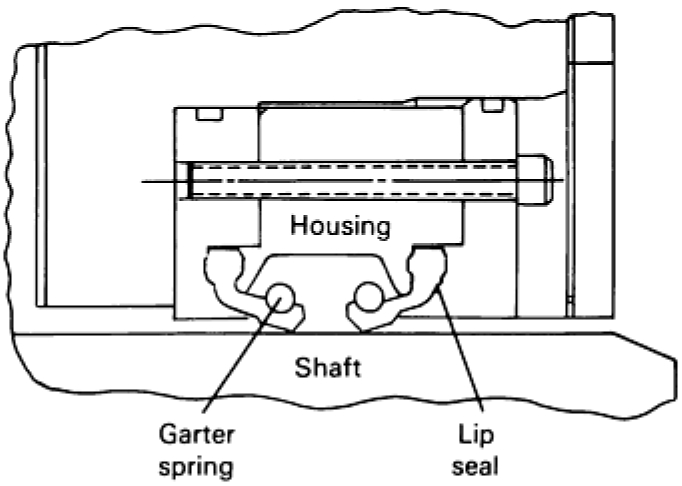

Fig. 3 Lip seal

Face seals are usually reserved for higher-pressure applications (Ref 2). They are used in such diverse sizes and applications as surface ship and submarine main propulsion shafts and high-pressure pump seals (Ref 3). The three elements (Fig. 1) are the mating ring, which in this case is stationary; the seal ring, which rotates with the shaft and floats axially to allow for axial shaft motion and is held against the mating ring by hydrostatic pressure, compression springs, or a combination of both; and an O-ring, which acts as a secondary seal.

Pressure differentials and face loadings (contact pressure) are often high, resulting in considerable heat generation and possibly high wear (Ref 4). At the low end of the load spectrum, elastomers such as nitrile rubber are satisfactory, but at the high end, ceramics, cermets, and composites are frequently necessary to minimize wear. Interface lubrication conditions are often complex, ranging from boundary conditions, to mixed conditions, to the hydrodynamic regime.

Hydrostatic face seals have been highly successful in those applications in which modest amounts of leakage can be tolerated in favor of a markedly reduced wear rate. Spiral grooved seals are a variation in which pumping grooves in one of the faces create a pressure opposing the differential pressure being sealed (Ref 5, 6). They have performed effectively in both liquids and gases, but depend on rotation to generate the seal pressure (Fig. 4).

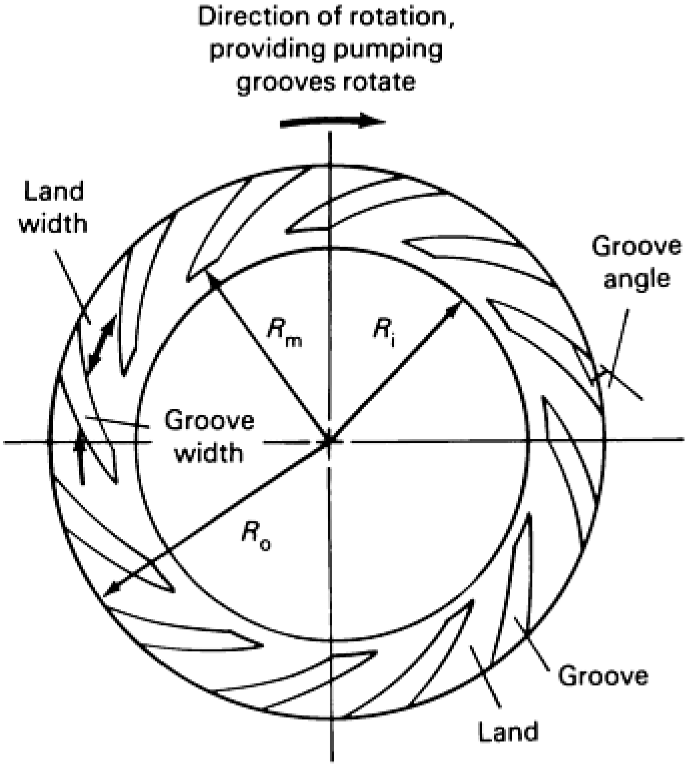

Fig. 4 Spiral groove seal

Piston ring seals are in the reciprocating category and deserve special mention. Engine piston ring seals are always metal, because of the high combustion temperatures, and are split to allow installation over the piston. There are several of these ring seals in series; the upper rings seal the air-fuel mixture and the lower rings seal the lubricating oil splashed on the cylinder walls. Although the rings have a small gap when installed, they provide effective sealing, because of the short duration of the high-combusting gas pressure, until an exhaust valve or port opens. The lubricating oil splashed on the cylinder walls is intended to provide a lubricating film for the piston and rings.

Gas-turbine seals pose a different set of problems because of high operating temperatures and speeds and the low-viscosity fluid being sealed (Ref 7, 8, 9). Compressors have similar rings from a functional viewpoint, but because temperatures can be limited to lower values, the use of polymer rings is increasing. They can be made self-lubricating and can therefore limit the dangers of an explosion (such as dieseling, which is due to the presence of oil) during compression, especially in air compressors. Hydraulic actuators and pumps use similar rings or seals to contain the high-pressure fluid

and are made from a mixture of metal and polymeric materials, depending on the pressure being sealed and the fluid properties.

Labyrinth seals, as their name implies, provide their sealing action via short and segmented tortuous paths (Fig. 5). These seals are ineffective at low speeds because they depend on rotary motion to generate a higher-pressure hydrodynamic fluid film across the close-clearance sections in order to provide the sealing action. They are effective in sealing low pressure differentials (that is, 138 kPa, or 20 psi, and less).

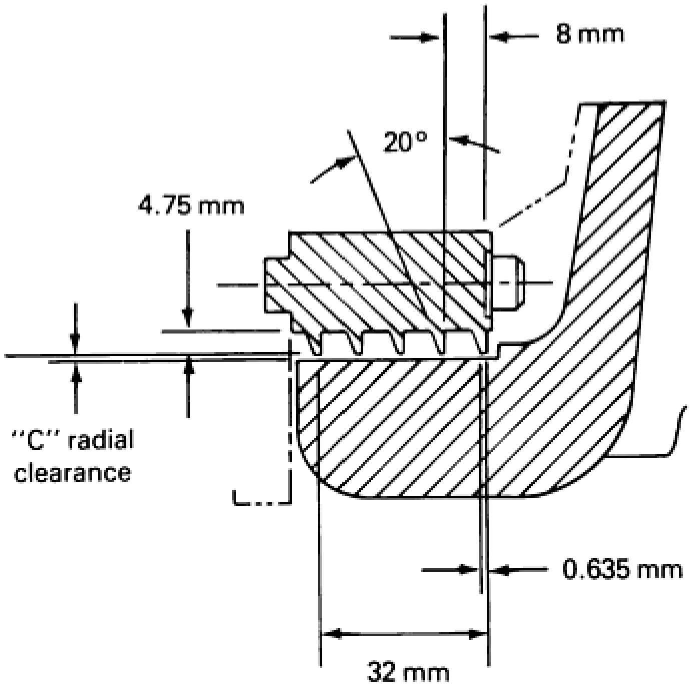

Fig. 5 Labyrinth seal

Hybrid seals that consist of packing integrated with a face seal, for example, can often provide protection in case of primary seal failure in those situations where such a failure, with significantly increased leakage, flooding, and consequent downtime, is intolerable. The packing is activated by fluid pressure leaking by the primary seal during the failure process. Another popular hybrid seal is a labyrinth in tandem with a close-clearance (capillary) floating ring seal. The labyrinth provides effective sealing for low-differential pressures at higher shaft rotational speeds, whereas the floating ring is more effective at lower speeds.

Seal materials include selections from almost all known classes of materials. Magnetic seals use the fluids themselves as the sealant (Ref 10.) Table 1 provides a partial list by application. Generally, those materials that have good tribological properties make good seal materials. The material should have a low coefficient of friction, which means a low shear strength at operating conditions. It also should be readily formable, and it is this property that makes polymers so popular today. Properties of some of the more popular hard face materials used for mechanical face seals are compiled in Table 2, whereas properties of soft face materials are described in Table 3.

Table 1 Seal specifications based on application

Seal application	Type seal	Seal material	Pressure range		Temperature range	
			MPa	**ksi**	**°C**	**°F**
Hydraulic cylinder flange	O-ring	Natural neoprene, nitrile rubber	0-62	0-9	0-95	32-200
	Gasket	Rubber				
Actuator rod	O-ring, quad ring	Neoprene, nitrile rubber	0-62	0-9	0-95	32-200
Engine/turbine manifold	Gasket	Copper, aluminum, asbestos	0-69	0-10	>540	>1000
Main shaft	Packing	Flax, asbestos, Teflon	0-7	(0-1)	0-95	32-200
Bearing housing	Lip	Nitrile rubber, Teflon	0-0.138	0-0.02	0-95	32-200
Wheel bearing	Lip	Synthetic rubber	0-0.034	0-0.005	0-150	32-300

Seal Friction and Wear Problems

All of the classical friction and wear processes are operative in seals (Ref 11, 12, 13). Ideally, a seal should operate on a hydrodynamic film that is just thick enough to prevent asperity contact and minimize wear. The seal contact pressure should be just enough so that the hydrodynamic film that is formed generates enough pressure to either resist or balance the pressure differential between the process fluid and the atmosphere. With this ideal balance, seal leakage would be minimized, as would friction and wear.

A typical example is provided by a lip seal running on a steel shaft sealing mineral oil, where the lip contact pressure is controlled by a garter spring. As long as the seal is lubricated with oil and the garter spring tension is correct, wear is minimal, occurring only at start-stop conditions, and the seal life is almost infinite. However, when the shaft surface finish becomes too rough, or when abrasives are introduced into the oil, or when the garter spring tension is increased to reduce leakage, the situation changes. Immediately, heat is generated in the fluid under the seal lip, and abrasives carried in the oil or generated as wear debris from the shaft are retained in the seal surface and held against the journal. As more wear debris is generated, the groove being cut in the shaft grows, with an attendant increase in oil leakage.

To either prevent or delay this sequence of events, it is required that the oil be kept clean, the shaft journal have the proper surface finish and hardness, and the garter spring tension be maintained at its proper value. The oil should be filtered so that suspended dirt particles are less than 10 μm (400 μin.) in diameter, the shaft surface finish should be 0.005 μm (20 μ in.) or less, and hardness should exceed a value of 40 HRC.

In this example, major contributions to the friction and wear process were made by heat and abrasion. It is fairly typical of rapid seal wear and failure that several processes frequently occur either simultaneously or sequentially. Because these are also normally dependent, any corrective action must be evaluated for its synergistic effect. In the above example, the generation of only a small amount of heat is sufficient to trigger the failure cycle. The role of abrasion, caused either by surface asperity contact, dirt particles in the oil, or wear debris, was then sufficient to carry the process to completion. Dirt particles ranging from 7 to 30 μm (280 to 1200 μin.) appear to be the most damaging.

Thermoelastic instability is another thermal process that often leads to seal failure (Ref 14, 15, 16). This phenomenon has been observed largely in harder, high-modulus materials that are used in face seals operating at the high contact pressures required to seal large differential pressures at substantial surface velocities. Included among these materials are ceramics such as manufactured carbon graphites, silicon carbide, and tungsten carbide, as well as some cermets. Typically, this phenomenon can occur when carbon graphite is run against high-cobalt materials. During this process, several carbide particles become heated and expand, rising above the surrounding surface, which increases friction, heat generation, and wear. These hot spots progress around the seal face in the carbide-containing material at a rate that is some fraction of the rotational speed, depending on contact pressure, coefficient of friction, and material properties. As a result, heat checking can appear in the harder material.

Heat checking is identified in these materials as fine radial cracks (across the seal face) that are visible to the unaided eye. These cracks are transcrystalline through the hard, brittle carbides. Failure then occurs as particles flake out of the surface or high-velocity water leakage along the cracks erodes the adjacent material.

Abrasive wear is often of concern and results from many causes, including particulates suspended in the lubricating oil, wear debris from inadequate lubrication, products of corrosion, airborne dust, and a rough surface finish. Glass reinforcing fibers used in Teflon seals and asbestos fibers used in braided asbestos packing are capable of cutting the shaft and may produce grooving to significant depths. Other available materials, such as graphite and bronze fibers, have sufficient strength to be used as reinforcements, but will not gall the shaft.

Adhesive wear occurs when the asperities of either two relatively soft materials or a soft against a hard material, often metal, rub against each other with enough heat and pressure to cause welding of the asperity peaks. The peak of the softer (lower shear strength) material then shears off with subsequent motion and forms wear debris.

Examples of materials that like to weld and therefore frequently experience this kind of wear include aluminum against aluminum, titanium against titanium, babbitt against babbitt, copper on copper, and bronze on bronze. Combinations of these materials, such as aluminum or babbitt on bronze, also have this tendency. All of these materials operate successfully against steel shafting when lubricated. Harder material combinations, such as stellite on stellite, are regularly operated against themselves quite successfully.

Cavitation often occurs in lubricating films when a fluid containing entrained air or a gas suddenly passes from a region of high to low pressure, forming bubbles that rapidly expand and then explode (Ref 17). The explosion tears particles of the surface material away and can ultimately remove enough of the material to cause leakage and failure. This process is obviously limited to high pressure and most commonly occurs with oil or water as lubricant.

This form of wear is most common at the inside edge of a high-pressure seal after the rubbing faces become divergent as a result of abrasive or adhesive wear. Once this starts, it is difficult to control. Some seals operate in a regime (Ref 18, 19) in which the fluid changes phase while in the seal face and, hence, may experience similar erosion problems. An example might be a hot water seal in which friction heating of the fluid causes it to flash into steam.

Corrosion is occasionally an operative form of wear in sealing applications. The formation of lead, tin, copper, and iron oxide in seawater can provide the abrasive material to initiate severe abrasive wear. Particular care must be taken in the chemical interactions that can occur between the seal, shaft, housing, and fluid that is present, as well as atmospheric materials, to ensure that corrosive wear is minimized.

Nitrile rubber against mild steel shafting in seawater in the presence of either monel or gunmetal (G-bronze) has been observed to produce severe crevice corrosion under stagnant conditions. Some stagnant adhesion of the rubber to the gland face and shaft has also been observed with subsequent tearing of rubber particles during rotation. Fretting may be present between two surfaces, with one metal having relative vertical/vibratory motion, such as in a valve seat or the joints of a housing around an O-ring. It is usually identified, when leakage increases, by the characteristic color and presence of iron oxide. It can sometimes be eliminated by changing joint materials or inserting a gasket.

Erosion is a frequent, if not preferred, form of wear in seals. It can be self-initiating, as in cavitation erosion, or can take place either along the cracks created by heat checking or in the diverging section of a circumferentially undulating face of a large, high-pressure seal. Particles are removed from the sealing surfaces by the velocity of the stream of fluid and any entrained hard particles. Because the process accelerates with increased gap height and leakage rate, it grows geometrically to an unacceptably high leakage rate and failure. Some materials are more susceptible to erosion than others, depending on their bonding and the grain or particle size.

Design Considerations

The environmental and operational conditions in which a seal must function should determine all of its other characteristics, such as material, geometry, surface finish, and hardness. The best seal for an application is the one that provides effective sealing of the fluid involved at minimum cost and with maximum life.

A number of specific fluid effects must be considered when selecting a seal for a specific application. Some fluids, such as water, are more prone to cavitation erosion than others, whereas fluids such as seawater, strong acids, and bases present more corrosive wear problems. Because water has a low comparative viscosity, it tends to produce a thinner lubricating film at high contact pressures and, hence, generates heat by asperity rubbing, which places high stress on the material.

The chemical compatibility of all of the materials in the shaft-seal-fluid interface is important to seal life. For example, PTFE seals generally perform better in chemical process plants because of their good resistance to attack by most caustic or acidic fluids, whereas natural rubber makes a poor seal in these applications. Special shaft and housing materials, such as stainless steel, monel, Inconel, titanium, and G bronze, must often be used when operating in corrosive environments such as seawater. Although these metals offer better corrosion resistance, they also are subject to crevice corrosion in the same way as elastomeric seals, and corrosion may progress at an accelerated rate when they lose their passivating film.

The operational factors that must be considered in generating a good seal design and in selecting appropriate materials start with the differential pressure that must be sealed. When using mechanical face seals, it is good practice to have the face contact pressure exceed the pressure being sealed by at least 344.6 kPa (50 psi), but to also keep it as low as possible to minimize wear. In a low-pressure lip seal design, a hydrodynamic pressure under the lip that exceeds the differential pressure by only 7 or 14 kPa (1 or 2 psi) may provide effective sealing. In the case of the lip seal, it is also desirable to keep the pressure generated as low as possible in order to minimize leakage. This balance between leakage, contact pressure, wear, and hydrodynamic pressure is delicate and controls the success or failure of a design.

A typical mechanical face seal is shown in Fig. 1. The face contact load is controlled by the sum of the spring load and the hydraulic closing force (Ref 20, 21, 22). The closing force is the hydrostatic pressure multiplied by the active shoulder area of seal ring, plus the total spring force minus the opening force, which is usually taken as the area of the seal ring nose multiplied by one-half the hydrostatic pressure. Shoulders on the outside diameter (OD) of the seal ring are often necessary to accommodate a secondary O-ring static seal. One-half the hydrostatic pressure is used in calculating opening force because it is usual to assume that the pressure decays linearly from the seal ring face OD to the inside diameter (ID). Such an assumption may not be quite correct, because the actual pressure decay is dependent on face geometry (that is, diverging versus converging wedge from OD to ID). This geometry may also change with face wear.

Figure 6 shows the seal ring force balance for an axially floating nonrotating seal ring. The relevant equation for the seal flank closing force is:

$$F_{HC} = P_{HS} \cdot \frac{\pi\,(OD^2 - ID_1^2)}{4} \qquad \textbf{(Eq 1)}$$

where F_{HC} is the hydraulic closing pressure, P_{HS} is the hydrostatic pressure, OD is the seal face outside diameter, and ID_1 is the seal ring skirt inside diameter.

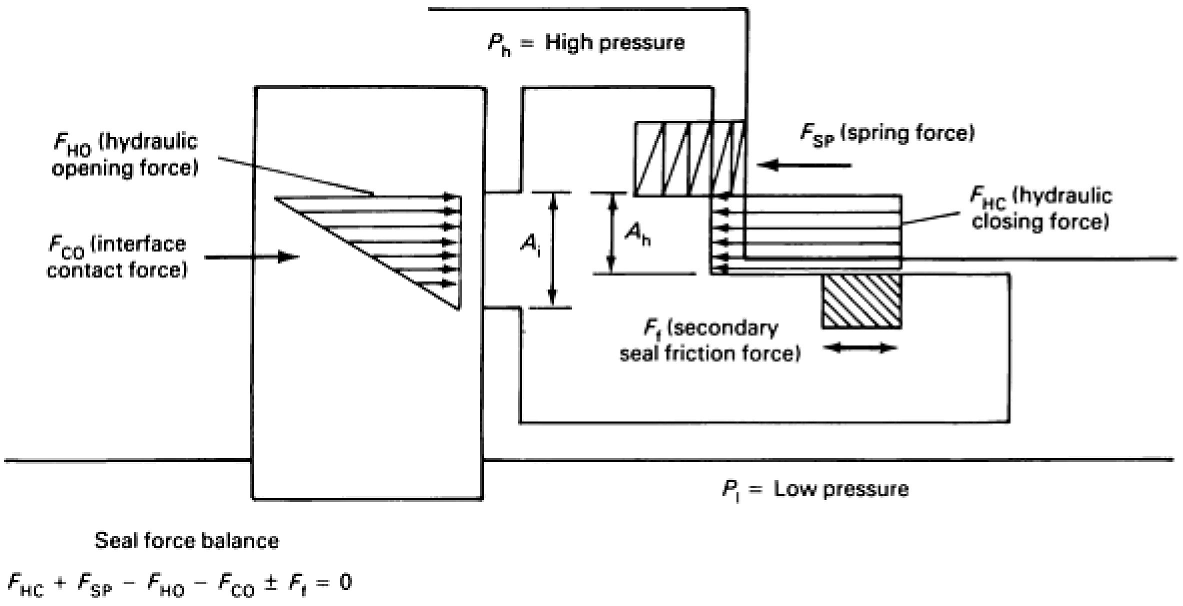

Fig. 6 Face seal force balance. A_i, face contact area, wear area; A_h, unbalanced seal ring area over which hydrostatic pressure acts

For the spring closing force:

$$F_{SP} = N \cdot K_s \cdot \delta \qquad \textbf{(Eq 2)}$$

where F_{SP} is the spring force, N is the number of springs, K_s is the spring rate (lbf/in.), and δ is the spring deflection (in.).

For the face opening force:

$$F_{HO} = \frac{P_{HS}}{2} \cdot \frac{\pi\,(OD^2 - ID_2^2)}{4} \qquad \textbf{(Eq 3)}$$

where F_{HO} is the hydraulic opening force and ID_2 is the seal face inside diameter.

For the face contact pressure:

$$P_c = \frac{4 \cdot (F_{HC} + F_{SP} - F_{HO})}{\pi\,(OD^2 - ID_2^2)} \qquad \textbf{(Eq 4)}$$

where P_c is the seal face contact pressure (psi).

It is obviously better to have the contact pressure increase and decrease directly with the pressure being sealed, and thereby have the lowest possible spring force. This reduces wear and thermal distress at the face (Ref 23). Reducing the hydrostatic closing force and increasing spring force increases wear during those periods when low differential pressure is being contained.

Material Selection

Material selection is usually based on whether the seal is to be static or dynamic, the range of pressures, and the compatibility of the fluid and seal materials. Static joints are usually sealed with a gasket or an O-ring. High-temperature gasket materials include asbestos and soft metals, such as copper, bronze, and aluminum. Steam turbine joints are often sealed using a very smooth, flat joint face bolted tightly together with a bead of Permatex gunned into a groove in the joint. Other high-temperature, formed-in-place joints are made of materials containing sodium silicate or RTV silicone rubber. Erosion and corrosive wear are often failure modes in these joints.

Lower-temperature flanged joints are gasketed with polymeric materials (vinyl, epoxy, and polyester), cork, or even paper sheets. A variety of O-ring materials are also used because of their reliability and availability. Natural and synthetic rubbers are used, although natural rubber usage is decreasing, because of chemical compatibility problems, except in those applications where its low internal damping is needed. All of these materials are capable of sealing both low and high pressures, depending on configuration.

As a dynamic seal, the reliable O-ring is often used to provide both high- and low-pressure sealing on pistons and in such applications as hydraulic cylinder actuator rods. Its widespread usage means that its properties are well-defined and it is readily available from manufacturer catalogs. In high-pressure applications, it is often necessary to use a PTFE back-up ring to prevent extrusion of the O-ring into the clearance space.

There are numerous variations on the O-ring theme for dynamic seals with special characteristics, including quad ring, cap, U-ring, and V-ring seals. The materials of choice include the same polymers used in O-rings, where PTFE, both filled and unfilled, assumes increasing importance. Lip seals in various forms are the seal of choice for low-pressure sealing applications.

The basic materials remain the same, although fillers become more necessary to help hold the lip form. These fillers can be cotton duck, flax, asbestos, glass, metal, and PTFE fibers. Garter and finger springs are also used to hold the lip in contact with the shaft. Fillers that are added to improve the lubricity of the lip include PTFE, graphite, and molydisulfide.

These same materials and combinations are used for packing, which is perhaps the oldest dynamic seal configuration in use. Packing is usually square in cross section and consists of a braided fiber that can be coated for lubricity and strength, and is frequently packed with a lubricant, such as graphite, petrolatum, and/or PTFE.

There are also many specially shaped packings, such as a chevron, which can be used in individual rings or staged as a normal packing. The existence of these packing options is a testimonial to their effectiveness in many applications. In general, packing lacks resilience and therefore loses effectiveness in applications where large radial shaft motions must be tolerated.

This is also true, to a lesser extent, of lip seals, which have difficulty in following radial shaft motions greater than 0.5 mm (20 mils). Both packing and lip seals have been mounted on a bearing-carrier ring, which moves with the shaft and is then sealed by a flexible diaphragm. This arrangement allows the seal to follow the large shaft motion, and has been used successfully in a number of applications.

Manufactured carbon graphites are the materials of choice for gas-turbine gas seals and high-pressure pump seals (Ref 24). Carbon graphite is often run as the soft face against a harder cermet or ceramic material. The carbon graphites are available in a variety of grades with different amounts and sizes of graphite grains dispersed in an amorphous carbon matrix (Ref 25).

Various metallic fillers can also be added to improve counterface polishing. The laminar graphite crystallites provide lubrication as they separate along low-shear-strength cleavage planes. A transfer film of graphite particles coats the counterface, resulting in low friction and wear. After a blank mixture has been converted in an inert gas furnace at 1500 °C (2700 °F), the porosity is sometimes filled with epoxy. The ring may be reheated, resulting in a lower-porosity material, with the filler converted to carbon.

If an even lower porosity is needed, the ring may again be filled with epoxy, but it is usually not reheated to convert the filler to carbon. A carbon-graphite grade, such as G-14 (Fig. 7a), has excellent lubricity and is therefore easy on the counterface surface, because of the large graphite grains. However, it should not be used at surface temperatures above 400 °C (750 °F), because the unconverted organic fillers begin to oxidize above that temperature.

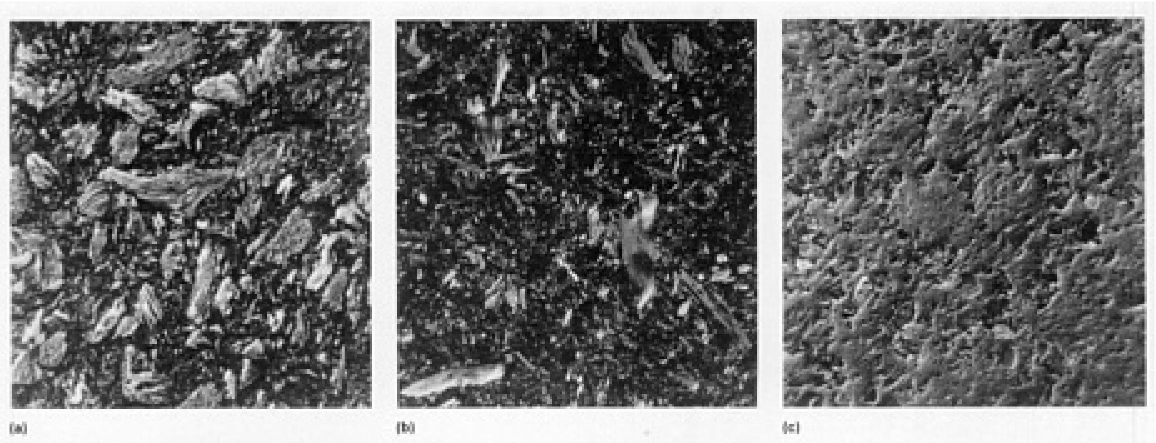

Fig. 7 Photomicrographs of carbon-graphite grades at 175×. (a) Grade G-14. (b) Grade P-658 RC. (c) Grade CDJ

A grade such as P-658 RC (Fig. 7b) has smaller graphite crystals and is stable up to about 550 °C (930 °F), because all the filler has been converted to carbon. It is harder on the counterface in terms of wear. An unfilled carbon, such as CDJ, is stable to 650 °C (1200 °F) and represents the best material for high-temperature operation. Because its graphite grains are small (Fig. 7c), its lubricity is reduced. These examples, photographed in polarized light and magnified 250 times, illustrate the difference in the size of graphite crystallites, although the percentage of graphite in each material is the same.

A carbon material such as G-14 is often run against steel shafting at modest pressures and against ceramic materials at higher pressures, because it is relatively forgiving of the mating material. At higher pressures and surface speeds, heat checking can be a problem for some ceramic material counterfaces, such as stellite. Tungsten carbide performs better as a counterface against unfilled carbons at higher temperatures, but can still encounter heat checking if the contact temperatures become high enough (Ref 25). Silicon carbide appears to offer excellent wear and thermal (heat checking) resistance.

Methods of Reducing Wear

When excessive wear occurs in a specific seal design, it can often be reduced by simply improving lubrication to the contact surface. This can involve either redirecting some of the fluid being sealed or packing the seal lips with grease. In a packing design, a change from one lubricant to another is often enough.

If the seal depends on hydrodynamic lubrication, then the addition of Michells or stepped pockets may significantly reduce wear. If contact pressures are sufficiently high or surface speeds are low enough, it may be necessary to change to a hydrostatic design in order to reduce wear to an acceptable limit (Ref 26).

Coatings have also been effective in reducing shaft wear. Effective coatings that can be applied directly to the shaft or to an intermediate sleeve under the seal include chrome oxide, aluminum oxide, anodized aluminum, nickel, and chrome. A number of very effective self-lubricating materials can be added as fillers to the seal material itself, which not only effectively reduces wear of the seal, but also of the shaft, because they form transfer films on the mating surface. Examples include carbon-graphite, graphite, molydisulfide, and PTFE.

Wear Testing

Three different kinds of wear testing provide useful data about the application of a specific seal design and/or material. Among these are evaluation in the specific operating equipment, bench or rig wear tests, and full-scale simulated tests. Great care is required to ensure that the laws of dynamic similarity are satisfied, that the instrumentation is appropriate and accurate, and that the test machine or equipment operation does in fact cover the range that will be encountered in service. All of these requirements tend to make such tests expensive.

It is customary to plot such test data against *PV*, where *P* is the face contact pressure and *V* is the velocity, and specific or seal nose wear rate for comparative purposes. Specific wear rates for a typical manufactured carbon graphite (see Table 3) rubbing against a silicon carbide hard face (see Table 2) are in the 0.6×10^{-9} to 6×10^{-9} $mm^3/N \cdot m$ range and increase in value with increases in *P* and *V*. If applicable wear data are available in the literature, it is more cost effective to use that data than to build a test machine, because of the problems associated with duplicating long-term equipment operation in a test machine. In such tests, leakage, wear, changes in surface character, temperature, lubricating film thickness, and friction torque can all be measured.

An abundance of sophisticated instrumentation is available to define these characteristics, both statically and dynamically. Metallurgical and scanning electron microscopes provide useful information on the structural and surface material character (Ref 27). Nearly as useful are the electron spectroscopy for chemical analysis (ESCA) and Auger microscopes. Such instruments as the Tallysurf and various laser metrology systems provide convenient means for determining wear and changes in the character of the surface.

Bulk material and fluid temperatures are normally measured by thermocouples or resistance temperature detectors (RTDs), whereas small local contact thermometers, and spectral, laser, and monochronomatic light interferometry are used to determine local surface and hot-spot temperatures. Lubricating film thickness is often measured using proximity gages of the optical, inductive, and capacitive types. All of these provide important information on both seal and material performance. Much of this information is in the open literature, manufacturer publications, and research laboratory reports (Ref 28).

Monitoring

In-service monitoring of seal performance is normally based on leakage. An upper limit is usually set for a specific seal and system, and depends on system size, the fluid being sealed, and equipment disassembly and seal replacement cost. For maintenance decisions, it is often adequate to estimate the quantity of leakage visually. In other cases, the leaked fluid can be collected in a calibrated container and measured volumetrically or it can be weighed to establish leakage per unit time. Often, the pressure differential across the seal is measured using standard pressure transducers. These readings are recorded to provide a time history of any degradation in performance. Less frequently, temperature, vibration, and/or friction torque are measured to assist in the evaluation or elaboration of performance.

Friction and Wear of Internal Combustion Engine Parts

J.R. Davis, Davis & Associates

Introduction

THE INTERNAL COMBUSTION ENGINE is one of the most important types of engineering power plants, encompassing gasoline piston engines used in passenger automobiles, outboard engines for motorboats, and small units for lawn mowers and other such equipment, as well as diesel engines used in trucks, tractors, earth-moving equipment, and locomotives. This article will examine the friction and wear phenomena that deleteriously affect engine performance and fuel economy. Emphasis will be on automotive engines; aircraft engines and reciprocating-type compressor and pump engines are described elsewhere in this Volume. The companion article on "Internal Combustion Engine Lubricants" in this Handbook should also be consulted.

Engine Types and Design Considerations

Principles of Operation (Ref 1, 2). In an internal combustion engine, fuel (gasoline or diesel fluid) is burned within the engine itself (in contrast to a steam engine, where fuel is burned in a separate furnace), and the combustion products serve as the mechanism that converts the latent energy of the fuel into mechanical energy. Characteristic features common to all commercial internal combustion engines include (1) the compression of air, (2) the raising of air temperature by the combustion of fuel in this air at an elevated temperature, (3) the extraction of work (energy) from the heated air and the resultant expansion of pressure, and (4) exhaust.

Figure 1 illustrates these steps schematically. For the intake stroke, the intake valve has opened and the piston is moving downward, drawing air and gasoline vapor into the cylinder. During the compression stroke, the intake valve has closed and the piston is moving upward, compressing the mixture. During the power stroke, the ignition system produces a spark that ignites the mixture. As it burns, high pressure is created, which pushes the piston downward. For the exhaust stroke, the exhaust valve has opened and the piston is moving upward, forcing the burned gases from the cylinder. As will be described, interaction of the moving parts during the engine cycle results in a complex tribosystem.

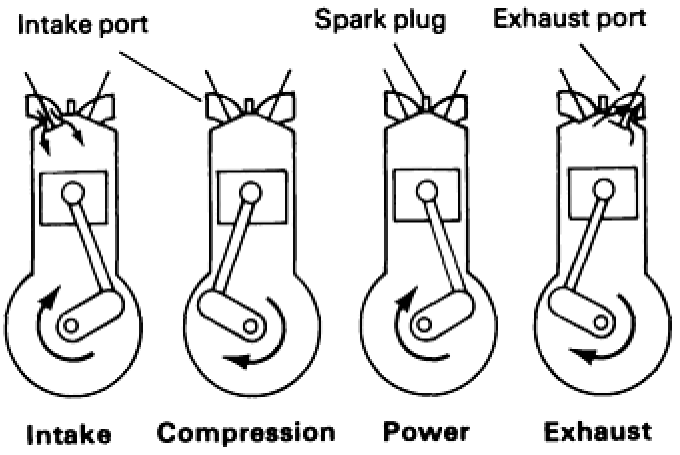

Fig. 1 Schematic of a four-stroke engine cycle. Source: Ref 1

Engine Types (Ref 2, 3). There are four types of internal combustion engines: four-stroke cycle engines (Fig. 1), two-stroke engines, rotary (Wankel) engines, and continuous-combustion gas turbine engines. Because they are the most common, four- and two-stroke engines will be described in this article. Both of these engine designs, which are based on the reciprocating piston principle, include spark-ignition and compression-ignition types. In spark-ignition (Otto cycle) engines, the fuel and air are mixed in either the carburetor or intake port (fuel injection) prior to entry into the combustion chamber. Gasoline is the most commonly used fuel in spark-ignition engines, although commercial gases such as blast-furnace gas, coal gas, coke-oven gas, and natural gas are used in large stationary engines. In compression-ignition engines, the intake system supplies only air, which is compressed before the fuel is injected into the combustion chamber. Compression-ignition engines use liquid of low volatility, such as fuel oil or diesel oil.

Four-stroke compression-ignition and spark-ignition engines are used in most automotive applications. Depending on the cylinder arrangement, four-stroke engines can be subcategorized as in-line (Fig. 2), V (vee), opposed piston, and radial types. Two-stroke spark-ignition engines are commonly used in lightweight applications, such as outboard motors, motorcycles, and snowmobiles, whereas two-stroke compression-ignition diesel engines are used in on-high-way trucks, buses, low-speed marine applications, and some railroad locomotives.

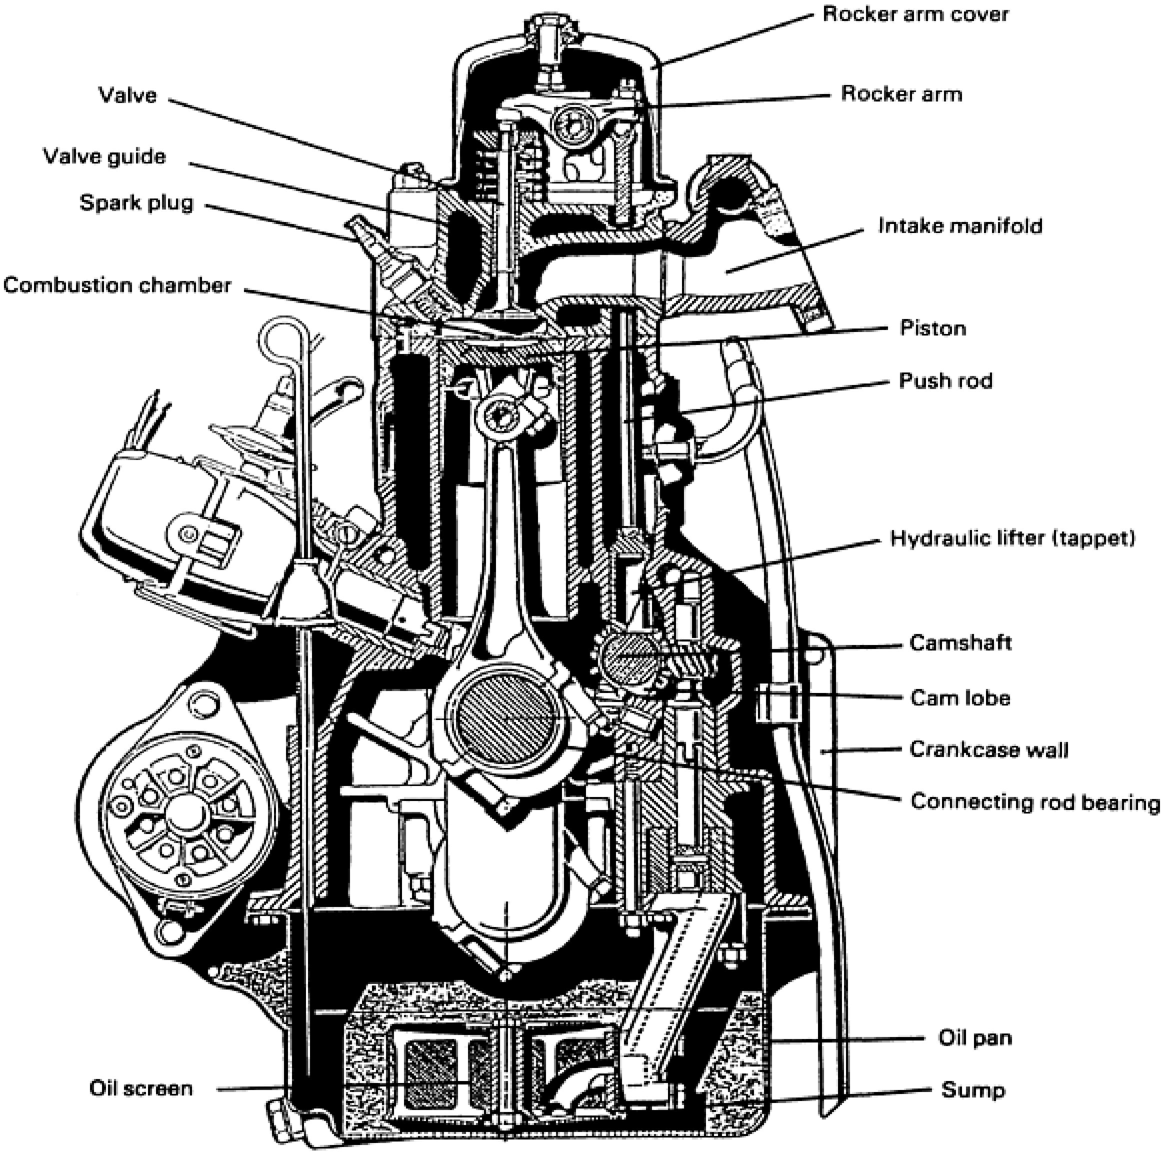

Fig. 2 Cross section of a six-cylinder, in-line automotive engine. Courtesy of S.Q.A. Rizvi, Lubrizol Corporation

General Features. Automobile engines have been produced with various numbers of cylinders over the years (from 2 to 16), but the most common engines in modern cars are in-line four-cylinder designs for smaller cars and in-line six-cylinder, V-6, and V-8 designs for larger cars. Smaller engines, both in terms of cylinder number and size (displacement), provide improved fuel economy. The displacement of modern passenger cars ranges, on average, from 1.6 to 5.7 L (98 to 350 in.^{3}).

All engines employ compact, rigid structures. Most cylinder blocks are made from gray cast iron, although aluminum is increasingly common, particularly in cylinder heads. Four-cylinder engines use three or five crankshaft bearings; the V-6 uses four, the V-8 uses five.

Liquid-cooling passages are provided around the bore of each cylinder as well as in the hot regions of the combustion chambers and exhaust ports in the cylinder head. Modern pistons are generally made from aluminum alloys (see the section "Pistons and Piston Ring Assembly" in this article), but gray iron or malleable iron pistons are used in heavy-duty diesel applications. Crankshafts are usually made from cast iron (gray iron or ductile iron) or forged steel. Similarly, connecting rods are made from cast iron (malleable iron), conventional steel forgings, or powder metallurgy steel forgings.

Detachable cylinder heads contain the inlet and exhaust valves (overhead valves). Some engines employ a single exhaust and inlet valve, while other designs feature three or four valves per cylinder. Exhaust gas is directed through short passages to the exhaust collector or manifold.

Fuel and air are delivered to the cylinder head by a compact inlet manifold, usually made from aluminum. Fuel management is provided by either a carburetor or an electronic fuel injection system. In most cases, feedback from an exhaust gas combustion sensor is used to provide precise control of the fuel/air ratio and to optimize the performance of the emission control system. Electronic ignition virtually eliminates the need for periodic ignition system maintenance.

Many of the engine components mentioned above are shown in Fig. 2. Detailed information on the friction and wear problems associated with some of these components is provided below.

Designers of advanced fuel-efficient, low-emissions engines are beginning to include ceramic parts because of weight and durability considerations. While the relatively high cost of ceramics may limit their current use, improvements in material cost, processing efficiency, and machining may eventually result in the use of increasing numbers of ceramic parts in the internal combustion engine.

Friction and Wear of Engine Components

Since the oil and gas shortages in the 1970s, significant automotive engineering efforts have been devoted to emission and fuel economy improvements in order to meet legislated emissions and Corporate Average Fuel Economy (CAFE) standards. These efforts include (Ref 4):

- Vehicle downsizing for reduced weight and rolling resistance, and exterior design improvements for reduced aerodynamic drag
- Engine downsizing to reduce the power-to-weight ratio (see earlier comments regarding engine displacement)
- Engine design improvements in weight reduction, volumetric efficiency, and improved combustion
- Drive-train improvements, for example, lockup torque converter, split-torque converter, overdrive, and reduced parasitic friction losses of drive-train components (see the article "Friction and Wear of Automotive and Truck Drive Trains" in this Volume)
- Advancements in exhaust treatment to meet emission standards, for example, catalyst technology
- Fuel metering with electronic, closed-loop engine control to maximize fuel economy and minimize emissions at various engine operating conditions
- Reductions in chassis friction and tire rolling resistance (see the article "Friction and Wear of Tires" in this Volume)
- Use of lightweight, durable ceramics and ceramic coatings

Fuel economy goals have also resulted in renewed interest in the understanding of engine friction and wear in the design of engine components with improved tribological performance. For example, recent studies have indicated that a 6.9 kPa (1 psi) mean effective pressure (MEP) reduction in engine friction yields a 1 to 2% fuel economy improvement in four-cylinder automobiles (Ref 4).

Contribution of Major Components to Engine Friction. At a typical engine speed of the Environmental Protection Agency (EPA) metro-highway (M-H) driving cycle, the major engine friction components in order of importance are (Ref 4):

- Piston ring assembly
- Valve train
- Crankshaft (bearings)
- Oil pump

Figure 3 shows the percentage of friction for these various components as a function of speed. The percentage of friction increases with increasing speed for the crankshaft bearings, connecting rod bearings, and pumps; the friction percentage decreases for the piston and ring assembly and the valve train assembly (Ref 5).

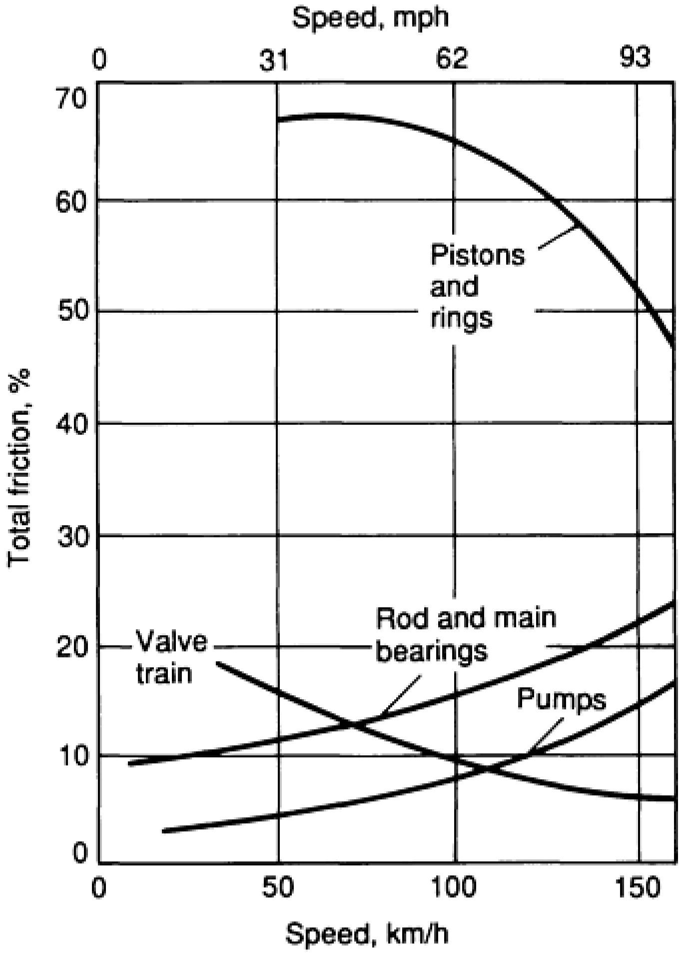

Fig. 3 Effect of speed on engine component friction. Source: Ref 5

Lubrication Regimes for Friction Components (Ref 6). A difficult problem in understanding engine friction is the wide variation in the magnitude of the friction forces observed--the coefficient of friction ranges from 0.2 for boundary lubricated engine components to 0.001 for hydrodynamically lubricated engine components. Figure 4 relates the various regimes of lubrication to the major engine friction components. The critical elements in the valve train, including

the cam-lifter interface and rocker-arm pivots, operate in the boundary to mixed regime, because high loads are encountered at low sliding speeds. Piston rings operate over the range of thick-film hydrodynamic to mixed lubrication, because the gas load and velocity of the piston ring vary extensively over one engine cycle. At top dead center of the piston stroke when the gas forces are maximum, the velocity of the piston ring is zero and contact occurs between the piston ring and the cylinder wall. The piston skirt, because of its large contact area and low loading, is primarily a thin-film hydrodynamic contact. Engine bearings operate in the hydrodynamic mode, except for brief periods during starting and stopping. More detailed information on the fundamentals of engine lubrication can be found in the article "Internal Combustion Engine Lubricants" in this Volume.

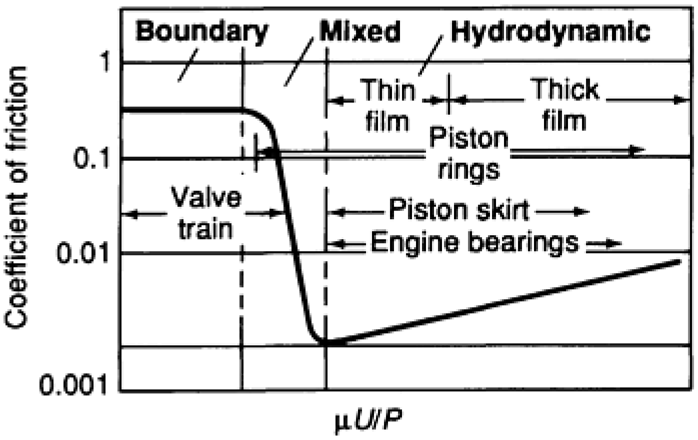

Fig. 4 Stribeck diagram showing lubrication regimes for major engine friction components. μ**, absolute viscosity;** ***U*****, speed;** ***P*****, unit load. Source: Ref 6**

Engine Wear (Ref 7). Normally, all reciprocating engines operate with lubrication. Oil of the wrong viscosity or oil that deteriorates in service can have a decided influence on wear of cylinders, cylinder liners, rings, camshafts, and valve trains.

The products of combustion of the fuel contain water vapor that carries potentially corrosive gases, such as oxides of sulfur, carbon, and nitrogen. If allowed to condense on engine parts, these oxides readily form acids and cause excessive corrosive wear. As an example, the relation between percentage of sulfur in the fuel and the wear of piston rings is shown in Fig. 5(a) and (b). Cylinder wear is similarly affected.

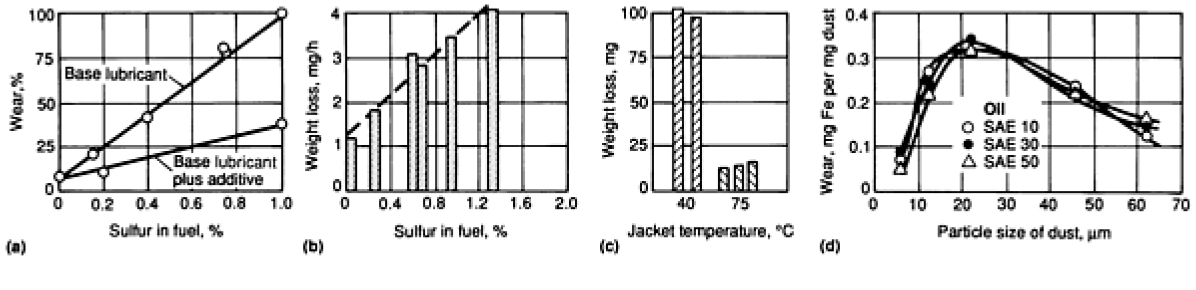

Fig. 5 Effect of variables on the wear of piston rings. Source: Ref 7

Corrosive wear is minimized by running the engine hot, by hastening warmup, and, especially with diesel engines, by using low-sulfur fuel. The results shown in Fig. 5(c) are typical in that they show reduced piston ring wear at temperatures above 65 °C (150 °F); wear of cylinders is similar. Also, lubricant additives will often inhibit corrosive effects, as illustrated in Fig. 5(a). The effects of lubricant additives are also described in the article "Lubricant Additives and Their Functions" in this Volume.

Other mechanisms associated with engine wear include:

- Adhesive wear (cylinder liners and piston rings)
- Abrasive wear (cams, rocker arms, and tappets)
- Scuffing (cylinder liners and piston rings)
- Pitting caused by fatigue wear (cams and tappets)

Pistons and Piston Ring Assembly

Among the many moving parts in an internal combustion engine, the piston and piston ring assembly are considered to be the components that contribute most to total engine friction and wear. It is estimated that piston ring friction amounts to approximately 50 to 70% of the friction loss of the piston assembly (Ref 8), and that the piston assembly is responsible for about 25% to as much as 75% of total engine friction losses (Ref 9, 10). References 11 and 12 are useful reviews of theoretical and experimental investigations related to piston ring tribology in the areas of friction and wear determination, friction reduction, lubrication, and oil consumption. Some of the findings reported in those papers are outlined below.

Pistons (Ref 13)

As stated earlier, most pistons for automotive applications are made from aluminum alloys. The universal acceptance of aluminum alloy pistons by gasoline engine manufacturers can be attributed to their light weight and high thermal conductivity.

Aluminum automotive pistons generally are permanent mold castings. The alloy most commonly used for passenger car pistons is 332.0-T5, an aluminum-silicon alloy that has a good combination of foundry, mechanical, and physical characteristics, including low thermal expansion.

Piston alloys for heavy-duty engines include 336.0-T551, a low-expansion alloy, and 242-T571 because of its higher thermal conductivity and superior properties at elevated temperatures. Chemical compositions and typical properties of cast aluminum piston alloys are given in Tables 1 and 2, respectively. A cross section of a piston is shown in Fig. 6.

Table 1 Chemical compositions of cast aluminum piston alloys

Alloy	Composition, wt%									
	Si	**Fe**	**Cu**	**Mn**	**Mg**	**Cr**	**Ni**	**Zn**	**Ti**	**Al**

theoretical value.

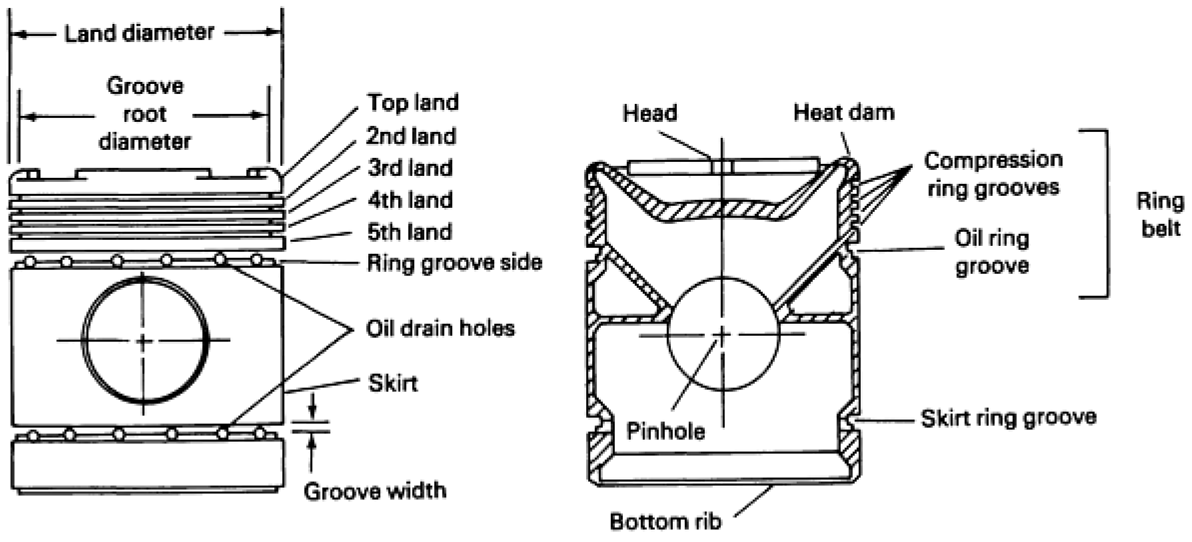

Fig. 6 Typical piston configuration per ANSI/ASME Standard B205

Piston Rings (Ref 11)

Piston rings are mechanical devices used for sealing pistons, piston plungers, reciprocating rods, and so forth. In gasoline and diesel engines, they are generally split-type, self-expanding metal rings. When they are placed in the grooves of the piston (Fig. 6) and provided with a lubricant, a moving seal is formed between the piston and the cylinder bore (liner).

Piston rings are divided into two categories: compression rings and oil-control rings. Compression rings, generally two or more, are located near the top of the piston (Fig. 7). Compression rings have to perform two basic functions--gas sealing and oil control--under the most hostile conditions, being exposed to high temperatures, high gas pressures, extreme stresses, impact, corrosion, and abrasion. They must be able to operate with a minimum of lubrication and still provide service at low wear conditions. Therefore, the basic design considerations are efficient sealing, light weight, and good material strength and minimum wear under elevated-temperature conditions.

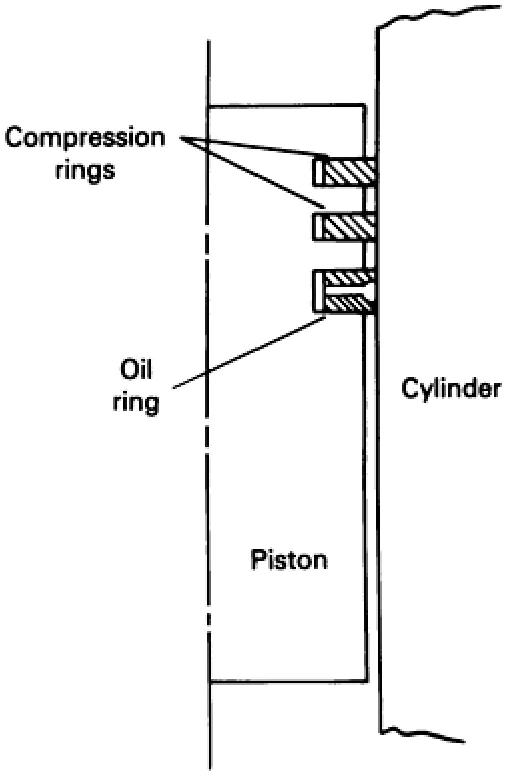

Fig. 7 Schematic of piston ring assembly showing location of compression rings and oil ring

Oil rings, generally one or more, are placed below the compression rings to prevent the passage of excessive lubricating oil into the combustion chamber, yet provide adequate lubrication for the compression rings. Major factors affecting this basic function are ring-bore contact pressure, ring-bore conformability, sliding surface characteristics, and drainage for the surplus oil. Other factors that influence oil ring design include amount of oil transported, oil viscosity, and engine operating and temperature conditions.

Ring Materials and Coatings (Ref 11). An ideal piston ring, material must meet the following requirements: low friction and wear losses, superior scuffing resistance, tolerances for marginal lubrication and rapidly varying environments, good running-in wear behavior, long-term reliability and consistency of performance, long maintenance-free life, and low production costs. Although no single material can meet all of these requirements, base materials exhibiting good strength, fatigue, impact, and wear properties can be coated with materials that have excellent wear, friction, and scuff-resistance characteristics.

Gray cast iron, with a hardness ranging from 200 to 400 HB, is the most commonly used material for compression and oil rings. Table 3 shows the various types of cast irons used in gasoline engine piston rings. Pearlitic gray iron produced by either centrifugal or sand casting methods has the widest use. In heavy-duty engine applications, alloy cast iron, ductile iron, and malleable iron are used. Harder materials, such as carbon steel or even bearing steels, may also be used.

Table 3 Typical piston ring materials

Source: Ref 11

Relatively thick coatings (up to 0.2 mm, or 0.008 in.) of plated chromium on the ring periphery provide the best compromise between scuffing, wear, and corrosion resistance and low friction and oxidation resistance at high temperatures. Generally, the use of chromium-plated top rings (with a hardness of 700 to 900 HV) run against cast iron cylinder liners can reduce the ring and liner wear by a factor of 2 to 3. Rings coated with flame- or plasma-sprayed coatings of molybdenum (in thicknesses up to 0.25 mm, or 0.01 in.) with a hardness of greater than 1000 HV are believed to have higher scuffing resistance than chromium-plated rings. The major limitation of molybdenum ring coatings is that they are subject to oxidation at 500 °C (930 °F), and at 730 °C (1345 °F) the oxide volatilizes.

Ceramic (Cr_2O_3), cermet (WC-Co, Cr_3C_2-Ni, and Cr_3C_2-Mo), and alloy (Mo-Cr-Ni) plasma-sprayed coatings have also been developed for achieving improved wear and scuffing resistance under conditions of marginal lubrication. Reference 14 reviews various ring materials and coatings.

Cylinder Liner Materials (Ref 11)

The cylinder walls are stressed mechanically by the high gas pressure and the side thrust of the piston, as well as thermally by the high gas temperature. Because all these stress-induced factors are cyclic, the cylinder liner materials must have good mechanical and fatigue strengths; otherwise, cylinder bore distortion or early material fatigue failure may result. In addition, tribological properties such as wear and scuff resistance must be satisfactory, because metal-to-metal contacts between piston rings and the cylinder liner do occur.

Most cylinder liners are made of gray cast iron. To increase their mechanical strength, additions of nickel, chromium, copper, and molybdenum are required. The addition of at least 0.3 wt% Cr to improve wear resistance is fairly common and is considered to be particularly beneficial when combined with 0.65 wt% Mo. Typical liner materials are shown in Table 4.

Table 4 Typical cylinder bore materials

Source: Ref 11

Steel cylinder liners also have been used, offering the advantage of much thinner walls. They must be hardened to at least 400 HB, however, for satisfactory resistance to wear and scuffing, or else be chromium plated. It should be noted that chromium-plated liners should not be run against chromium-plated piston rings, but rather against plain cast iron rings or rings with other types of coatings.

Aluminum alloy A390.0 cylinder liners with high silicon content (~17% Si) have also been used. Some engine test results show that the liner wear of cylinders made from this material is lower than that of conventional cast iron liners (Ref 11, 14).

The surface finish of the cylinder bore is another key factor influencing oil consumption, scuff and wear resistance, and engine life (Ref 15, 16, 17, 18). Generally a clean, burr-free, consistent surface finish is required. An average surface finish of 0.5 to 0.8 μm (20 to 30 μin.) is recommended. More detailed information on bore finish specifications can be found in Ref 16.

Piston Ring-Cylinder Liner Scuffing (Ref 11)

For piston rings and cylinder liners, scuffing is primarily the result of the breakdown of the lubricating oil film separating the sliding surfaces. This leads to metal-to-metal contact, causing local welding between the ring and the liner.

Piston ring scuffing is generally a running-in problem and is particularly likely to occur if full load and speed are applied too rapidly. It can also occur after longer running periods if the lubrication conditions deteriorate. The symptoms of scuffing in an engine are usually high oil consumption and blow-by, and sometimes a noticeable engine knocking noise. If scuffing is allowed to proceed, it may cause piston seizure or a major increase in piston clearance, resulting in a heavy knocking noise. However, in some cases the prime scuffed area does not spread, but heals itself, and the engine is still able to perform satisfactorily. Some of the methods used to reduce the incidence of scuffing include:

- Fitting the piston rings with the running surface preshaped to a profile resembling that obtained after running-in so that less running-in wear is required
- Providing a surface finish on the cylinder liner that is coarse enough to increase the wear rate of the rings. If the rings are preshaped, however, the finish should be made finer than if they are flat
- Using a small amount of mildly abrasive material as a coating or filling on the liner or rings that will help to maintain an adequate initial wear rate
- Increasing the oil supply to the upper rings during running-in, which helps flush out wear debris and counteract any local deficiencies in the oil distribution

Factors Affecting Piston Ring Wear (Ref 7)

The principal factors that influence wear of piston rings are speed, temperature, load, frequency of use, dirt, corrosion, surface finish (see above), and quantity of lubricant.

Speed influences ring wear largely as a function of piston travel per kilometer. The rate of ring wear in a high-speed engine of a given power rating is higher than that of a low-speed engine of the same rating in proportion to the distance traveled by the rings. Design weaknesses of rings, pistons, and cylinders become more evident as speed increases.

Although radial face wear is the prime consideration, wear of ring and groove sides cannot be ignored. Engine speed affects side wear because it affects the acceleration forces on the rings.

Temperature. Although high temperature occasionally causes wear by interfering with lubrication of cylinder surfaces, low temperature is a far more frequent source of excessive piston and ring wear. As coolant temperature falls below 65 °C (150 °F), cylinder and ring wear increases rapidly because of corrosion caused by condensate that carries corrosive combustion products, as shown in Fig. 5(c). When it is impossible to maintain proper temperature, lubricating oils that contain additives are helpful (see the article "Lubricant Additives and Their Functions" in this Volume).

Engine load affects the wear rates of both cylinders and rings principally through its influence on temperature and corrosive wear. Engines in light-load service generally have a high rate of corrosive wear. High loads seldom cause wear problems unless design weaknesses cause scuffing because of distortion or destruction of the oil film by hot spots.

Frequency of Use. Engines operated the most miles per year have the lowest rates of cylinder and ring wear. Low annual mileage usually means short runs, more starts per mile, and detrimentally low operating temperatures; the sensitivity of an engine to this type of wear is largely determined by its warmup rate.

Airborne dirt is a chronic cause of excessive ring wear. Proper design and maintenance of filter equipment is essential, as is prevention of air leaks between filters and the engine. Dirt in the lubricating oil is a less frequent problem but, again, proper design and maintenance of oil filters and seals are vital.

Abrasive Particle Size. When the particle size of dirt in an engine reaches a certain size, wear subsides and the dirt particles often reduce friction rather than increase it. Test data in Fig. 5(d) for piston ring wear indicate that abrasion is most severe at a particle size of about 20 μm.

Reducing Piston Ring Assembly Friction

Piston assembly design modifications have resulted in substantially reduced engine friction. As shown in Fig. 4, the light loads and large contact areas associated with the piston skirt promote a hydrodynamic contact. In order to reduce a hydrodynamic friction, skirt areas have been reduced in recent designs. For example, the slipper-type piston skirt design is typically preferred to the full trunk design. Skirt length can have a significant impact on friction level (Ref 5, 19), as shown in Fig. 8. Decreasing the effective skirt length from the original design length reduces friction and improves engine economy for both low-speed, low-load and high-speed, higher-load operation.

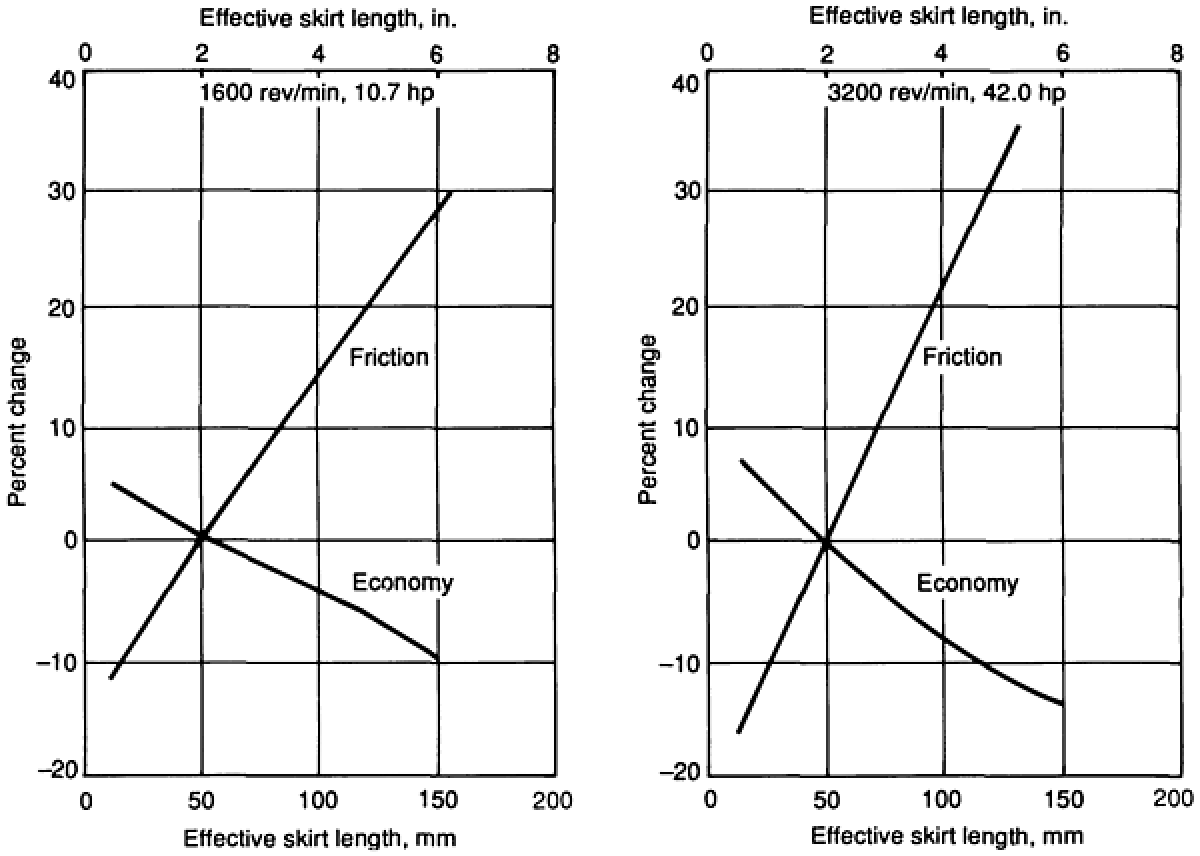

Fig. 8 Effect of piston skirt length on friction and fuel economy. Source: Ref 6

Recent developments in finite-element modeling of pistons have led to a better understanding of operating skirt profiles (Ref 20). These developments, coupled with piston dynamic analysis, can be used to optimize piston skirt design for reduced friction.

Ring size and ring tension effects on friction have been examined in a movable-bore engine (Ref 21). This engine was a single-cylinder diesel engine containing four piston rings. Data from these tests show that substantial reductions in ring friction can be realized by reducing ring tensions and face widths. References 4, 6, and 12 provide detailed information on tests that have been developed for determining general friction considerations for piston assembly design.

Valve Train Assembly

The valve train assembly includes such components as the camshaft, cams, tappets (hydraulic lifters), valves, valve seat rings, valve springs, and rocker arms. As the camshaft rotates, the cams use pushrods and rockers to operate the cylinder valves, which admit the fuel or expel the exhaust gases. In an overhead camshaft engine, the cams lie above the valves and move them directly. It is estimated that as much as 25% of total engine friction losses are attributable to the valve train assembly (Ref 6). Contributions of specific components to valve train friction torque loss are shown in Fig. 9 (Ref 22).

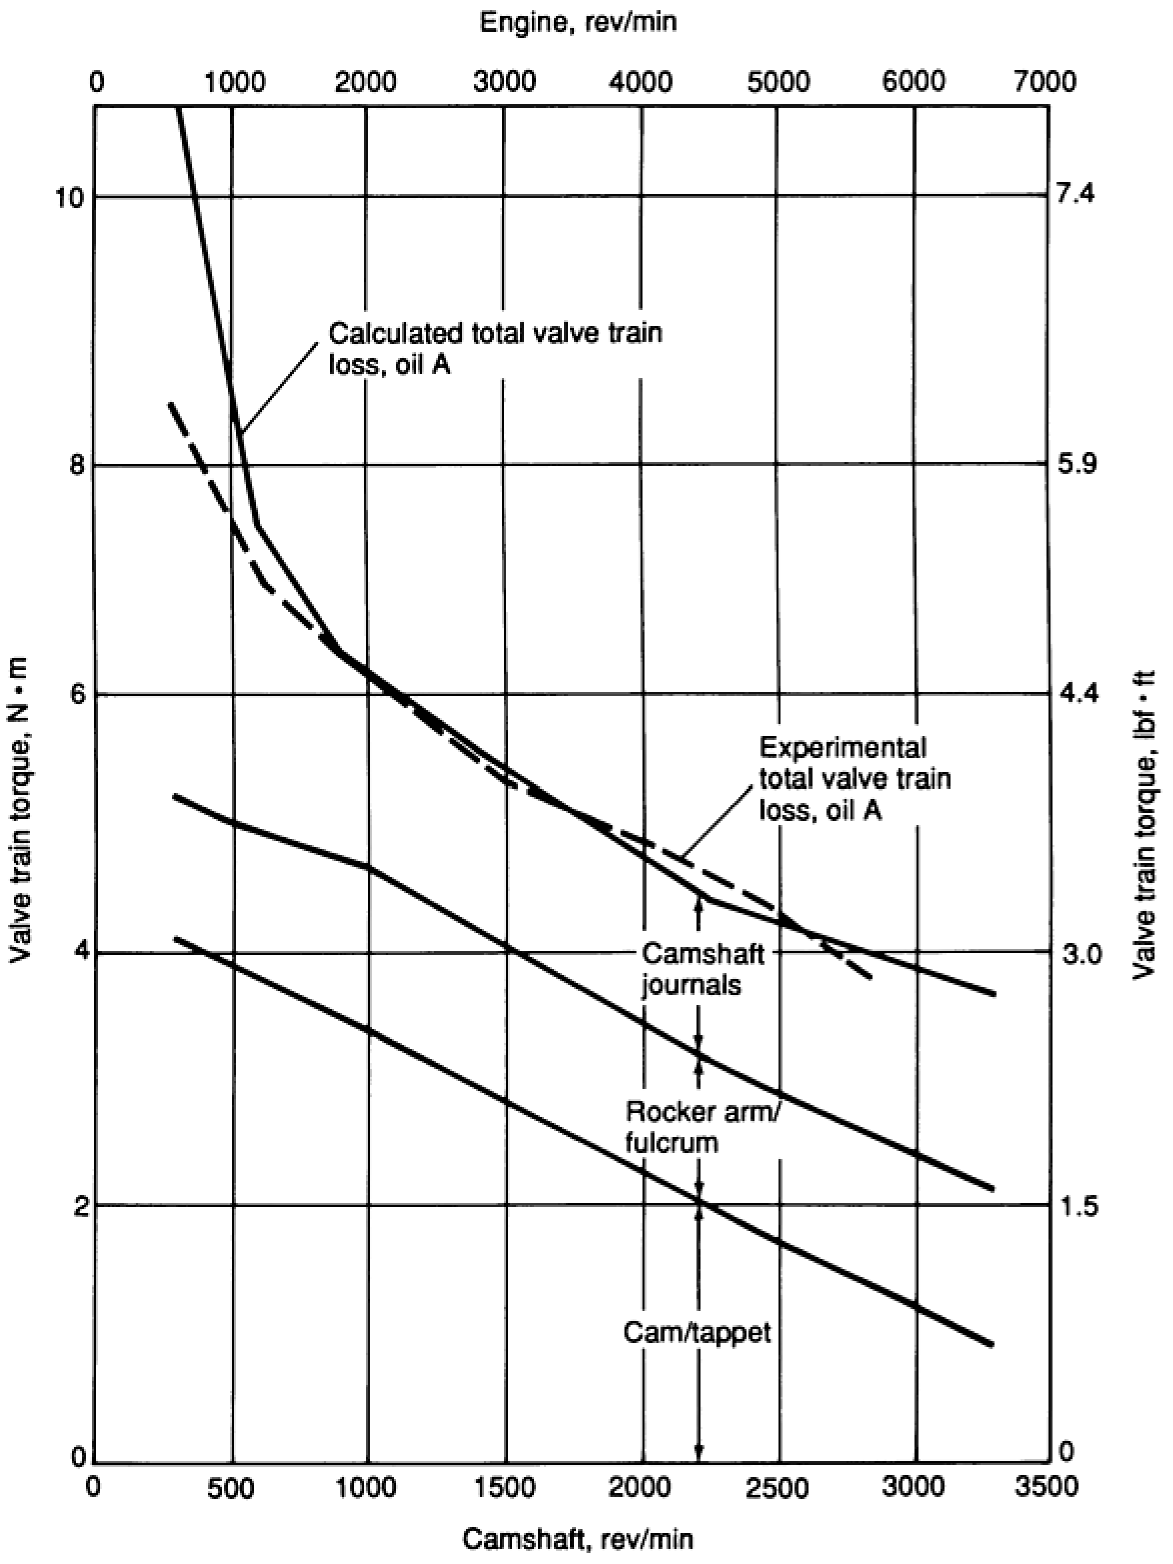

Fig. 9 Total torque loss and torque loss for the critical valve train friction contacts versus speed calculated for a

non-friction-modified SAE 30 oil at 100 °C (212 °F). Source: Ref 22

Valve Train Friction (Ref 6). Valve train design presents a challenge because high loads must be carried over the entire speed range of the engine. Loads acting on the valve train at low speeds are caused primarily by valve spring forces, while at higher speeds inertia forces generated by component mass dominate. Several valve train designs are shown in Fig. 10, including the pushrod, the direct-acting overhead cam, the end-pivot overhead cam, and the center-pivot overhead cam (Ref 23). Boundary lubrication is the predominant lubrication regime in the valve train (Ref 24), as shown in Fig. 4, and the major energy losses occur in the cam-lifter interface and in the rocker-arm pivot. As shown in Fig. 11, the torque required to drive the valve train is lowest for the direct-acting design. This is because there is only one sliding contact. The other design alternatives exhibit high friction because of the additional rocker-arm pivot loss.

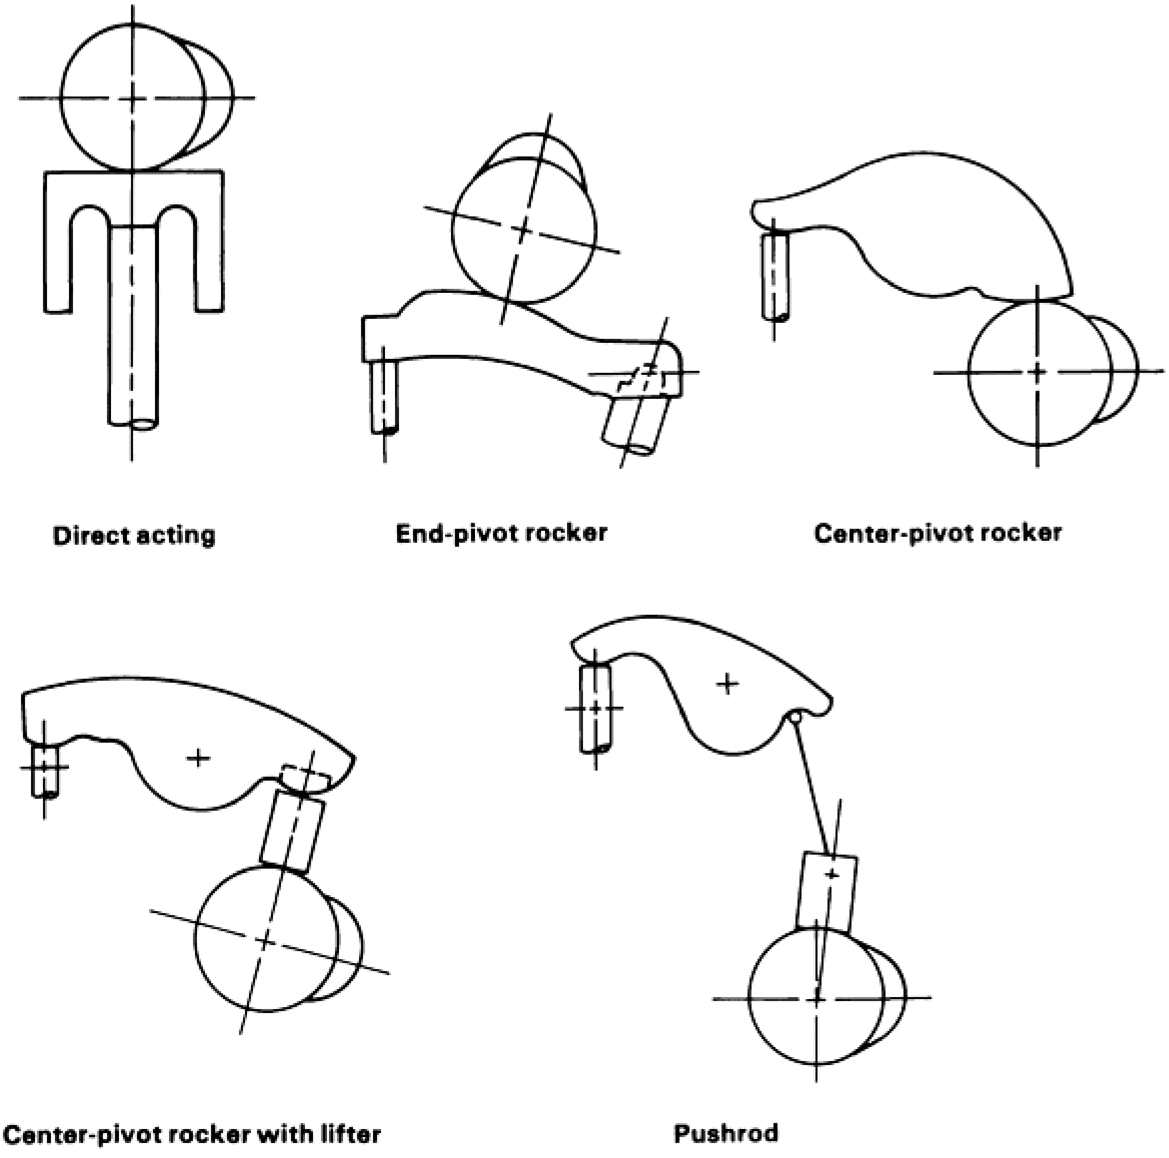

Fig. 10 Valve train designs. Source: Ref 23

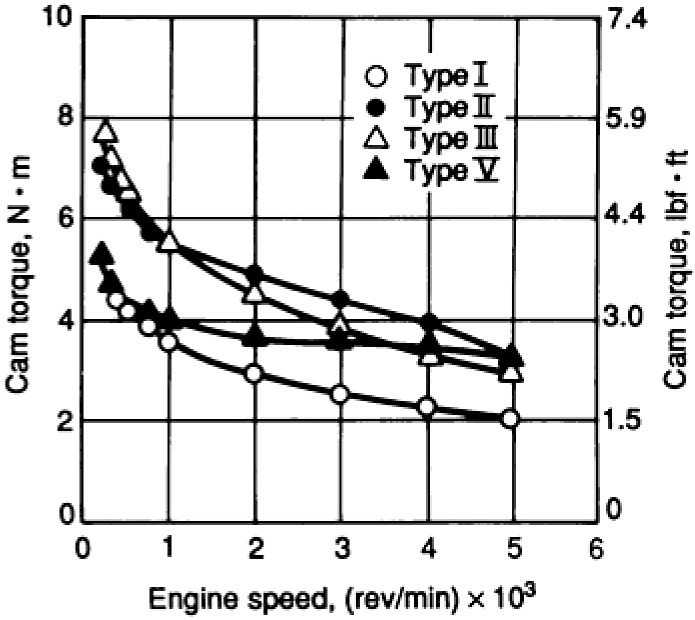

Fig. 11 Energy losses in various valve train designs. See also Fig. 10. Source: Ref 6

One effective method of reducing valve train friction is to use rolling-element bearings at critical locations. Such bearings are well suited to carry high loads at low speeds. Such designs (Fig. 12) have been used in racing engines. Rolling-element bearings are included at the cam-lifter interface, the rocker-arm pivot, and the interface between the rocker nose and the valve stem. Studies have shown that the valve train torque can be reduced by as much as 50% at 1500 rev/min using rolling-element bearings; the projected vehicle fuel improvement is 2.9% (Ref 4). Cam roller-followers of silicon nitride and partially stabilized zirconia are beginning to find application in diesel and automotive engines because they can replace a needle-bearing-type roller with a single, simpler rolling element, thereby reducing the weight of the engine. Disadvantages of the rolling-element bearing design include the susceptibility of the bearings to rolling-contact fatigue (see the articles "Friction and Wear of Rolling-Element Bearings" and "Rolling Contact Wear" in this Volume) and increased complexity and cost.

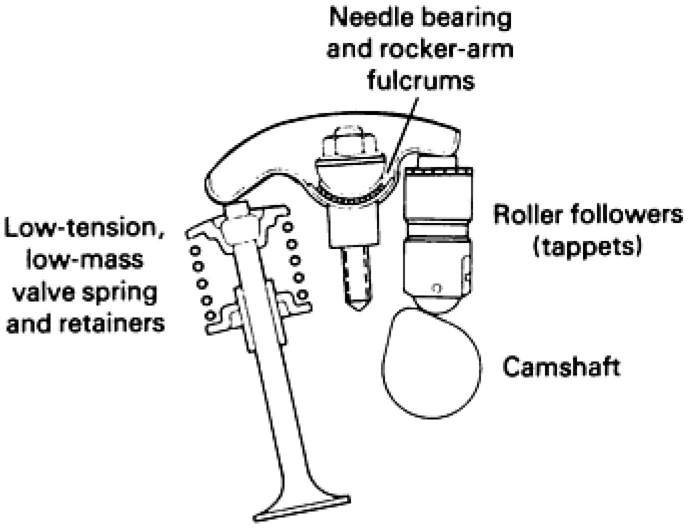

Fig. 12 Low-friction valve train design incorporating rolling elements. Source: Ref 22

An alternative to the rolling-element bearing approach is a reduction in valve spring load (Fig. 13). The projected improvement in fuel economy is about 0.5% (Ref 4).

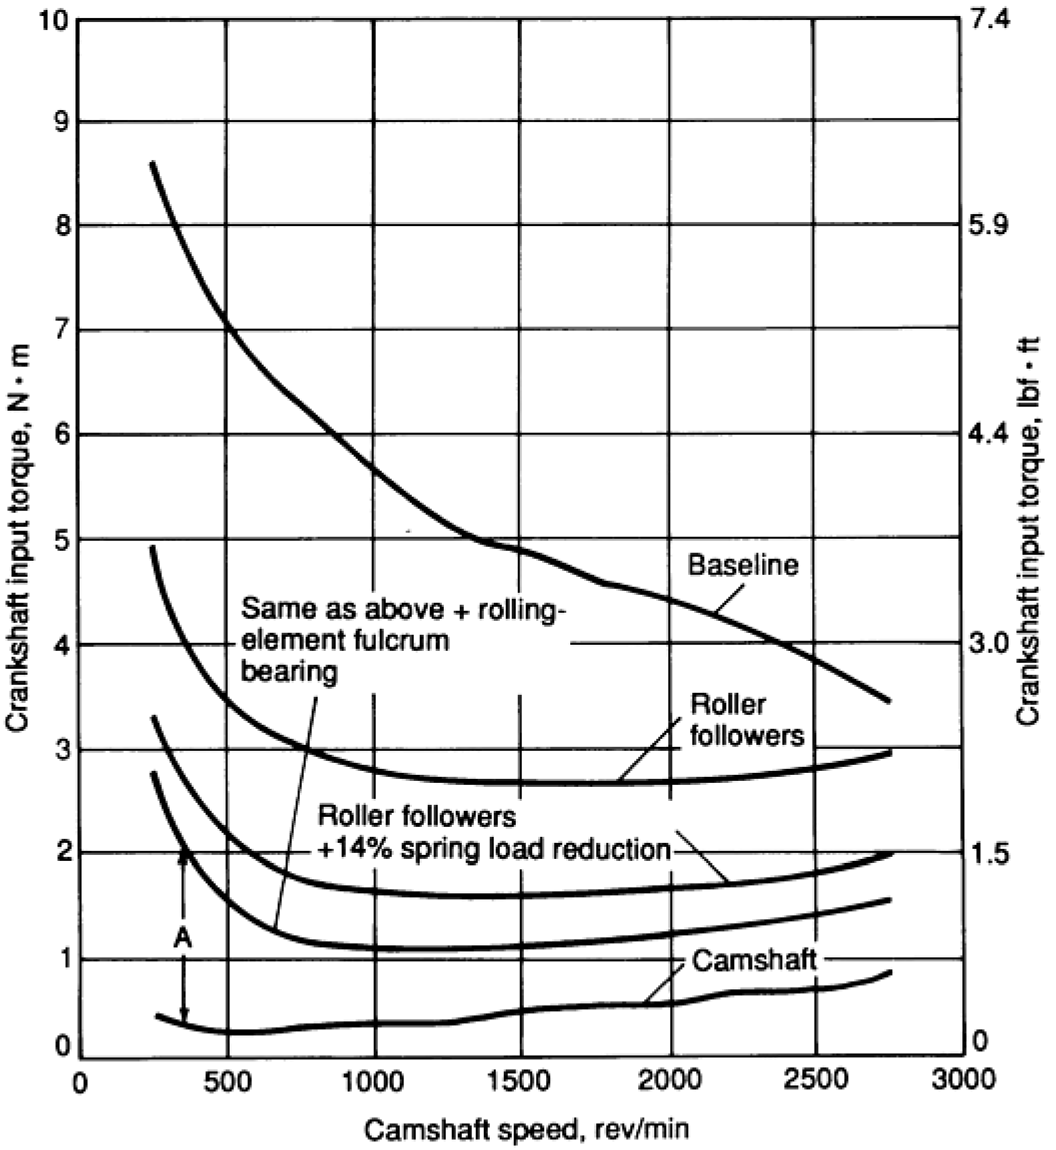

Fig. 13 Effect of reduced valve spring load on camshaft friction. Included in region A are valve guides, seals, rocker arm tips, fulcrum, tappets, and rollers. Source: Ref 6

A number of studies have also been conducted on valve train friction in terms of lubrication principles (Ref 22, 25, 26). These analyses have shown that oil viscosity has a relatively small effect on overall friction loss, but that a marked reduction in friction can be obtained with oils containing friction modifiers, or additives. Results from these studies (see Table 5 and Fig. 14) suggest that selection of the proper lubricant may reduce friction levels to those obtainable by component redesign.

Table 5 Lubricant characteristics for valve train friction analysis

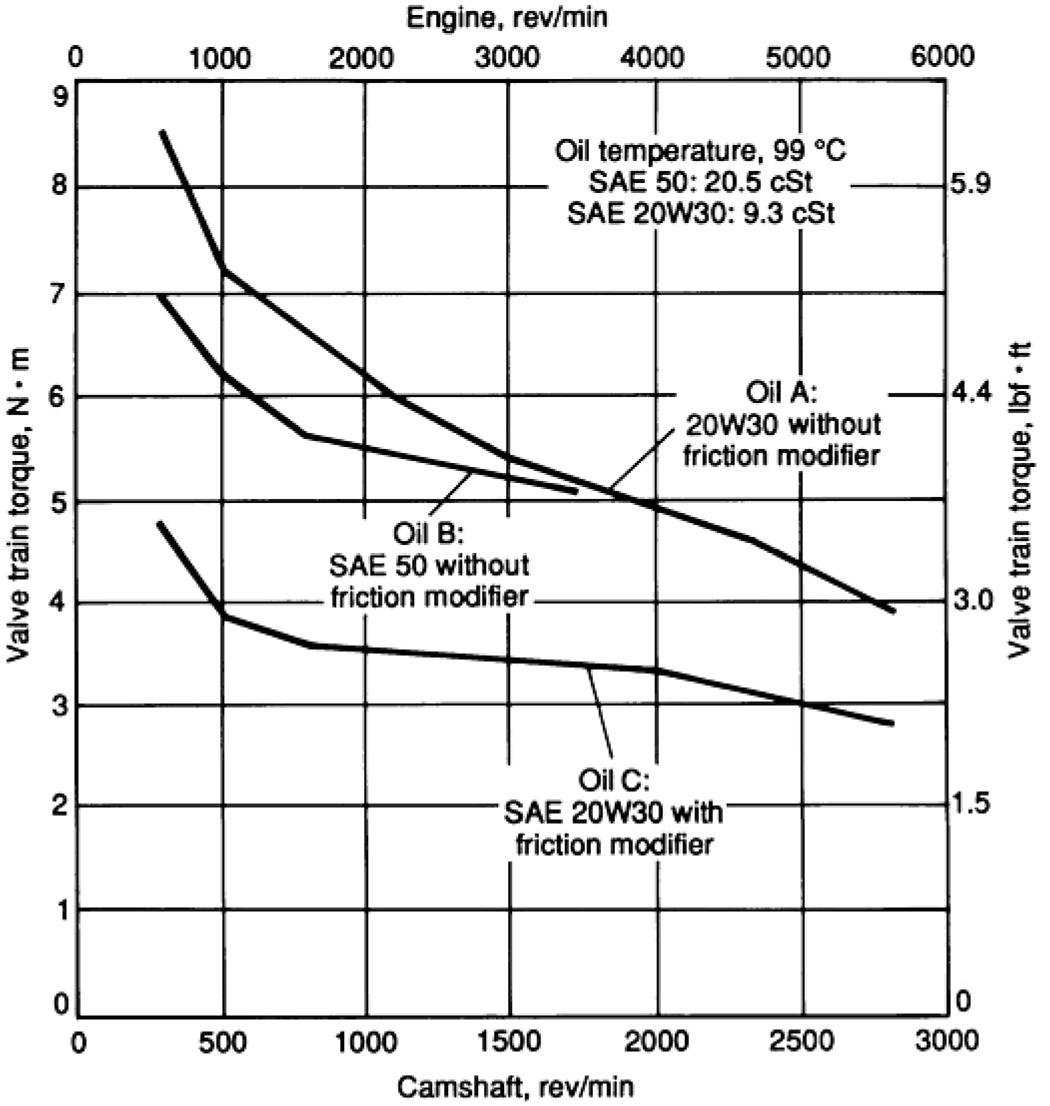

Fig. 14 Effects of oil viscosity and of a friction modifier on friction torque loss. See also Table 5. Source: Ref 22

Valve Train Wear. As with friction, the cam-tappet interface is also the most critical wear consideration. Under heavy duty, cams and tappets suffer from burnishing (due to adhesive/abrasive wear processes), scuffing (due to severe adhesive wear processes), and pitting (due to fatigue wear processes) (Ref 27). The wear modes for cams and tappets are very similar to those for gears (see the article "Friction and Wear of Gears" in this Volume).

The wear of cams and tappets can be reduced considerably by selecting hard material combinations or by hardening the cam material by heat treatments, thermochemical treatments, or by applying coatings. Hardenable gray iron camshafts (SAE Grade G4000d) are the most widely used; steels may be water-quenched carbon steels, oil-quenched alloy steels of

0.5 to 0.7% C, or a carburizing grade. The most common tappet material for automotive applications is gray cast iron of composition similar to the following: 3.20% C, 2.25% Si, 0.80% Mn, 1.10% Cr, 0.60% Mo, 0.55% Ni, 0.20% max P, and 0.10% max S (Ref 7). Ceramic materials such as silicon nitride are finding increased use as tappet shims and wear pads.

Types of coatings and surface treatments that can be adapted for cam and tappet materials to reduce wear include (Ref 27):

- *Running-in coatings,* such as phosphate coatings, chemically produced oxide coatings on ferrous metals, and electrochemically deposited tin and aluminum
- *Hard Surfaces.* Surfaces of cams can be hardened by diffusion treatment, such as carburizing, nitriding, and Tufftriding
- *Hard coatings,* such as TiN and TiC, can be applied by physical vapor deposition or chemical vapor deposition to cams and tappets to achieve low coefficients of friction and wear

Silicon nitride valves, while currently expensive, have been used very successfully in high-performance racing engines. Their low mass and high stiffness allow them to be used at the high speeds (>10,000 rev/min) typical of such engines.

Crankshaft Bearings (Ref 6)

Large loads are carried by hydrodynamic journal bearings (Fig. 4) with low energy losses during the engine cycle because of the complete separation of the two rubbing surfaces by a fluid film. Analysis of crankshaft bearing friction has been carried out by computer solutions, which calculate complete bearing performance (Ref 28, 29). Loads on crankshaft journal bearings vary in magnitude and direction because they are composed of inertial loads caused by compression and expansion events.

Bearing clearance and journal diameter are two important parameters that are controlled during the engine design process. The effect of bearing clearance on calculated bearing performance is shown in Fig. 15. As clearance increases, the bearing friction loss decreases, while the minimum film thickness exhibits a local maximum. Durability considerations suggest that to prevent bearing wear, maximum film thickness must be maintained. Thus, most journal bearings are designed to provide film thicknesses on the order of 2.0 μm. The friction power that could be saved by increasing journal bearing clearance beyond this maximum film thickness point is overshadowed by requirements for maintaining an adequate minimum oil film thickness.

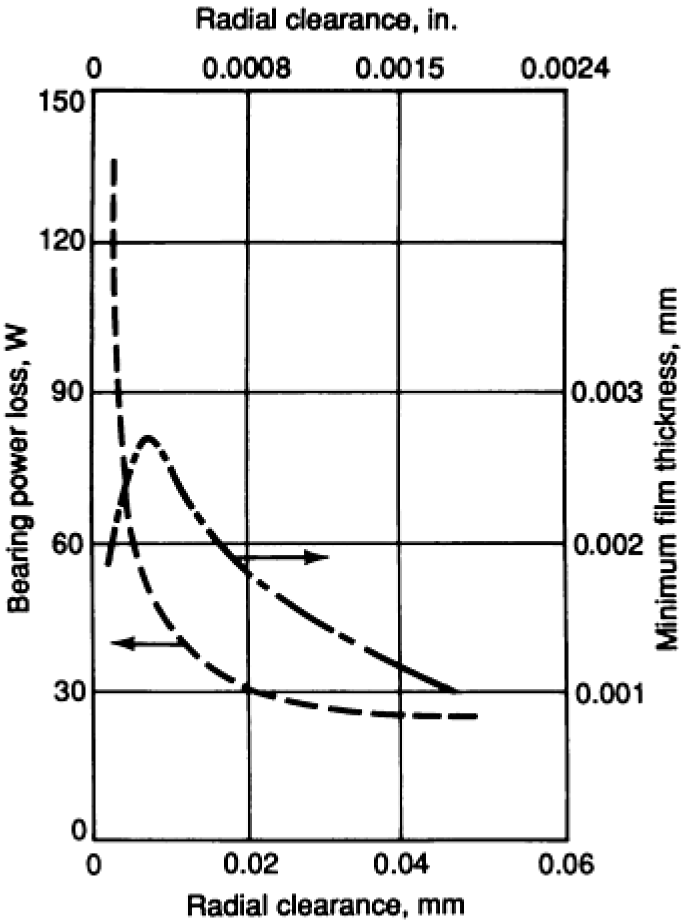

Fig. 15 Effect of bearing clearance on bearing performance. Source: Ref 6

Journal bearing diameters also significantly affect bearing power loss. Studies have shown that decreasing the rod journal diameter results in a 3 to 4% reduction in engine friction and a corresponding 1% improvement in fuel economy (Ref 19). It should be pointed out, however, that bearing diameter also controls the torsional strength of the crankshaft. Therefore, a design decision must be made between decreasing bearing diameters to reduce friction and the resulting loss in crankshaft strength.

Oil Pumps (Ref 4)

The types of oil pumps generally used in engines are the spur gear, internal-external gear, and tip-sealing gear (Fig. 16). These gears are typically driven at engine speed or half engine speed. Pump choice and drive ratio are usually dictated by available design space (especially length) and the selected drive mechanism. Once the location and drive are determined, noise, pressure fluctuations, cost, and efficiency trade-offs are considered.

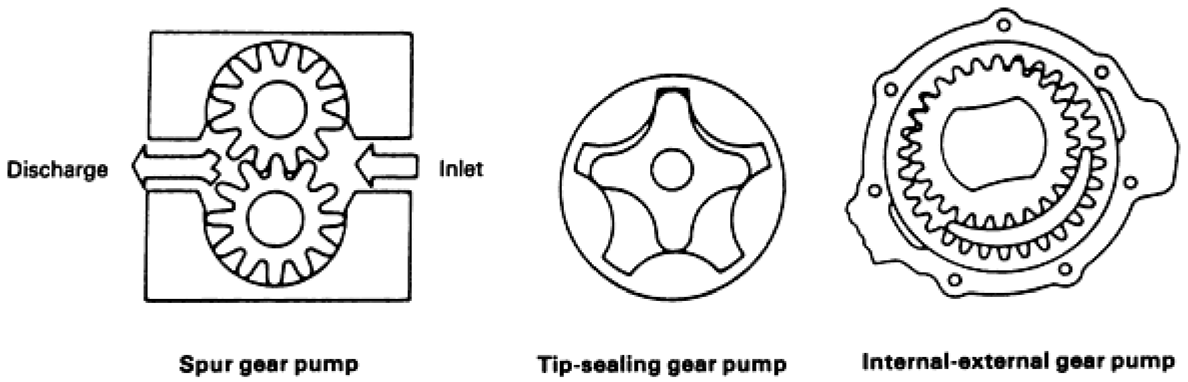

Fig. 16 Oil pump gear designs. Source: Ref 4

Engines with the camshaft in the block typically have a common drive shared by the distributor and oil pump; spur gear of tip-sealing pumps are used in such applications. These pump designs have relatively small diameters, which minimize friction losses between the gear outer diameter and the housing. Engines with overhead camshafts have no convenient half-speed oil-pump drive, especially if the distributor is driven from the camshaft. In this case, the designer must choose between providing an auxiliary shaft at extra cost or installing the pump on the crankshaft. The crankshaft option is usually selected for cost considerations, but the length of the pump is normally limited. This in turn forces selection of a thin pump (usually an external-internal gear type) with a large-diameter gear to provide the required displacement. The diameter of the outer gear is a function of the inner gear size required to go over the crankshaft. The large diameters of crankshaft-driven pumps result in higher losses because of the increased frictional torque. Figure 17 compares the input requirements measured for different pump designs. Fuel economy gains of 0.6% can be attained through proper pump design.

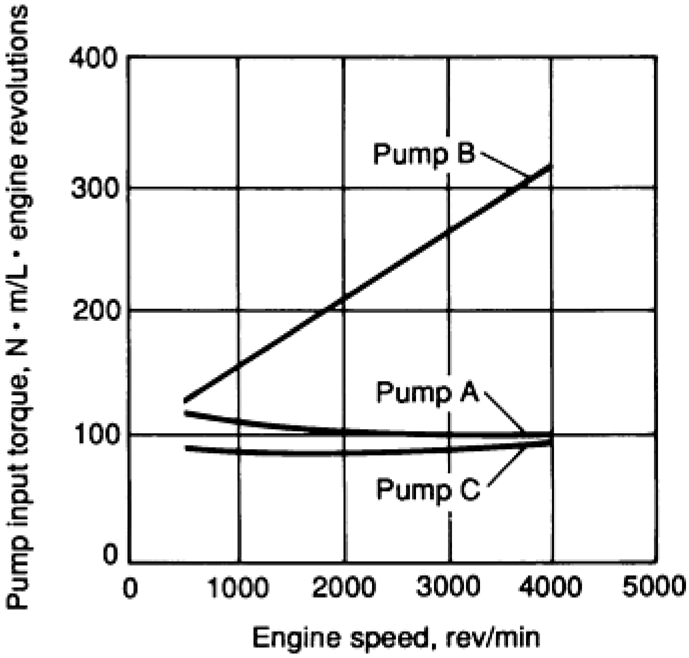

Fig. 17 Normalized oil pump power consumption. Pump A: tip-sealing gear, half-speed drive, 67 mm (2.6 in.) diameter. Pump B: internal-external gear, engine speed drive, 100 mm (4 in.) diameter. Pump C: tip-sealing gear, half-speed drive, 41 mm (1.6 in.) diameter. Source: Ref 4

Future Outlook

As new alternative fuels and more efficient engine designs are introduced, ceramics and ceramic coatings and composites will replace some of the traditional engine materials. Part of the reason for this substitution is that alcohol-based fuels are naturally less lubricious than traditional fuels and more durable surfaces are required to support their use. Aside from the cam roller-followers and valves mentioned above, other candidate parts for the use of ceramics include valve guides, tappet shims, turbocharger rotors, fuel injector pins, head plates with integral valve seats, and exhaust port liners. Despite the increased use of advanced ceramic materials, steels, cast irons, and aluminum alloys and their composites will remain important structural materials for the internal combustion engine.

Friction and Wear of Automotive and Truck Drive Trains

William Kelly, Borg-Warner Automotive, Inc.

Introduction

NORMAL WEAR CHARACTERISTICS of several major automotive power-train components are described in this article. The wear descriptions provided here are intended as sources of useful reference information for:

- Evaluating components in vehicle performance analyses
- Identifying minimum acceptance criteria in component endurance and durability testing
- Delineating a general indication of the expected operating life for major power-train elements in normal service applications

It should be emphasized that the issues addressed below represent those wear characteristics found in normal operating use. Typical operating life estimates have therefore been included. Abuse, neglect, and external influences beyond those normally associated with typical land vehicle operation are too varied in their effects on wear and too complicated to be considered within the scope of this article.

Empirical data, when available, are presented. Information deemed proprietary by the source, relative to specific wear-resistance methods, has been protected by normalized graphical methods, where required. However, the results of those wear-resistance preventative measures are detailed as much as possible. Typical wear-resistant features and designs are described for elements such as thrust surfaces and high-torque transmission components. The wear discussions in this article are confined to macroscopic views of wear effects. Applications are categorized by main vehicle component areas, and include automatic and manual transmissions, transfer cases, engine components, and wheel end components.

Automatic Transmission Components

The major source of wear for automatic transmission components has always been attributed to energy dissipation in the friction elements. The typical placement and use of friction products in an automatic transmission are shown in Fig. 1.

Clutch bands and clutch plates make up the friction element interface of the major wear components. The methods employed to minimize the wear effects on these friction surfaces are described in the section "Clutch Bands and Plates" in this article. Wear effects that result from seal degradation and the subsequent abrasive contamination are observed as a constant source of concern. However, from the normal wear perspective, seal wear associated with a properly designed and applied sealing system should not be significant during the normal operating life. A review of the normal maintenance procedures for automatic transmissions, where seal replacement is not specifically identified or required, supports the preceding statement. In addition, the proper maintenance and replacement of the automatic transmission fluid (ATF) or gear lubricant should not result in appreciable wear contributions, provided that adequate maintenance intervals are identified.

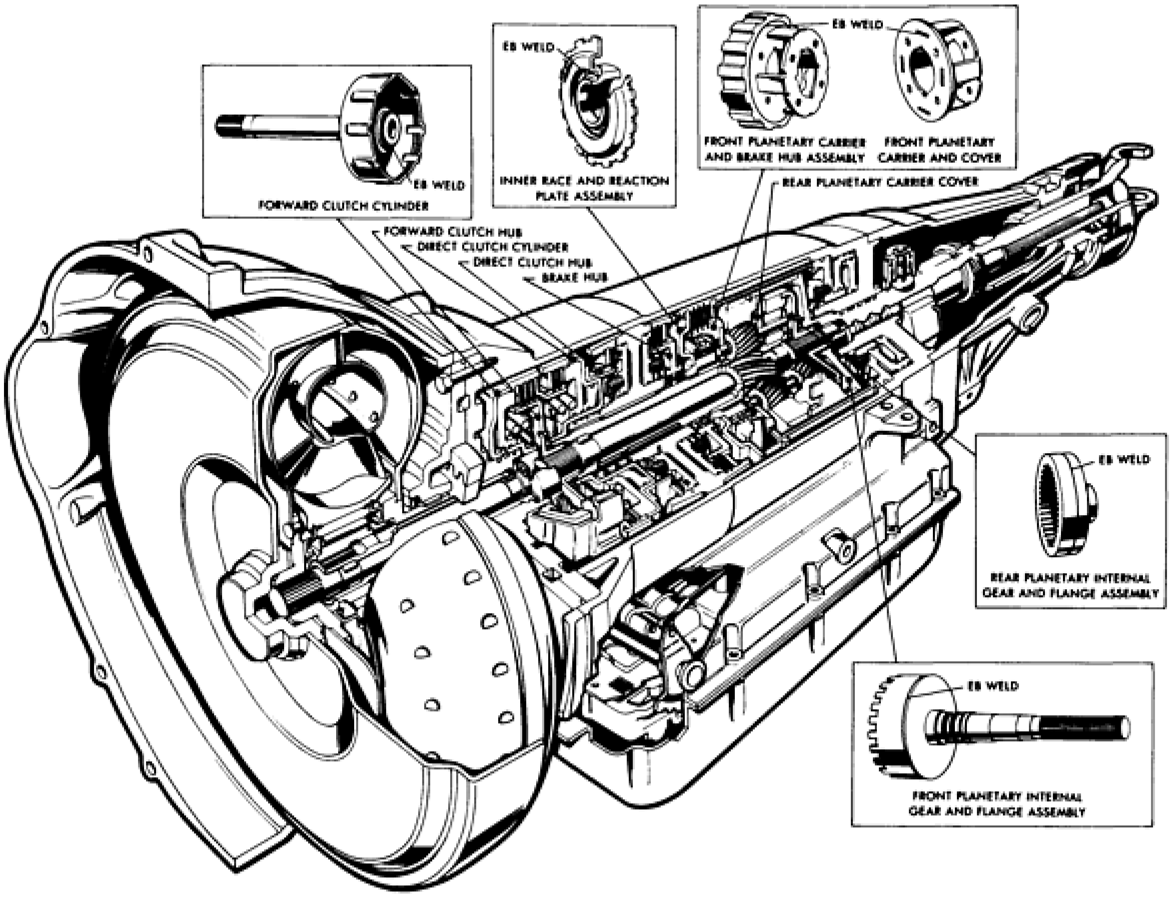

Fig. 1 Borg-Warner Model 12 automatic transmission. EB, electron beam

ATF Issues. The main method of wear protection relative to fluid maintenance is to maintain low levels of solid particulate contamination in the fluid reservoirs. Imbedded magnets, pump inlet filter screens, external cooling systems, and regularly defined fluid replacement schedules assure the highest performance levels in the automatic transmission. Because ATF is used to provide a heat rejection path, hydraulic power supply, and lubrication, many additives are used to serve the multipurpose functions for the fluid. Some applications result in up to a 10 vol% additive content in ATF.

Much literature has been dedicated to wear resistance and the related properties of ATF (Ref 1, 2). Specific benefits and detriments of the additives used to enhance ATF operating characteristics must be closely evaluated in the early development stages of a new product. For example, the compatibility of the ATF to the insulation systems of electrical components should be confirmed. This is typically done through the use of hydrolytic stability testing for the insulation system in short-term, high-temperature test programs.

Clutch bands and plates are fabricated from steel stampings with a variety of material coatings that provide the friction interface. In general, low-energy applications (~820 W/m^2) utilize paper-based or organic friction products, whereas high-energy applications (~1600 W/m^2) utilize bronze-base or semimetallic friction products. The performance

of both paper and semimetallic products, when properly applied and adjusted, has been observed to be acceptable over the full vehicle operating life (193,100 km, or 120,000 miles) without replacement. The normal wear associated with this type of application is 50 μm (2 mils) per band apply or clutch plate. For example, a five-plate clutch pack can be expected to wear a total of 250 μm (10 mils). The normal wear that is characteristic of a paper-lined clutch plate for 193,100 km (120,000 miles) of vehicle service is shown in Fig. 2. The distribution of this acceptable level of wear is critical to the overall success of the friction product application.

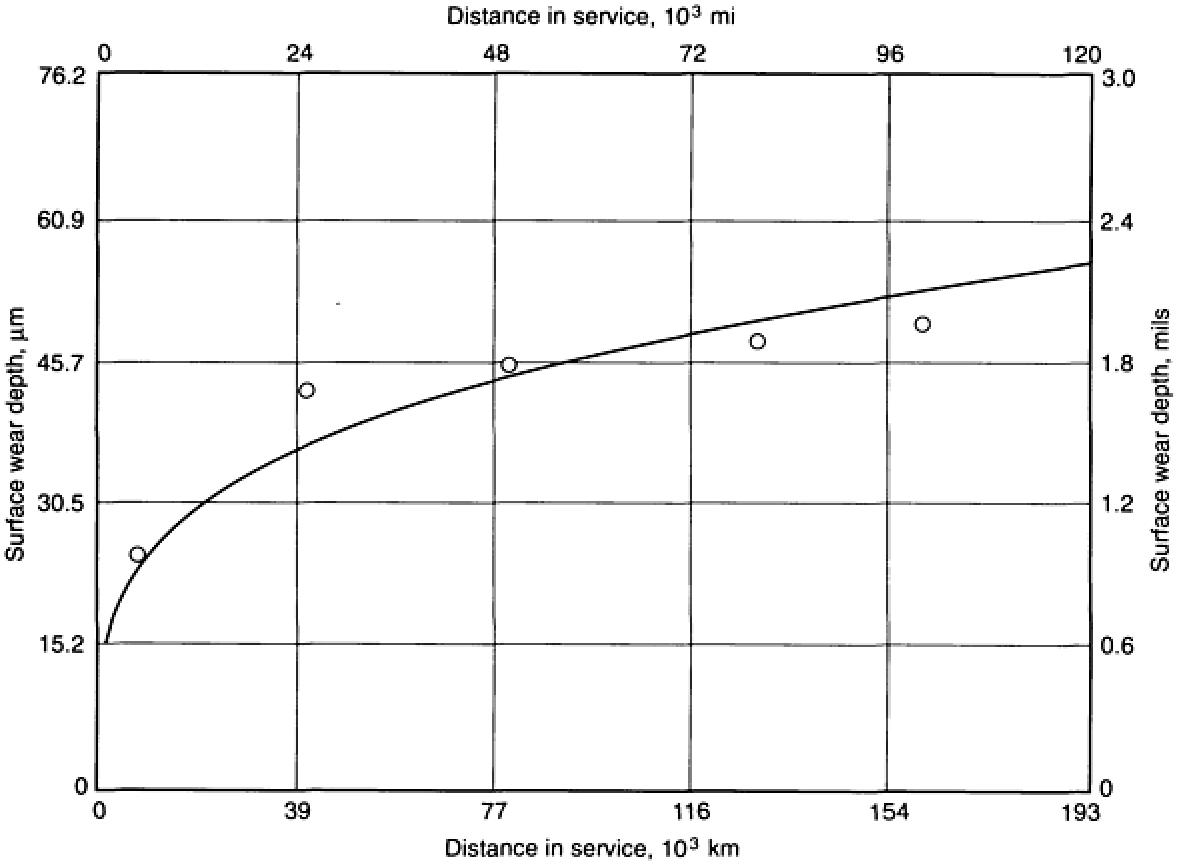

Fig. 2 Paper clutch material wear characteristic curve

Much work has been done in the design community to assure a high level of evenly distributed wear, thus providing a maximum life expectancy for the application. Paper and organic friction products characteristically have a more even wear distribution, compared with semimetallic and full-metallic clutch plates, because of the lack of resilience or compressibility of the metallic-based products. The basic elements for the successful application of friction products in automatic transmissions are provided in Ref 3.

With the increased use of electronically controlled transmissions, optimized shift strategies can be easily implemented to provide low-energy shift requirements throughout the entire engine speed and torque schedule. The engine management function typically allows a slight reduction in spark and fuel injection prior to the clutch plate or clutch band application. Once the shift has been completed in the transmission, the engine firing schedule is returned to normal. Typical shift times in the transmission are held below 0.7 s. The amount of engine retardation and elapsed shift time for optimal shifting are tailored to each application. The engine spark and fuel injection inputs can be reduced by up to 20% in some vehicles, with little noticeable effect to the driver.

Proper management of the hydraulic shift system also contributes to maintaining the lowest possible levels of wear. Some aspects of the hydraulic control system design for automatic transmissions are provided in Ref 4.

Clutch band and plate wear take the form of surface burnishing and polishing. High spots and surface imperfections are usually worn away very rapidly in early clutch applications, forming a wear-resistant surface with excellent wear-

resistance properties. In the case of paper and organic materials, compression set usually makes up the balance of the total estimated wear depth.

There are many variables, beyond energy dissipation, that must be considered when selecting the proper friction material for an application. Generally, material characteristics such as the rate of thermal conductivity, resilience, and fluid absorption play key roles. With respect to operating conditions, the presence or absence of lubrication fluid is the most critical, followed closely by a thorough understanding of the rate of applied load, engagement cycle time, and overall capacity objectives.

A review of the performance of automatic transmissions being provided to the market indicates that the optimization of design and manufacturing characteristics has been successfully achieved, resulting in high performance levels and satisfactory durability and reliability.

Manual Transmission Components

A typical manual transmission being produced in the early 1990s is shown in Fig. 3. The major source of wear varies, depending on the type of fluid fill used. Table 1 illustrates the variety of fluids used in manual transmissions currently in production.

Table 1 Various manual transmission fluids

Transmission	Manufacturer/application	Lubricant used
4-speed	GM/MC9	DEXRON II
4-speed	GM/M20	SAE-80W-90
5-speed	Getrag/MG290	SAE-05W-30
5-speed	Mitsubishi/Ford	SAE-80W-85
5-speed	Mazda/Ford	MERCON

Note: Fluid types based on review of 1990 GM and Ford light truck service manuals

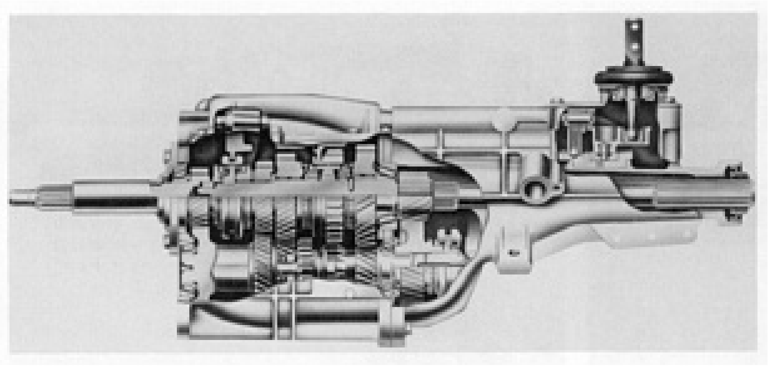

Fig. 3 Borg-Warner T-5 manual transmission

Engine oil and gear lubrication units generally experience little or no observable wear in the normal vehicle operating life. In this type of lubrication environment, gear mesh and bearing performance is generally superior to that of ATF-filled assemblies. An area of wear that is considered noteworthy in the gear lubrication equipped units is blocker ring tooth profiles and come synchronizer friction interfaces.

Synchronizer Wear. Examination of manual transmissions after extensive vehicle mileage accumulation often reveals some material loss on blocker ring engaging teeth. The wear takes the form of tooth edge rounding and flattening, which results from forced engagement under nonsynchronized conditions within the synchronizer assembly. This phenomenon is commonly referred to as clash. Detailed discussions of the symptoms and effects of clash, along with design practices to minimize its effects, are provided in Ref 5.

With respect to the come clutch friction interface, surface wear is a direct function of the energy dissipation when lubrication flow and availability are not compromised (as in the automatic transmission discussion). The same material selection rules apply relative to energy dissipation levels. Low energy requirements are best served by paper- and carbon-base products. High-energy applications utilize semimetallic or bronze-base materials. It is generally believed that cone geometry has increased sensitivity to uneven wear distribution, when compared to clutch band and clutch plate designs. This may be true, because of difficulties in maintaining proper cone-element alignments. Cone clutch performance for gear lubrication units in cold-weather applications is noticeably degraded, when compared to an equivalent ATF application. High-viscosity oils do not evacuate from the cone interface as readily, resulting in lower-than-anticipated dynamic friction values at the interface. This results in higher manual effort shifts and potentially accelerated blocker ring wear.

Cluster Gear Wear. In ATF-filled units, it has been observed that some cluster gear interface or mesh area wear would be considered normal. Typically, total wear of 125 μm (5 mils) would be permissible between the interfacing gears. The distribution of this amount is not considered to be critical, although it is obviously undesirable to accumulate the entire wear allowance in one gear set. The wear takes the form of surface polishing and some material loss at the tooth involute form (TIF). Detailed discussions relative to the mechanics of gear mesh wear are provided in Ref 6. The main preventative methods used to enhance wear characteristics for gears are to properly select base material and surface finish and to optimize gear design to provide the best pitch line velocity for a given torque capacity requirement.

High pitch line velocities can produce high localized heat zones in the contact area, because of friction. Therefore, reducing the load and speed conditions at the gear TIF improves wear characteristics. With regard to optimized gear design, some general sizing rules have proven successful over the years. Figure 4 illustrates the relationship between manual transmission torque capacity and center distance.

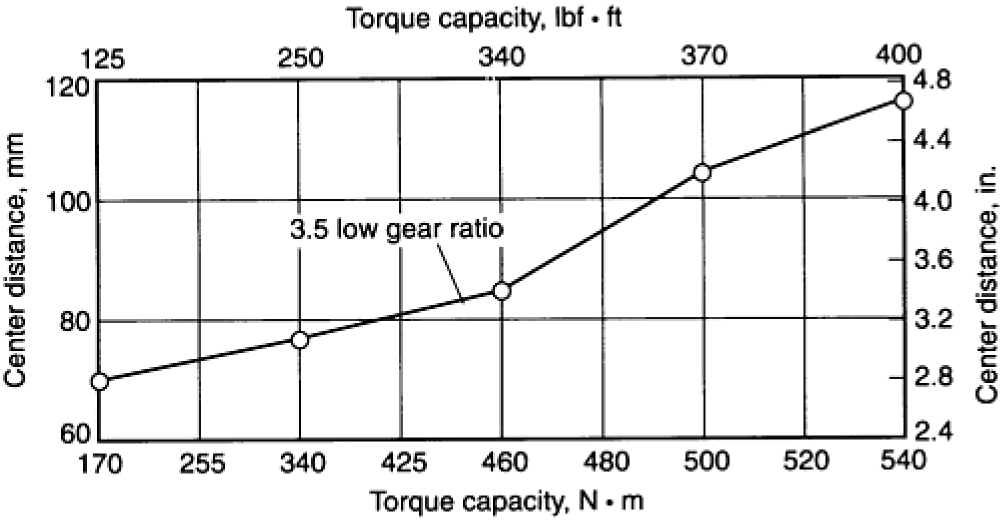

Fig. 4 Transmission torque capacity versus center distance

Significant departures from this generic curve have been achieved and are in production. However, large incremental improvements in torque capacity for no change in center distance are difficult to achieve and usually involve more exotic gear material selection, as well as additional surface finish and hardening processes. It should also be noted that the resulting ratings obtained from an individual line of the torque capacity graph are directly proportional to the depth of the first-gear ratio. Higher numerical first-gear ratios result in increasing the center distance requirement for a specified torque capacity objective.

Tapered roller bearings are widely used in current designs for manual transmissions. To a transmission designer, a significant source of wear involves the loss of bearing preload in the transmission, resulting in increased endplay and, consequently, revised gear mesh conditions. Figure 5 depicts the change in preload over the useful life of the transmission. Normal transmission wear can result in up to 250 μm (10 mils) of endplay on a unit that may have been originally assembled to a preload of from 50 to 75 μm (2 to 3 mils).

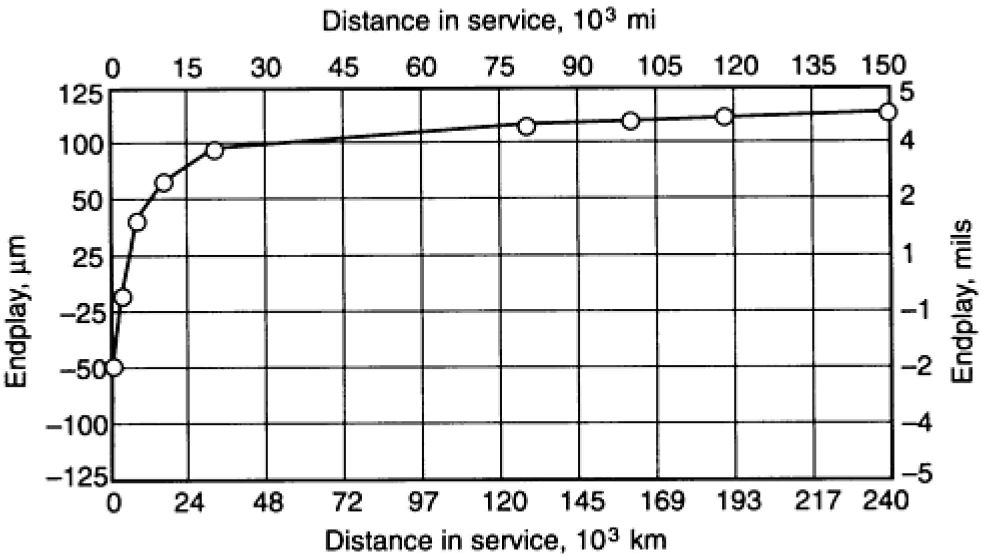

Fig. 5 Characteristic curve for change in assembly preload

There is some debate as to the root cause of the loss of preload. An acceptable premise for the wear may be that the tapered roller bearing elements, namely the outer bearing race, has reseated itself in a position determined by the dynamic action of the transmission during normal operation. Sensitivity studies have been performed, in which excessive (exceeding 250 μm, or 10 mils) endplay units have been built and subjected to various long-term durability tests. Test results indicate that the transmission can maintain satisfactory in-vehicle performance with no appreciable added wear.

Transfer Cases

Although the function and duty cycle for transfer cases vary significantly, their normal wear attributes are quite similar. Part-time units (Fig. 6), like those found in many popular off-road vehicles and light-duty trucks, exhibit chain and sprocket wear that is similar to those units that operate on a full-time basis (Fig. 7).

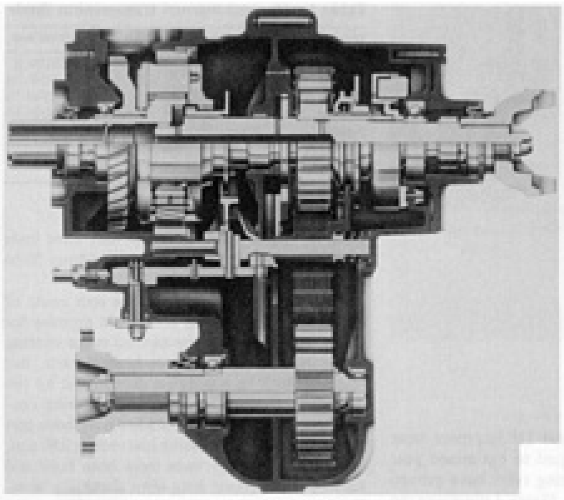

Fig. 6 Borg-Warner part-time transfer case

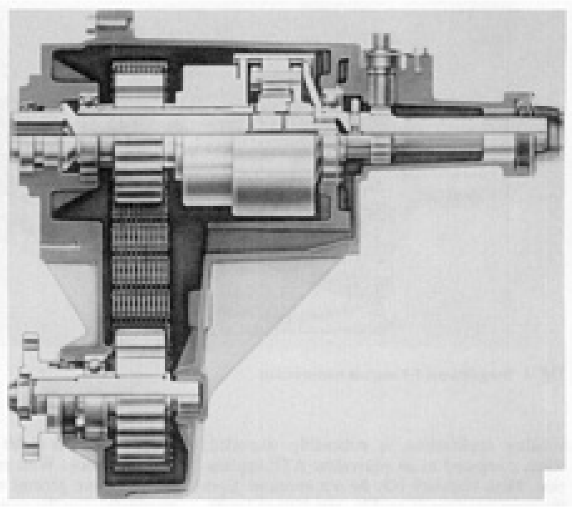

Fig. 7 Borg-Warner full-time transfer case

Sprocket and Chain Wear. The wear observed on the sprockets is a direct function of the chain mesh pattern. Many sprockets utilize sintered powdered metal technology to form the sprocket tooth. The normal wear for this tooth includes a depth from 125 to 250 μm (5 to 10 mils) on the tooth flank in a pattern formed from the hardened chain links. Local pitting zones are not unusual with long life or with heavy usage rate units that have interconnected pitting zones, forming a solid line across the tooth profile.

Some applications use wrought steel or forged sprockets, for which the wear characteristics are somewhat different. The drive sprocket wear appears as a series of depressions that are usually closely aligned with the chain-link construction. The driven sprocket wear takes the form of smearing across the chain sprocket mesh line. Drive sprocket wear is always heavier than that of the drive sprocket.

The wear of the chain has its own unique characteristics. The expression for chain wear is usually termed stretch. The maximum allowable stretch cannot exceed the length required to ensure that the chain will remain on the sprocket during operation. The point at which the chain can leave the sprocket tooth form can be described in terms of percent of pitch elongation. Chains that elongate beyond 25% of pitch are considered failures. The typical expected chain elongation for properly lubricated chain running on specified sprocket tooth forms is shown in Fig. 8. Experience with properly sized and lubricated full-time units has shown that normal expected chain stretch, in terms of percent of pitch, is on the order of 5 to 10%.

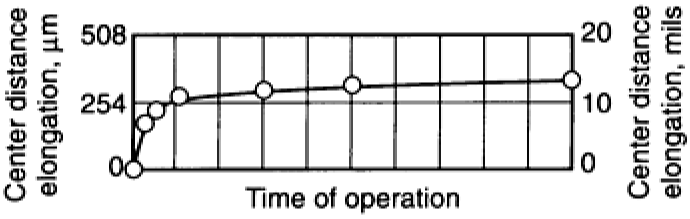

Fig. 8 Typical wear for chain applications

Several chain-link construction methods are in use today. Figure 9 illustrates two of the available configurations.

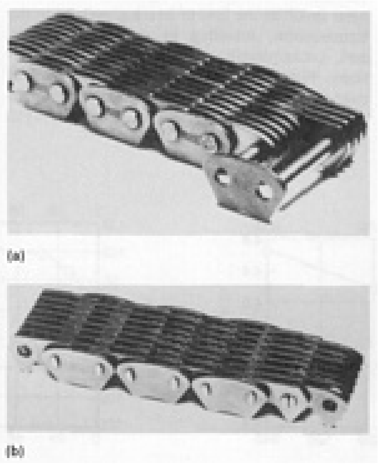

Fig. 9 Chain design examples. (a) Round-pin design. (b) Rocker-joint design

For transfer cases, the basic approach taken to accommodate the sprocket tooth form wear and chain stretch potential is to design an adequate chain operating envelope into the surrounding castings to ensure proper lubrication and minimize the development of churning effects. When sizing a chain for a given application in a transfer case, the maximum available engine torque and vehicle weight ratings are used to determine the chain pull load. Equations 1 and 2 represent the maximum available engine torque and skid torque, respectively.

$$T_{\text{stall(automatic)}} = E_t g_a t_s \quad \text{(Eq 1)}$$

where E_t, the maximum available engine torque, is 300 lbf · ft; g_a, the highest numerical gear ratio, is 2.7; and t_s, the torque converter stall ratio, is 1.8.

$$T_{sf} = \frac{\mu R_r F_{gawr}}{A_r \, 12 E_p} \quad \text{(Eq 2)}$$

where μ, the coefficient of friction, is 0.8; R_r, the tire rolling radius (dynamic), is 11.93 in.; F_{gawr}, the front axle gear wear rating, is 2926 lb; A_r, the axle ratio, is 3.62; and E_p, the power-train efficiency, is 0.85.

The application torque through the chain is directly related to the chain pull force and, consequently, to the degree of chain stretch observed over the useful life of the product. Figure 10 shows actual field measurements made on chains in service in an all-wheel drive application for units ranging from very low mileage accumulation to over 160,900 km (100,000) miles) of service. Curves of this type are developed for part-time units, as well. However, because of the variability associated with the degree of full-load chain service, wear data are not as easily interpreted.

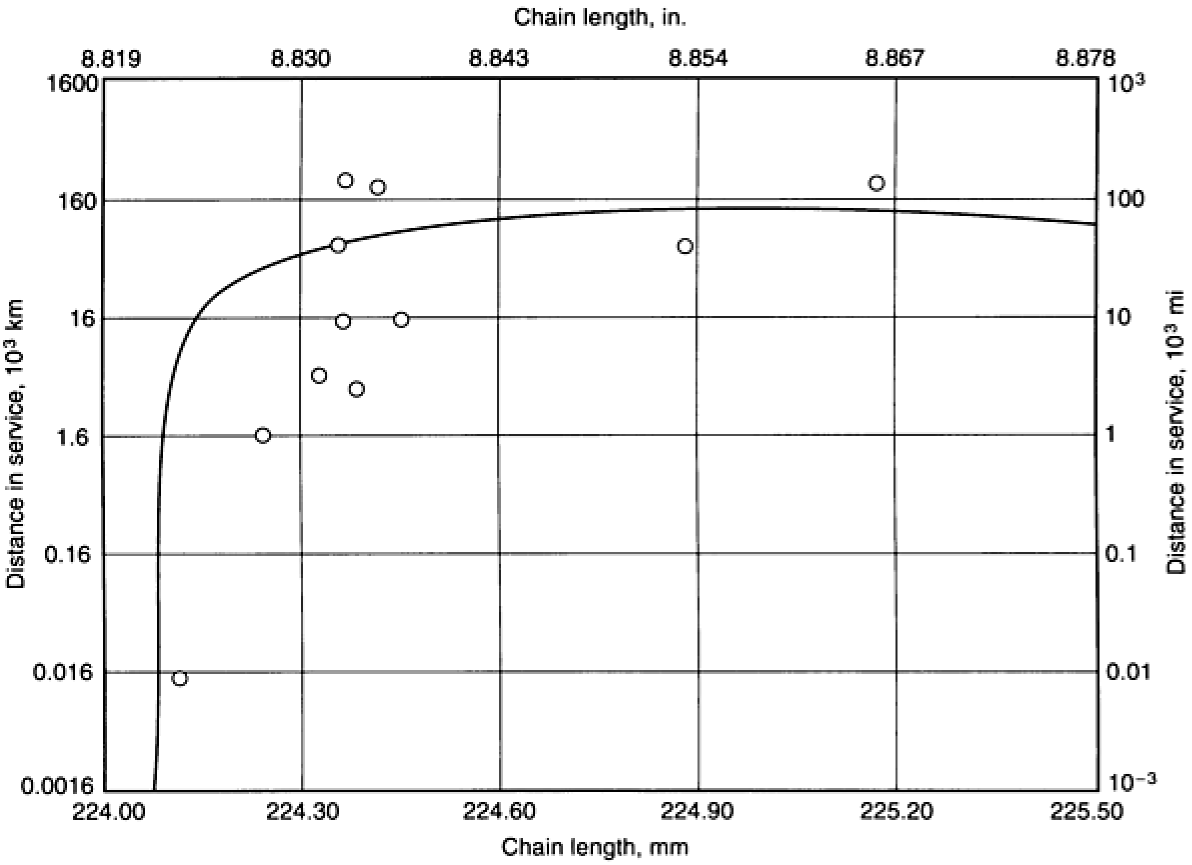

Fig. 10 Chain stretch field data

Another important wear characteristic observed in part-time transfer cases equipped with speed-reducing gear sets and internal shift systems is thrust surface wear. Because of the part-time nature of the transfer case operation, the potential for combined high-speed differences and axial loading for internal components is high. The two major wear areas can be found in the shift system fork pad and the helical reduction gear set thrust surface areas.

Thrust Surface Wear. Many transfer cases manufactured today use cast aluminum or cast iron shift forks with polymer inserts for dog-clutch movement. After many miles of continuous duty, the polymer insert material may wear to the point that the dog-clutch positioning is compromised and the vehicle does not maintain drive. This condition is precipitated by small axial loads or thrust loads between the rotating dog-clutch flange and the stationary polymer insert pad.

Material selection for the insert pad must consider the degree of thrust load applied, in conjunction with maximum speed differential and anticipated duty cycle. The load and speed relationship to wear has been well investigated and documented in terms of polymer compositions. Material suppliers are generally able to provide load and velocity capability for a material, *PV,* as well as wear factors, *K,* which are usually defined as the ratio of volumetric material reduction, *W,* to applied force, *F,* velocity, *V,* and elapsed time, *T.*

$$K = \frac{W}{FVT} \quad \textbf{(Eq 3)}$$

In addition to superior *PV* performance, polymeric materials should have high impact resistance in this type of application, because of the cyclical nature of the thrust loading. This characteristic separates the fork pad wear thrust materials from those used in reduction gear sets. In the gear set applications, the speed difference ratio between two thrust members is held constant, because of the nature of the gear set design. The forces developed between thrust surfaces in reduction gear sets is directly related to the gear set geometry (helix angle) and the axial power-train compliance.

Although the gear set geometry effect is readily available through calculation, the power-train axial compliance is a much more difficult parameter to quantify. When high thrust loads are present and the application variability is significant, thrust washers are provided on all interfacing surfaces. The most widely used and successful thrust washer material is VESPEL, a DuPont product. It is a polyimide resin that can be available in direct-formed shapes or machined from solid stock.

Engine Components

This section reviews the interesting wear characteristics for engine turbochargers. Significant material is provided in the article "Friction and Wear of Internal Combustion Engine Parts," relative to wear.

The durability and reliability of turbochargers is often underestimated in the North American marketplace. Turbochargers can provide 99.5% reliability for 160,900 km (100,000 miles) of vehicle service. For the turbocharger designer, the key challenge, with respect to wear prevention, revolves around a thorough understanding of sealing and cooling in an environment where shaft speeds can reach 150,000 rev/min and maximum gas temperatures can be 705 °C (1300 °F). A cross section of a typical turbocharger design for an automotive engine application is shown in Fig. 11.

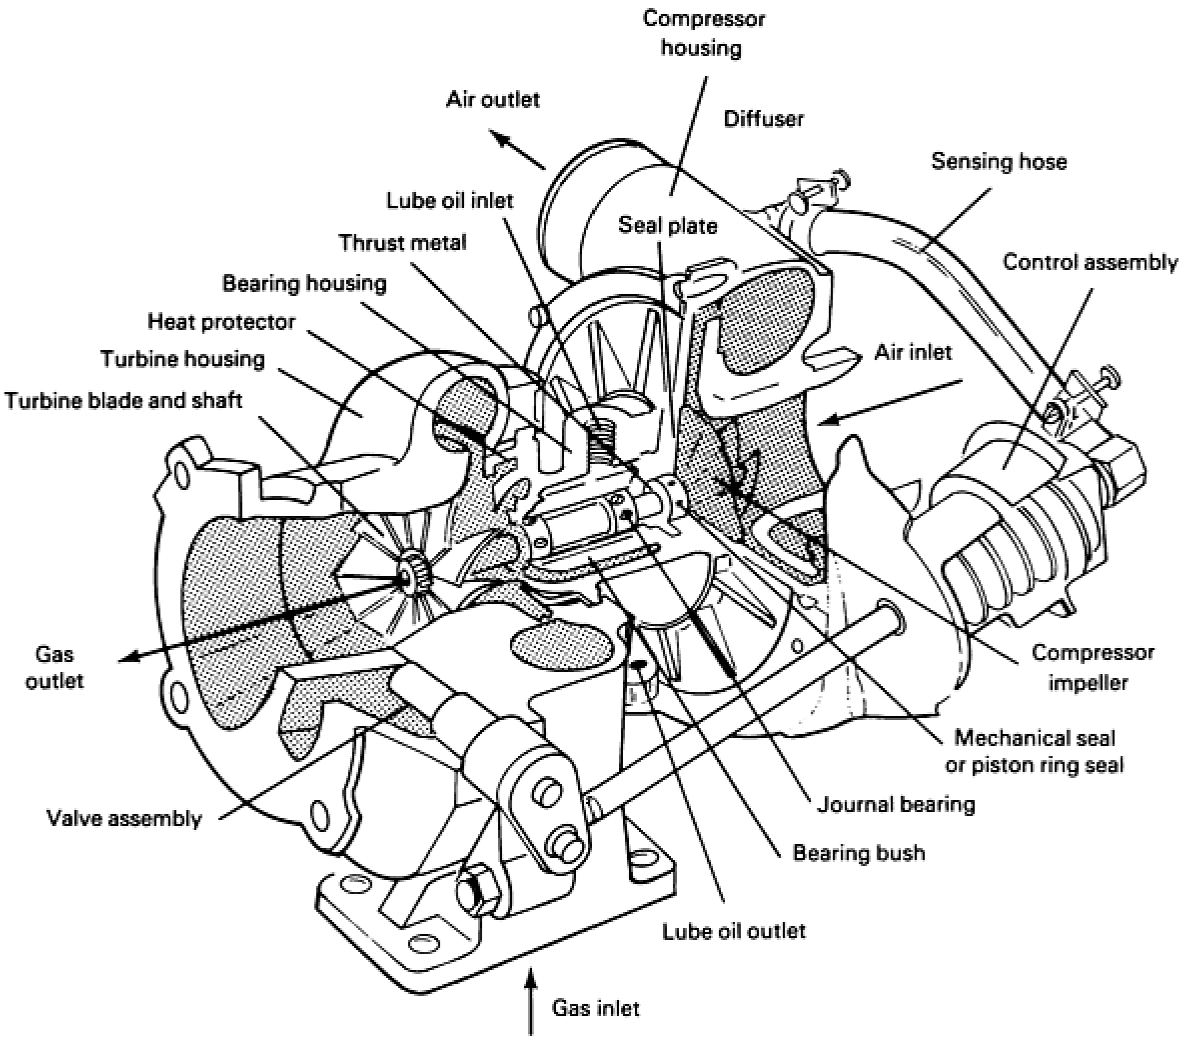

Fig. 11 Warner-Ishi RH series turbocharger

As is the case for most mechanical systems, rotating members must be provided with adequate lubrication to ensure long-term operation. The turbocharger uses an intricate lubrication strategy to deliver controlled quantities of oil to mainshaft journal bearings and bushings, in order to minimize wear and take advantage of hydrodynamic and aerodynamic sealing technologies. In early turbocharger designs (before the use of fuel-injection systems), the compressor housing/turbine

housing interface design utilized a mechanical seal with a carbon-base material and a combination thrust washer seal plate that provided controlled deformation and material transfer to account for the very high *PV* conditions created by the normal operation of the turbocharger. Unlike seals found in normal power-train applications, turbocharger mechanical seals were most efficient and effective at very high operating speeds and pressures. At low speeds, the seals were inefficient and accounted for high drag losses in the assemblies. Many of the turbochargers used with fuel-injection-equipment engines use metallic piston ring seal designs. These designs emphasize improved aerodynamic features to lower the "blow-by" potential in the piston seal location.

With respect to the wear and deformation that occurs at the thrust plate, a review of the general maintenance procedures for turbochargers indicates that the expected wear on the thrust washer seal plate for an "end-of-life" unit would range from 25 to 38 μm (1 to 1.5 mils) of endplay. The most significant wear contributions have been observed in the gasoline-engine-equipped systems, where very high operating temperatures are present and external cooling systems may not be readily available. Under these circumstances, the mainshaft bearing temperatures can become elevated to the point that evaporative lubrication residue (coking) can significantly reduce the efficiency of the hydrodynamic bearing system. Diesel-engine-mounted systems have traditionally operated at much lower temperatures and have improved performance.

Some designers are in the process of evaluating fluoropolymer sealing systems. These systems are required to function in the same high-speed, high-temperature environment as the mechanical seals. Because fluoropolymers have good thermal degradation resistance at high temperatures and very good self-lubricating characteristics, their use in this type of application has promise.

Wheel End Components

Part-time four-wheel drive vehicles require the ability to engage and disengage the front drive axle during vehicle operating mode changes from two- to four-wheel drive. For many years, this function has been provided by automatically engaging wheel end hubs. Figure 12 illustrates a typical torque-activated automatic locking hub.

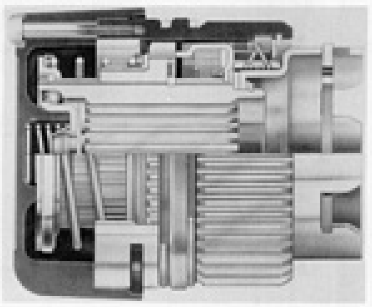

Fig. 12 Borg-Warner automotive 17-01 automatic locking hub

Because the principle of operation for the locking hub requires that a near-synchronous shift potential be provided by some external torque source, and because the locking hub has no internal synchronizer capacity, the preventative wear and long-term durability objectives are based on providing very high wear resistance for small, thin cross-section gears and cam surfaces. The lack of a renewable lubrication supply and the difficulties in providing long-term sealing features under the extremes of temperature and vibration result in careful material selection, exotic lubrication strategies, and inherent design features that will allow nonsynchronized gear mesh to take place without much resulting wear.

Typically, a dog-clutch arrangement is employed to provide the physical connection between the wheel end and the axle shaft spindle. The axial displacement of the dog clutch is accomplished with the positive displacement features of cylindrical cam surfaces under rotation. The dog-clutch/cam surface interface depth of wear is usually not allowed to exceed 125 μm (5 mils) over the life of the product. The wear tolerance is usually taken up in the cam follower tips and flanks and in the inner cam surface. Springs are used to assist in the axial displacement of the dog clutch during the engagement cycle. Because there is typically no internal synchronizer feature, the spring duty cycle is a direct function of the success of penetration of the dog clutch into the overspeeding receiving gear.

Special tooth chamfers are employed in an effort to reduce tooth edge or butt wear during the penetration. The chamfer surface may be expected to wear on the order of 380 to 635 μm (15 to 25 mils) for the full service life. The degree of wear is directly related to the multiple high-speed engagement duty cycle. Engagement systems that do not provide some gear tooth form chamfer in the dog clutch often show heavier wear and undesirable shift quality as a result of repeated tooth edge engagements. These types of systems generally have a higher degree of brinelling in the tooth edge area, to the point that the effective tooth form is wider, thereby further reducing the likelihood for successful dog-clutch penetrations.

Friction and Wear of Automotive Brakes

Arnold E. Anderson, Consultant

Introduction

AUTOMOTIVE BRAKE LININGS, as a group, include those used for passenger car and light truck drum and disk brakes, heavy truck and bus drum brakes, and off-road vehicle drum, band, and disk brakes. This article addresses all of these friction materials that nominally operate dry. Wet brake linings, that is, those that are oil immersed, are beyond the scope of this discussion.

Brake friction and wear characteristics are sensitive to brake design and lining composition effects, as well as to temperature, rubbing speed, pressure, and prior usage history. Wear of the brake drum or disk is often more sensitive to road dust and local rust debris than to friction material composition.

The wear and frictional behavior of these material pairs is amazingly complex, and is characterized by nonsteady-state high-temperature and high-pressure processes. Contact asperities reach flash temperatures ranging from 1000 to 1100 °C (1830 to 2010 °F) in about 1 ms, and then cool as other contacts become active. To avoid thermoelastic instabilities, heterogeneous and often highly anisotropic friction materials have been developed. Because meaningful patent protection is difficult to obtain, friction materials tend to be highly proprietary formulations.

Poorly understood tribological mechanisms and obscure compositions preclude the ability to present a classical, scientific approach to brake lining friction and wear. However, a survey of brake performance effects is provided, along with plausible explanations or underlying basic mechanisms. Material selection criteria for different brake designs and intended usages are also discussed.

Automotive Brake Linings

Automotive brakes include drum and disk brakes for passenger car, light truck, bus, heavy truck, and off-road vehicles. Drum brakes predominantly use internal expanding shoes with brake linings that load the majority (typically 50 to 70%) of the drum rubbing surface. Most automotive disk brakes use shoes that load a much smaller portion (from 7 to 25%) of the disk rubbing surface.

Disk brakes faster cooling, with their larger exposed surface areas and better cooling geometry, but are more vulnerable to either liquid or solid particulate contamination. Because of cooling, contamination, and other basic design issues, front disk brakes and rear drum brakes are commonly used. The friction material is called a brake lining, whether it is used on drum or disk brakes. Disk brake linings are also called pads, drum brake linings are known as segments or strips, and heavy truck drum brake linings are called blocks.

Brake linings are the sacrificial wearing element and the primary determinant of frictional behavior. However, the brake drum or disk material, usually a gray cast iron, also can affect brake lining friction and wear. Automotive friction materials have been formulated for about 90 years. There are three broad classifications of friction materials: organic, metallic, and carbon.

Organic friction materials were exclusively composites of one or more binder resins, chrysotile asbestos fiber, and a blend of additives that modified friction, improved wear, reduced cost, aided processing, changed color, and so on. Currently, there are three subclasses of these resin-bonded friction materials:

- Asbestos, also called organic brake linings
- Nonasbestos organic (NAO), using a variety of fibers
- Semimetallic, or resin-bonded metallic (semimet)

Semimet linings are separate from the other NAO linings because they have a restricted composition range, with unique friction and wear properties. Semimet linings comprise about 65 wt% total iron content, 10 to 25% steel wool, and the remainder is commonly a porous iron powder. Graphite, usually synthetic, is about 15 wt%. A heat-resistant phenolic-type binder is about 10%.

NAO brake lining formulations are rapidly evolving, and may eventually develop into several subgroups. Currently, these formulations designate what they do not contain, such as nonasbestos nonmetallic. Over 1200 different fibers, acicular materials, and other reinforcing agents have been tested to date. Because most NAO materials use a blend of different fibers and other reinforcing agents, the number of potential combinations is staggering. The most commonly used fibers are glass (including chopped glass fiber, mineral wool, and many proprietary species), metal, ceramic, para-aramid (Kevlar), cellulosic, and other organic forms. Acicular materials, such as wollastonite, and plate-like materials, such as attapulgite, are also used as reinforcing agents in NAO linings.

The binder resins used in organic friction materials are typically thermosetting polymers, often a two-step phenolic type. Both liquid and powder resin forms are used. Rubber and cashew (derived from an oil in the nut shell) binder resins also are used in brake linings.

For good wear properties, cured brake lining resins should be tough, heat-resistant, and have predictable thermal degradation behavior. Binder resins that readily break down into oily decomposition products are suited only for light-duty drum brake linings. Their oily decomposition products combine with solid wear particulates to form a surface film material that enhances low-temperature wear life. However, such linings would likely self-lubricate (fade), wear excessively, and/or slough away in hard service. A binder resin requires thermal stability for the most severe brake usage anticipated.

Resins that form a stable char at the rubbing surface are better for higher-severity applications, but may provide a lower friction level. When used in heavy-duty friction materials, they do not provide "oily" breakdown products at the rubbing interface to retain wear particulate at low-severity conditions. Consequently, low-temperature wear life can be poor. Organic additives can be used to enhance light-duty wear. Cashew particles, at 7 to 12 wt%, are often used to provide such wear debris reutilization.

More-stable organic compounds can be used to enhance wear in higher-severity applications. Para-aramid, at levels from 2 to 3 wt%, has been shown to effectively improve wear life under more stringent usage conditions. Resins and other organic brake lining constituents that char or form oily degradation products, depending on usage conditions, may provide inconsistent friction and wear.

Wear properties of the friction material also may be enhanced by the appropriate choice of inorganic constituents. In general, lining additives can be used to improve strength, thermal expansion, heat absorption, friction, or other properties. The friction material rubbing interface can be thought of as a high-temperature, high-pressure, nonequilibrium thermal reactor. The effects of most friction material additives on brake performance cannot be predicted accurately because of insufficient fundamental knowledge. Consequently, most brake lining formulation is achieved through trial and error, coupled with prior experience and testing expertise. A formulation involves many compromises, and is beyond the scope of this article. The remaining two classes of friction materials have unique performance characteristics, but with limited automotive applications.

Metallic brake linings can be based on either copper or iron. Most are solid-state sintered, often with inorganic additives to improve performance. These have been developed for very high power input densities. For example, solid-state-sintered bronze and mullite linings are used in race car and high-speed railroad brakes. Sintered iron with graphite is used on some heavy-duty brakes, both disk and drum, as well as on a few production passenger car drum brakes.

Another metallic friction material is cast iron. Although this venerable material is used on some old railroad tread brakes, no new automotive applications are known to use cast iron as the brake lining. However, it is the predominant countersurface material used for automotive drum and disk brakes. Therefore, it remains a friction element, although not a brake lining.

Carbon-based brake linings, such as carbon-carbon, were developed for military and commercial aircraft disk brakes. Some are now used on racing cars where weight is critical, performance is demanding, and cost is secondary. Carbon-carbon friction materials are made from carbon fiber (also called graphite fiber) that is bonded with amorphous carbon. Organic resins are either baked at high temperatures or a chemical vapor deposition process is applied to generate this amorphous carbon binder. After further processing, the resultant friction material is essentially pure carbon with a very low porosity. A 2000 °C (3630 °F) operating temperature and a high specific heat property permit carbon-carbon materials to provide weight savings of nearly 85% when replacing cast iron in suitable applications.

Brake Lining Wear

Brake lining wear life frequently is measured in imprecise terms, often as some number of miles or kilometers in service. Brake adjustments for wear, when required, usually are made on the basis of either usage time or distance traveled, utilizing prior experience. Such rough measures are acceptable for many users, but unacceptable to most researchers and engineers. In this article, the brake lining specific wear rate denotes the mass worn (in mg) per unit of frictional work (in MJ, or about 0.37 hp · h). Good brake linings have values from 40 to 100 mg/MJ (0.003 to 0.008 in.^{3}/hp · h) at low temperatures. High usage temperatures can increase these wear rates by one to three orders of magnitude.

Substantial testing may be required for wear documentation, because brake lining wear rates change greatly with temperature, and brake usage varies enormously in automotive service. This testing can be reduced by understanding the mechanisms of wear, which can be investigated through model studies.

Break-In Wear. During the necessary burnishing, or wearing in, of brakes, both the brake drum or disk and the friction material wear at a temporarily high rate. Brake lining wear rates are usually stabilized by the time the major brake drum or disk asperities (those due to machining) have been rounded. Normally, the lining break-in wear volume is small, compared with the total available wear volume. Many break-in factors exist. The more important of these have been reported by Rhee and Thesier (Ref 1).

Brake Torque Effects on Wear. Most organic linings show essentially no wear variation with applied force, but semimet linings almost invariably show rates of specific wear that are several times higher than normal at very low loads. This high lining specific wear rate produces a characteristic fine red wear particulate (mostly ferric oxide) and results in a greatly altered cast iron countersurface wear rate (described more fully later). With this one major exception, brake lining wear rate can be considered independent of applied load.

Brake Rubbing Speed Effects. Organic brake linings show little variation in their specific wear rate with braking speed, when tested from low initial cast iron temperatures. There typically is a slight rise of wear rate below a rubbing speed of 2 m/s (6.5 ft/s). Brake asperity "flash" temperatures are known to vary primarily with speed, as has been described by Blok (Ref 2) and, more recently, by Lim and Ashby (Ref 3). Above 1 m/s (3.3 ft/s), asperity temperatures appear to range from 1000 to 1100 °C (1830 to 2010 °F). It is presumed that the variation of lining wear rate and the associated variation of friction level are related to this flash temperature transition. At very high rubbing speeds, the lining wear rate increases. This increase is greater when the initial brake drum or disk temperature is high. It is presumed that this speed effect is simply the result of higher interfacial temperatures. Model wear data, presented later, support this presumption.

Semimet friction materials also exhibit unique behavior with speed. At rubbing speeds below 2 m/s (6.5 ft/s), semimet lining wear rates also increase, but to a significantly greater extent than do the organic linings. Thereafter, the semimet brake linings provide a nearly constant specific wear rate with rubbing speed, until a transition condition is reached. Higher speeds then generate much higher lining wear rates (to 100 times, or more). During full brake dynamometer testing of semimet brake linings, it was found that four brake stops from 160 km/h (100 mph) produced as much lining wear as over 500 brake stops from 50, 65, 100, and 130 km/h (30, 40, 60, and 80 mph).

There are differences among commercial semimet brake lining formulations in terms of rubbing speed transition values. Higher transition speeds were found with a semimet lining that contained a small amount of para-aramid pulp. It is conjectured that this high-strength thermoplastic material provided enhanced near-surface brake lining strength and helped to prevent "friction welding" wear of the lining to the brake rotor.

Brake Temperature Effects. The variation of brake lining specific wear rate with brake drum or disk cast iron temperature is shown in Fig. 1 for four representative lining classes. The friction materials are divided into semimet (SM), light-duty (LD) organic, heavy-duty (HD) organic, and original equipment (OE) organic classes. Because asbestos and NAO materials have overlapping wear properties, they are not separated.

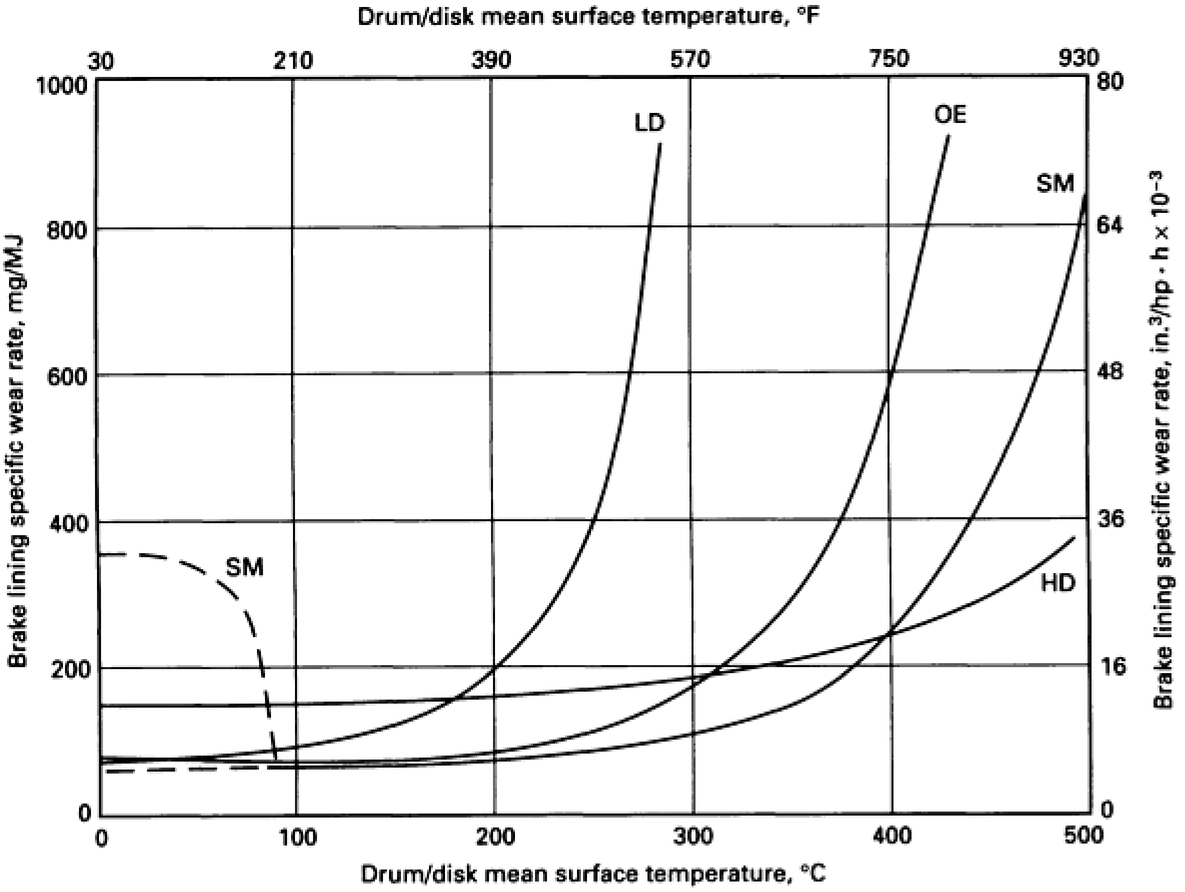

Fig. 1 Temperature effects on brake lining specific wear rates

Semimet linings also exhibit a typical behavior that requires some explanation. These friction materials establish a transfer layer to the cast iron during break-in and initial service. Until established, the semimet wear rates are several times the normal rate.

This cast iron conditioning process occurs faster with higher surface temperatures, higher rubbing speeds, and higher unit pressures. It also varies somewhat among the different semimet lining formulations, and even with differences of cast iron countersurface, such as texture, residual stress, and oxidation.

Once the cast iron surface is conditioned, it is believed that a back-and-forth transfer of material takes place. Material exchange between the cast iron transfer layer and the semimet lining surface helps to keep the measured lining wear rate low. No direct cast iron contact or wear occurs, except for incidental scoring that is due to particulate contamination, after the transfer layer is established. This is further described in the section on brake drum and disk wear.

Brake Usage Severity Effects. Figure 2 shows the wear life behavior for several classes of brake linings under different severities of usage. It can be seen that no friction material type is best for all usage conditions. Inexpensive aftermarket (AM) friction materials have acceptable wear lives under light usage conditions, but wear rapidly under more stringent conditions. Heavy-duty (HD) friction materials have a lower wear life variation with usage severity than most automotive materials, but are superior in wear behavior only for severe-duty usage. Sintered metallic friction materials also may have this wear characteristic, with low variations of wear rate at different usage conditions. Semimet (SM) brake linings are best in the middle range, but poor in very light duty conditions. Original equipment (OE) brake linings have a broad range of acceptable wear life. From Fig. 2, it should be clear that friction material wear life values are essentially meaningless unless usage conditions are specified. It is not possible to select the optimum friction material for wear without knowledge of the customer brake usage distribution.

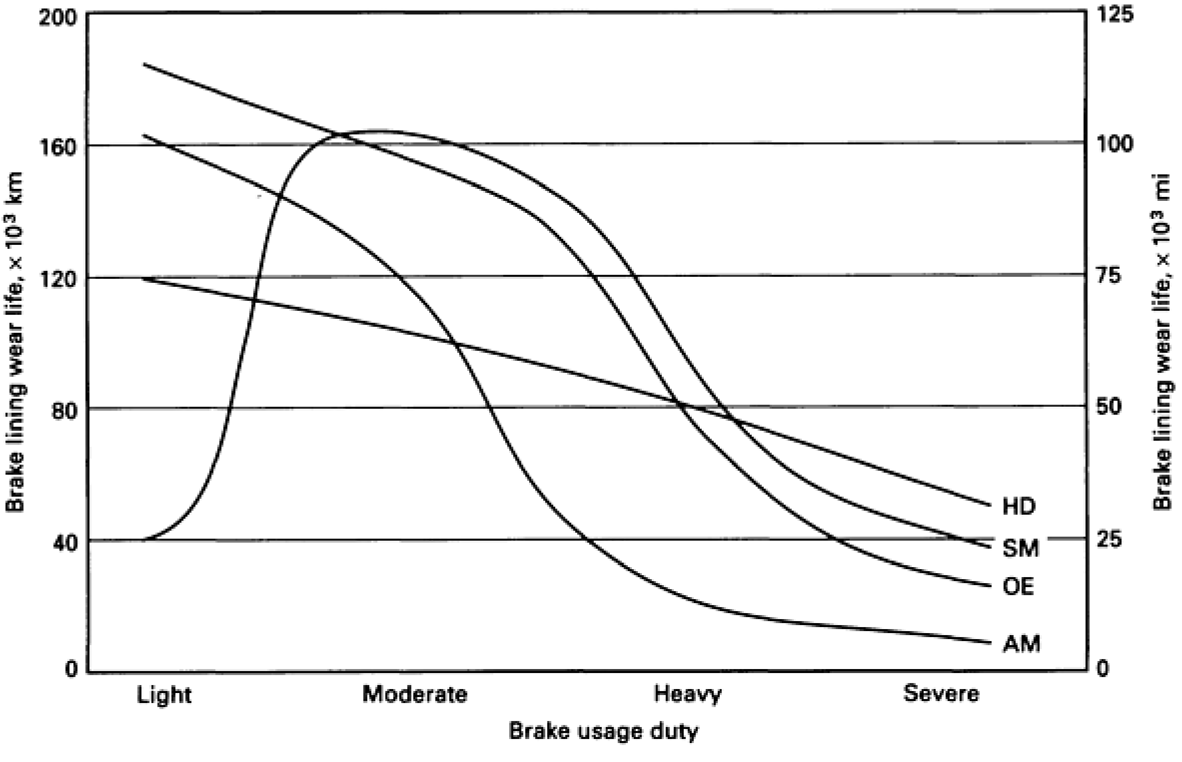

Fig. 2 Brake lining wear life versus usage severity

Brake lining Wear Modeling

Archard's equation is applicable to automotive brake systems only at very low rubbing speeds and component temperatures. Consequently, this linear relation between volume of wear and the product of sliding distance and applied load is not generally applicable for brake wear modeling. Forcing friction material wear data to fit polynomials of speed, rubbing distance, and load terms has been tried, but with very limited applicability.

Rhee (Ref 4) and others have related measurements on friction material wear with the brake cast iron temperature. These data indicated an essentially constant wear rate for low temperatures and a nearly exponential one at elevated temperatures.

Lining Cure Effect. Weintraub and Bernard (Ref 5) derived a model equation which showed that some pyrolytic gas chromatography (PGC) peak areas of a brake lining resin behaved in an orderly manner with curing time and temperatures. Simple laboratory-prepared formulations were used. They also showed that laboratory friction material wear rates for these simple brake linings were linearly related to these PGC peak areas. This work led to a simple, second-order Arrhenius-type model that was expressed as:

$$m = W + Kte^{(R/T)} \qquad \textbf{(Eq 1)}$$

where m is the mass loss (on a test of fixed frictional work), W is a wear constant, K is related to the Arrhenius collision coefficient, R is related to the Arrhenius activation energy, t is the brake lining cure time, and T is the brake lining cure temperature.

Additional studies by Weintraub, Anderson, and Gealer (Ref 6) showed that this wear relationship was applicable to additional friction material binder resin types in brake lining model formulations that approximated production linings.

Interfacial Temperature Effects. A similar expression was shown by Anderson (Ref 7) to be applicable to most brake lining wear data, but now relating the in-use friction material wear rate with the mean interface temperature by

$$V = A + Be^{(C/T)} \qquad \textbf{(Eq 2)}$$

where V is the specific wear rate (wear volume per unit frictional work), A is the low-temperature lining wear constant, B is a friction material wear constant, C is another friction material constant, and T is the average interface temperature during braking.

This equation has been quite effective in relating brake lining wear data with testing conditions for a broad range of materials, over most of the brake operating temperature range. Model formulations and production friction materials had full-brake wear behavior that was found to be well-characterized by this relationship. The production linings had several organic components, making the applicability of this equation surprising. Experimental values found for the constant C appear to have functional significance. For most friction materials, this activation-energy-related term has been determined experimentally to vary from 65 to 85 kJ/mol (16 to 20 kcal/mol). Such values might well be expected from bimolecular reactions in the wear process.

Because the constant term A dominates at low operating temperatures, it is easily determined experimentally. However, following some severe usage conditions, especially after high friction material soak temperatures, the value of A was found to increase and subsequently remain at this increased value. The increase appeared to be associated primarily with the friction material soak temperature, but also with some dependence on the time at temperature. It does not appear to be simply related to the mean interface temperature during braking. Thus, a better model expression would have the constant term replaced by one that includes prior thermal history. This new term also could include particulate contamination factors for an even more sophisticated model.

As the temperature increases, the thermally sensitive Arrhenius-type term increases in influence. The temperature required in the above wear equation is the mean rubbing interfacial temperature. This is not easily measured, but it can be calculated. The readily calculable interfacial temperature rise for the brake application is added to the measurable bulk cast iron temperature of the brake drum or disk. Values for B and C can then be determined from experimental wear data for temperatures, usually in the 150 to 350 °C (300 to 660 °F) range.

Whether this wear equation is technically correct or not is not at issue. It generally works well, and unique wear mechanisms appear to be involved when it does not. To a pragmatic experimentalist, this has been quite acceptable.

Brake Drum and Disk Wear

Gray cast iron is the dominant material for both brake drums and disk brake rotors. Brake cast iron typically has a type A graphite, with a pearlitic matrix and low ferrite and carbide content. Normal brake iron provides adequate damping and good resistance to thermal fracture in hard service.

The wear of either the cast iron or other countersurface is not readily determined by the Arrhenius-type model relationship. It appears that several mechanisms affect the specific wear rate of the cast iron. These include abrasive, adhesive, and oxidative terms. The abrasive terms include components from the abrasive content of the friction material, external contaminants, and abrasive particles that are "manufactured" at the rubbing interface. The latter can result, for example, from vitrification (firing) of clays at the hot rubbing surface.

Brake Lining Chemistry Effects. Some friction materials have constituents that are chemically active at the rubbing interface. Such brake linings have been found to be extremely responsive to changes in the cast iron chemical composition. Hatch (Ref 8) described the effect of titanium and rare earth oxide content on lining friction. Examples of large brake effectiveness differences with the same brake lining, but different cast irons, were shown. Regrettably, this article did not make clear that most friction materials do not provide any detectable difference in effectiveness, only the few that chemically interact with the cast iron.

With one such disk brake lining, the in-service cast iron wear life was increased by a factor of 50 when the titanium content was increased from 0.02 to 0.04%. The presence of small, hard particles in the cast iron from the titanium was credited for the improved wear resistance on this countersurface. Titanium content control can be particularly effective in disk brakes, if parasitic drag of the brake linings causes local wearing of the rotor. Cast iron machinability considerations limit the useful titanium content of 0.05%.

Graphite Morphology Effects. The graphite size and shape were found to affect the cast iron and lining wear rates for many brake linings. "Damped" gray cast iron, with its very large graphite flakes, has been used in some brake applications to decrease brake squeal. However, this iron is weaker, and tends to have poorer wear resistance than conventional brake iron. It also increases brake lining wear rates for some friction materials. This presumably results from the cutting action of sharp iron edges found around the large graphite flakes. Linings with hard resins and rigid matrixes were found to have lower wear rates with decreasing graphite size.

Special cast iron brake test parts were made with very fine graphite structures and with about 0.04% titanium. Using a hard and abrasive nonasbestos truck brake block, this permanent mold cast iron provided a 30% reduction in the brake lining wear rate, and had a 240% improvement in cast iron life, compared with a conventional brake cast iron.

For the NAO heavy truck brake blocks in particular, the cast iron chemistry and graphite morphology can exert a strong influence on the countersurface wear life. It appears that many nonasbestos materials cause the cast iron to become a more active member of the friction and wear couple. Consequently, closer control of the cast iron may be required. Each new friction material should be tested for cast iron sensitivity, to ensure acceptable service life.

Normal Cast Iron Wear. Usually, a worn cast iron rubbing surface develops a satin gray appearance. Low-abrasiveness passenger car brake linings provide cast iron specific wear rates from about 0.2 to 1 mg/MJ (1.6 to 8 × 10^{-5}in.^{3}/hp·h) in the absence of external contamination or rusting. Countersurface wear and scoring can result from abrasives that are an intended friction material constituent. Some abrasive content to the friction material is desirable, for example, to remove rubbing surface rust after periods of extended nonuse and to control brake lining transfer. Such abrasives also can be used to increase the lining friction level, or to control cast iron crack growth in severe-duty brake linings. Cast iron wear rates from 5 to 16 mg/MJ (4 to 13 × 10^{-4}in.^{3}/hp ·h) can result. At the higher values, the weight loss of cast iron can exceed that of the brake lining wear.

The cast iron wear rate is sensitive to a number of factors. An abrasive will wear the cast iron if it has higher hardness, higher melting-softening temperature, and sufficient particle size. Litharge and barite are both softer than cast iron at room temperature. With normal brake usage, barite will increase the cast iron wear, whereas litharge will not, because barite has a higher softening temperature than cast iron. Even materials that meet the hardness and softening criteria may not produce severe cast iron wear, unless they are of a size that can cause abrasion.

A brake lining matrix hardness varies considerably with formulation and with temperature for a given formulation. Some brake linings soften significantly, and can produce cast iron wear rates as shown in Fig. 3, trace A. Other linings have a nearly constant matrix hardness, and result in wear like that of trace B. The cast iron wear rate increases at elevated temperatures, mirroring the lining wear rate. When abrasives are evenly distributed throughout the brake lining, cast iron

wear rates directly follow the lining wear rates. If external abrasives are present and dominant, wear behavior like that of trace C results. The decrease of cast iron wear at higher usage temperatures then appears to result from softening of the brake lining matrix and abrasive clearance from higher lining wear rates.

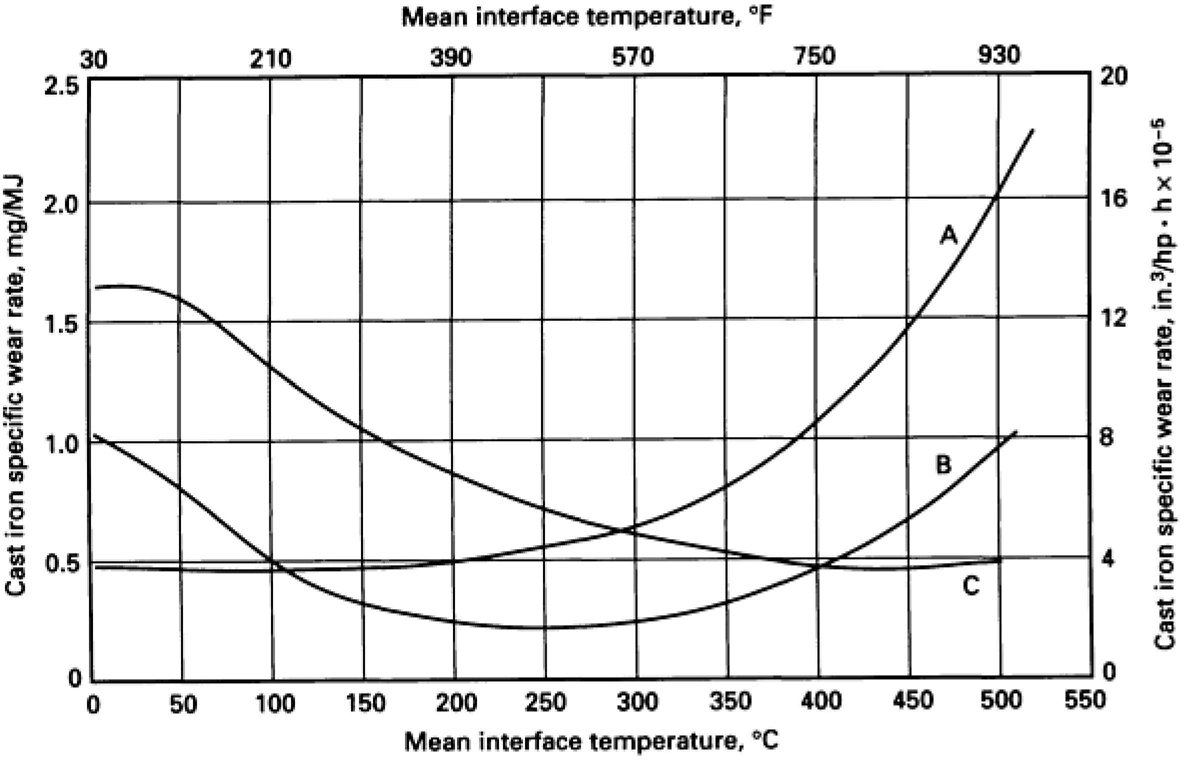

Fig. 3 Cast iron specific wear rates versus brake temperature. See text for discussion.

Local Cast Iron Wear. Brake rotors can generate local brake lining contact zones when there is a significant axial runout. Figure 4 shows the axial runout and thickness variation (TV) of a rotor that had minimal brake usage, but developed a thickness variation from parasitic wear (unintended brake dragging) during highway driving conditions. Road dust contamination aggravated the wear. Similar wear patterns have been seen with semimet brake linings, because of their magnesium oxide abrasive content.

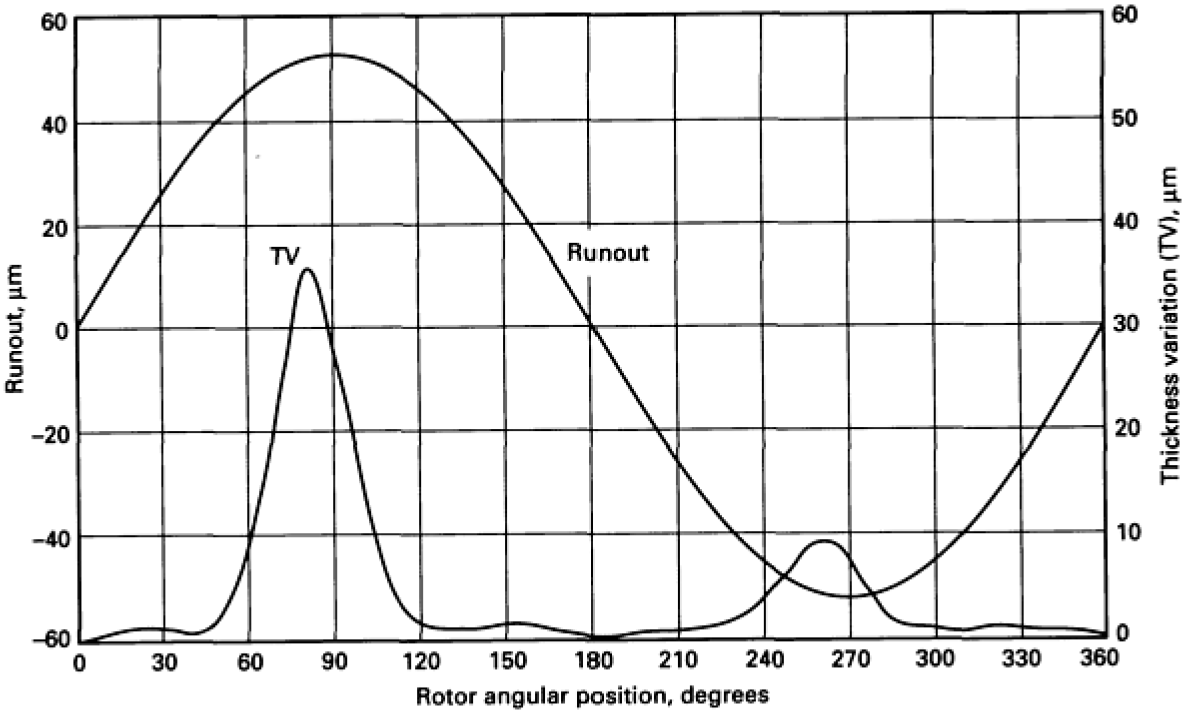

Fig. 4 Rotor axial runout and thickness variation from local drag wear

Highly localized cast iron wear is found on the inboard face of the rotor, centered at a site slightly in advance of the maximum runout position. The resultant brake pedal vibrations from this wear were sufficient to require the remachining of the rotors after only 17,000 km (10,560 miles) of dusty highway service. Often, a small increase of cast iron matrix hardness and hard particle content will reduce the local cast iron wear rate greatly.

Extreme scoring of cast iron can result from an inadvertent contamination of the lining by abrasives. For example, silicon carbide was a "tramp" impurity in the synthetic graphite used in a semimet brake lining formulation. After 2000 km (1240 miles) of customer service, one rotor face was deeply scored over the entire rubbed surface. The opposite rotor face showed no scoring, with the original grinder marks still evident on the surface. Both brake linings were of the same semimet formulation, but from different production batches, one with silicon carbide and the other without. Laboratory testing showed the contamination level at a few tenths of a percent.

Hot spotting of the cast iron can produce local wear at the heated sites. If martensite is formed on the cast iron surface, local high spots will result. Martensite and hot spotting have been addressed by Anderson and Knapp (Ref 9).

External Abrasive Effects. Dust or splash shields can be used to reduce disk lining and rotor cast iron wear from particulate contamination, but attendant restricted brake cooling may increase lining wear rates. External contaminants can be kept from drum brakes by labyrinth seals or shrouding with a small loss of cooling efficiency. However, retention of normal wear products and accumulated rust particles within the brake sometimes then contribute to increased wear rates. With riveted linings, the cast iron wear may be heavily biased along the path of the rivet holes, particularly those at the leading edge of the linings. Careful testing and intelligent compromises may be needed to balance cooling and contamination effects.

Transfer coatings onto the cast iron can be generated by semimet brake linings, as described in the section on brake lining wear. These coatings can vary from a few tenths of a micron to 40 μm (1.6 mils) or more. Once formed, the wear of the original cast iron becomes zero, except from local scoring that is due to abrasive action. However, the transfer coating is by no means static.

With extended operation at low temperatures and especially for rubbing speeds below 2 m/s (6.5 ft/s), the coating will deplete. This appears to result from a preferential transfer to the friction material, because very low lining wear rates are measured during the period when the coating is depleting. Once depleted, the brake lining wear rate increases by a factor

of about 4. The cast iron then wears at a substantial rate, and its appearance changes from a dark blue-black coloration, with a matte finish, to a shiny gray. With time, the cast iron usually develops uneven wear across the rubbing path. During near-transition usage, the cast iron coloration includes bands of brown, blue, and purple.

With continued low-temperature, low-speed usage, the cast iron wear mass removal rate has been found to approach that of the friction material. If these conditions continue, the disk brake linings will wear out at about 20% of the expected mileage, and the rotors will have become unserviceable from the high and generally uneven wear. Normally, such high wear rates are associated with severe usage. In this case, a change of wear mechanism causes high wear under very light-duty, low-temperature usage.

If the cast iron wears under light-duty conditions, but not under hard service, one might redesign the brake to ensure higher temperatures. This measure is acceptable, within limits. Continued high temperature and hard brake usage cause another unique condition. The transfer layer may become so thick that it locally delaminates from the cast iron rotor. This occurs when the transfer layer thickness is about 30 μm (1.2 mils). Figure 5 shows a cracked and incipient failure state for the semimet transfer layer on a medium truck disk brake rotor that had seen severe service on a mountainous test route. Local high spots, around 1 mm (0.04 in.) in diameter, signal these delamination sites. The light bands near the center of the photograph are regions where the coating has broken away locally.

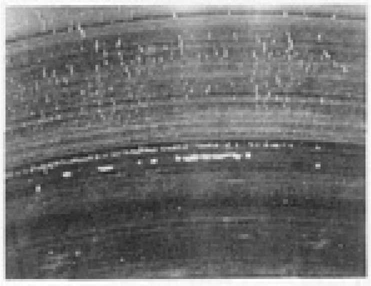

Fig. 5 Semimet transfer layer cracks and blisters

Figure 6 shows a more severe case, with the same semimet lining and brake usage. The cast iron is visible at the bottom of the recesses, where the transfer coating has flaked off. Machining marks could still be seen at these sites. Based on a simple scratch test, the coating was found to be quite adherent. Presumably, the delamination process resulted from high thermal strains at the coating-cast iron interface.

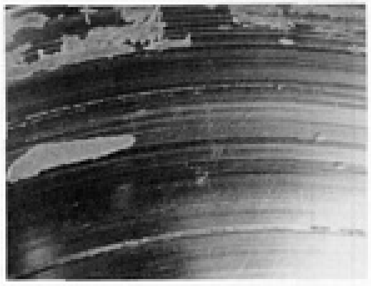

Fig. 6 Semimet transfer layer delamination

Design analysis of brakes for semimet linings thus appears to involve assurance that light-duty brake usage will not produce rotor wear and severe usage will not result in transfer layer delamination. Consequently, optimal design would prevent these usages in most operating situations, and would result in rare occurrences of either wear type. The greater the variation of usage severity in customer service, the greater the possibility of such cast iron wear issues.

Toxicity of Brake Wear Debris

When brake wear debris is considered, asbestos fiber is a common concern. However, several studies of brake lining wear emissions have shown only about 0.03% asbestos in the airborne wear debris. The low emission results from the high frictional contact asperity temperatures. Chrysotile asbestos converts to forsterite at about 800 °C (1470 °F), well below brake flash temperatures. Organic brake lining fiber emissions averaged 0.7 μm (28 μin.) in length. Therefore, the vast majority of the airborne asbestos did not meet the definition of a fiber by the Occupational Safety and Health Administration, the World Health Organization, and other authorities. Epidemiological data for automotive brake mechanics have shown no detectable excess cancer risk. The Environmental Protection Agency, using computer models for fiber exposure and cancer risk, predicted about 15 excess cancer cases a year from all U.S. brake wear.

Semimet brake wear emissions appear to be of minimal toxicity. Fibers from the wear of other nonasbestos brake linings have not yet been collected and measured. These include mineral wool, glass fiber, slag wool, titanate fiber, phosphate fiber, carbon, and para-aramid fiber.

Although lead was removed from most brake linings by 1980, barium, usually in the form of barium sulfate (barite) powder, is often found. Such heavy metal wear particles may affect chest x-rays of brake mechanics. Brake usage generates some fused-ring aromatic material, but in miniscule quantities, like those in lettuce. Until complete and definitive brake wear toxicity studies are completed, it would be prudent to minimize dust exposure from any brake wear debris.

Automotive Brake Frictional Characteristics

Brake linings inherently have some performance attributes, such as fade and fade recovery, but full evaluation of a friction material requires that it be installed into a full brake system. Vehicle brakes are required to operate under a wide range of conditions, from hard braking with a heavily loaded vehicle on a steep downhill slope to minimal brake usage on interstate highways. Vehicle brakes should be highly reliable and minimally affected by temperature, water, or other contaminants. Brake lining friction must be consistent throughout the life of the material.

Brake Design Basis. Brakes are designed primarily on the basis of wear, pedal travel, brake system stability, and effectiveness properties. Brake effectiveness is defined as the ratio of the brake friction torque to the applied force. This term is used, rather than friction coefficient, because brake geometry factors often make the brake torque not linearly related to friction level. For example, effectiveness must be used to describe frictional performance of drum brakes, because of their large self-actuation characteristics.

Self-Actuation. Frictional forces acting on the shoes of a simple drum brake may cause it to be further loaded against the drum, increasing its effectiveness. Such shoes are referred to as leading. Friction force on a trailing shoe causes it to oppose the application force, decreasing effectiveness. The increase in brake shoe loading, which is due to friction and geometry effects, is referred to as self-actuation.

Although the geometric considerations of self-actuation influence brake effectiveness, it also is influenced by frictional properties of the brake lining. Figure 7 shows design effectiveness curves for different brakes as a function of friction coefficient. Assuming a nominal friction coefficient of 0.4 for each 1% change in friction coefficient, the brake effectiveness changes by approximately 3.5% with a duo-servo drum brake (two leading shoes, coupled), and by 2.6% on a leading-trailing drum brake, but the change is just 1% for a nonservo disk brake.

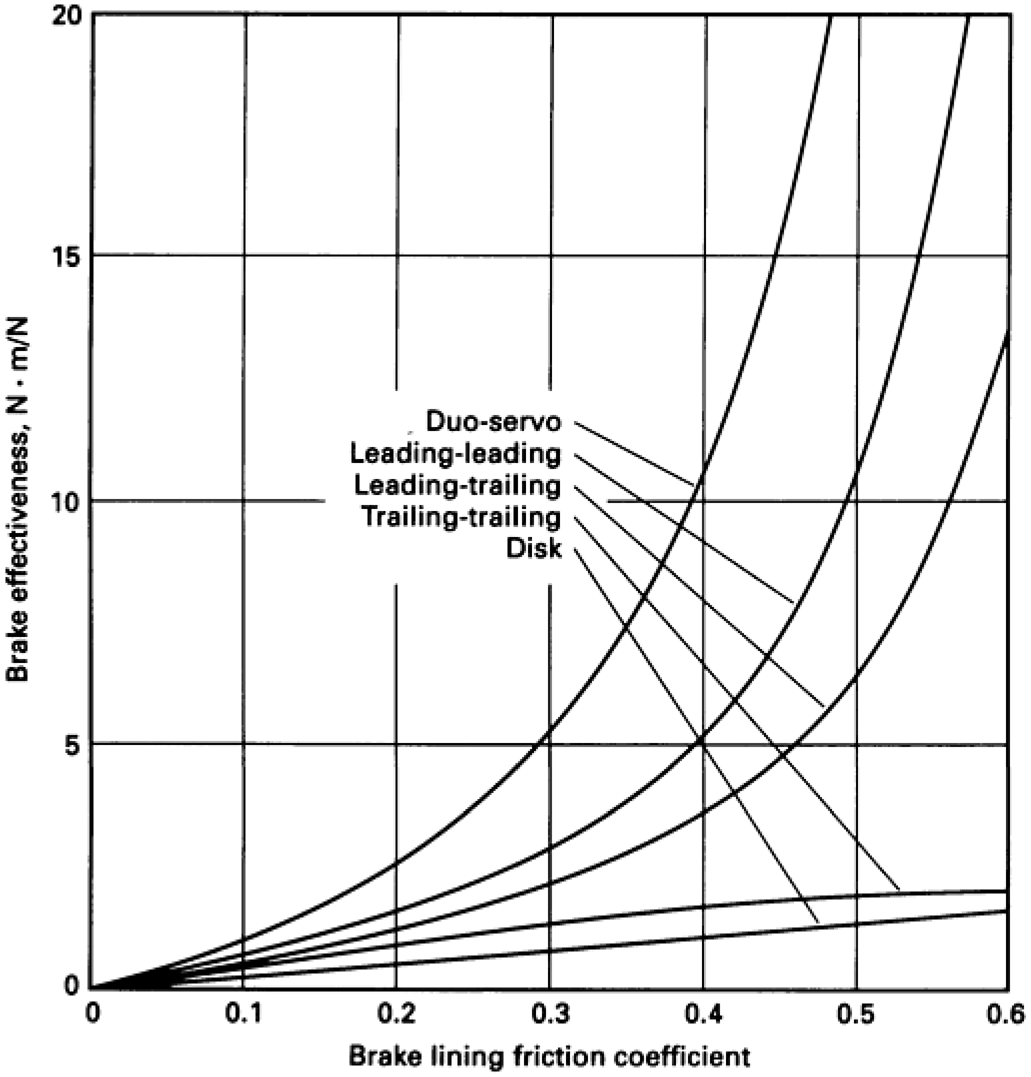

Fig. 7 Effectiveness versus friction coefficient for several brake types

Design Factors. In addition, the design of brakes can affect the degree to which friction material wear and thermomechanical properties influence brake effectiveness. A large change of brake effectiveness is possible, for the same value of friction coefficient, simply because of a change of lining pressure distribution. Figure 8 shows the change of effectiveness on a leading shoe that results from different pressure distributions. For a given value of friction coefficient, the effectiveness may vary by a factor of 4 as the pressure distribution varies from center-biased to end-biased. On a drum brake, the lining pressure distribution is affected by the stiffnesses of drum, shoes, and brake linings, in addition to thermal distortions, wear patterns, and prior usage history effects.

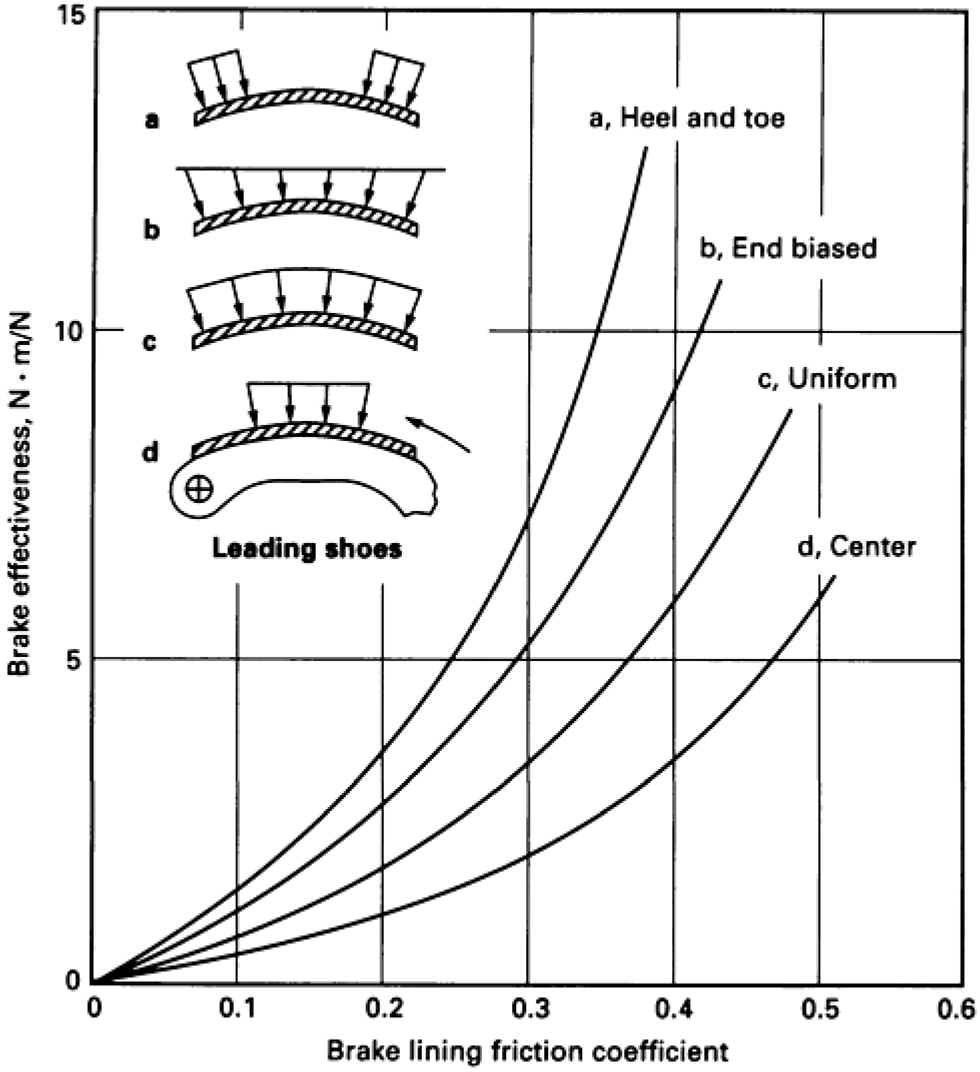

Fig. 8 Effectiveness variation with pressure distribution, based on type of leading shoe

The brake designer can achieve the same brake effectiveness by several combinations of lining geometry, brake shoe geometry, and lining coefficient of friction. Thus, changing friction material type (as from asbestos-organic to one of the nonasbestos types) may provide significant effects on brake system performance, because of different coefficients of friction, different thermal expansion coefficients, and different compression stiffnesses.

Many brake design parameters are interrelated. For example, a large value for lining thermal expansion may require added running clearances to avoid parasitic drag. This results in greater brake actuator travel, which may then necessitate further brake system redesign. A complete introduction to brake design is beyond the scope of this article. The preceding discussion was presented to introduce design issues and to illustrate the virtual impossibility of simple substitutions.

Brake Frictional Performance

Some friction material effectiveness measures that are evaluated during new vehicle brake system qualification experiments include: burnish and green performance, fade resistance, fade recovery, delayed fade, speed sensitivity, effectiveness drift, and environmental sensitivity. Each of these important performance characteristics is further described below. These are the most important of a much larger set of brake performance attributes that are evaluated during brake system development.

Green Effectiveness. When a friction material is new, it is unburnished and its contact with the drum or disk depends on many manufacturing tolerance stack-ups. With a new brake assembly, effectiveness often is lower and more variable than after the friction material is fully burnished. This initial behavior is called the green effectiveness.

The initial brake lining friction values may vary because of surface texture effects, surface contamination effects, contact pressures, and brake lining composition. Particularly with drum brakes, the green effectiveness also depends on the initial contact geometry. Design dimensions are chosen to provide lower initial effectiveness from the contact geometry. This minimizes the possibility of the overeffectiveness of new brakes, which is due to either rust or some other contaminant that increases initial friction.

Burnished Effectiveness. After the drum or disk has contact over the full rubbing surface, and when a stable char layer has formed over the entire brake lining contact area, the brake is said to have been fully burnished. Typically, the brake performance has stabilized by the time that 85 or 90% of the brake lining has contacted the brake drum or disk. An exception to this exists for the semimet brake lining. Semimet frictional behavior is discussed separately, because it has several unique characteristics.

Fade Resistance. Brake fade refers to a loss of brake effectiveness, generally as the result of excessive brake temperatures. However, five types of brake fade can occur:

- Thermal, which is due to high brake bulk temperatures
- Delayed, which is due to resin migration during cooling
- Blister, which is due to near-surface lining blisters
- Flash, which is due to high-speed, high-load braking
- Contamination, which is due to partial lubrication from water or oil

Poor brake fade behavior could be exhibited by high-quality materials, if used is inappropriate brake applications. Brake lining fade behavior is meaningful primarily in the context of a particular brake lining, brake, and vehicle usage situation. Depending on the brake usage sequence and lining fade response behavior, a driver may either sense impending fade as a gradual increase of brake pedal force requirement or he may not have any warning. Good brake lining choices provide a gradual and progressive loss of effectiveness to warn of impending brake fade. Good applications do not provide the driver with surprises.

Fade recovery refers to the ability of the friction material to quickly regain normal brake effectiveness after thermal fade. As the brake disk or drum cools, the friction level should return quickly to the prefade level.

Delayed fade is a phenomenon that can occur with some drum brake friction materials. During the fade recovery, brake effectiveness may drop unexpectedly, causing a temporary, but pronounced, increase of brake pedal force requirement. A delayed fade is insidious in that it is unexpected. It occurs well after a period of hand brake usage and usually with no warning signs.

Blister Fade. New brake linings may contain volatile material from fabrication, which, if not released by the end of the burnish process, could cause high internal gas pressures upon rapid heating, as during a hard brake application. In some situations, a near-surface blistering results in a rapid, brief loss of brake effectiveness. Friction is lost because of excessive contact pressures at the blister sites and from the evolved gases. A characteristic of blister fade is brevity. Effectiveness is lost for a few seconds during a hard brake application, and then returns to near-normal. Repetition of the hard brake application will not produce a second blister fade, because the volatile material has been eliminated from the near-surface region.

Flash fade is related to the blister and green fade, but occurs only at very high brake power levels, usually at very high speeds. The rapid decomposition of near-surface organic constituents produces a gas-pressure-lubricated braking surface. The brake lining friction may not be low, but the evolved gas pressurizes the friction material to counteract the applied force. High surface area brakes, and those with high organic contents, are most vulnerable. Prior brake usage at moderate-to-high brake lining soak temperatures reduces flash fade severity.

Contamination Fade. Water, oil, or a combination of these on the surface of the brake lining or brake drum/disk can generate an elastohydrodynamic fluid film that effectively makes a bearing from a brake. Different friction materials have

different porosity, compliance, and wear characteristics, and thus may be quite different in sensitivity to contamination. High surface area brakes, such as drum brakes, are more prone to contamination fade. However, even automotive disk brakes can exhibit such a fade, if saturated by either water or oil/water. This effect is similar to that from oil/water films on the road surface, affecting tire friction.

Speed Sensitivity. All brake linings exhibit different frictional behavior as the rubbing speed changes. The speed sensitivity varies with material type and composition. It also varies with temperature, pressure, and prior usage history. To ensure proper brake balance over a wide range of stopping speeds, the brakes on each axle should exhibit similar effectiveness characteristics.

In general, brake effectiveness decreases with increasing speed. Disk brakes provide less speed spread, or difference in brake effectiveness at different braking speeds, than do drum brakes. This is primarily due to the low servo factor of disk brakes. Duo-servo drum brakes, with high self-energization, are the most sensitive to speed. Good front-to-rear brake balance at all speeds is difficult to attain on vehicles with front disk brakes and duo-servo rear drum brakes. Highly speed sensitive disk brake lining need to be paired with low-speed-spread drum brake linings to compensate fully for the 3- to 4-fold difference in brake servo factors.

Environmental Sensitivity. Contaminants such as water, oil, dust, and rust alter brake effectiveness. For example, contaminant oil films of 0.2 μm (8 μin.) thickness can raise the brake friction coefficient by 55% at low vehicle speeds. This can make some drum brakes virtually self-locking. However, at 0.5 μm (20 μin.), an oil film can lower friction by elastohydrodynamic action. Because of low oil tolerance and high sensitivity, even an oily fingerprint can cause significant effectiveness change.

Wet Friction. The performance of vehicle brakes when wet also represents a safety concern. Disk brakes usually are less affected by water than are drum brakes, largely because of their lower inherent servo factor. However, both disk and drum brakes may show large effectiveness losses when wet. A small amount of oil, together with water (as with tires) increases the lubricating action.

When wet, some friction materials provide a greater loss of brake effectiveness than others. These usually also take a considerably longer time to recover friction capability after wetting. Permeability, homogeneity, and compression stiffness are some of the brake lining properties that help determine wet friction response. A complete understanding of this behavior is not known. Full brake dynamometer and vehicle tests are used to establish the wet friction behavior of brake systems.

Moisture Sensitivity. Friction materials are typically somewhat porous, fiber-reinforced composites that are capable of absorbing atmospheric moisture when a vehicle is parked, such as overnight. This moisture has been shown to change break effectiveness temporarily for some friction materials. Glass and para-aramid ten to increase friction when moist. Other materials tend to lower friction in moist environments.

Drum brake linings also change in thickness with time when exposed to high-humidity conditions. When the brake lining ends thicken, relative to the center, brake effectiveness increases.

Rust Effects. Another moisture effect results from rusting to the cast iron disk/drum brake lining surface when a vehicle is parked for some time, causing "stiction." Under adverse environmental conditions, it is possible for some friction material to rust-bond to the cast iron. A substantial torque can be required to break this bond. Thereafter, the rusted surface of the brake drum or disk may generate an uneven brake torque with brake angular position.

Rusting of the brake drum or rotor can occur independent from rust-bonding. In this situation, the brake effectiveness tends to be high at low speeds and low-to-normal at higher vehicle speeds. Whether rust prevails or not depends on the relative abrasiveness of the brake lining and rotor surface, as well as the brake usage conditions.

Although some of the above characteristics can be investigated in the laboratory, environmental testing is required to establish acceptability of friction material formulations in full vehicle service usage. The ideal brake assembly exhibits little or no moisture sensitivity. When present, it usually persists for a few brake applications, and then disappears when brake heat drives the moisture from the brake lining or when wear removes the surface rust. A small abrasive content in a brake lining may be beneficial in removing minor rusting from the brake drum or disk. Brake lining formulations also can contain agents to control minor rusting in service.

Effectiveness Drift. To ensure consistent vehicle braking performance, the brake effectiveness characteristics should be stable throughout the life of the brake linings. The brake effectiveness of some friction materials can deteriorate with accumulated usage history, time, and wear. The formation of a surface glaze on some brake linings, during prolonged light-duty usage, has been associated with a loss of effectiveness. Linings with low wear rates tend to glaze more readily that do those with poor wear life.

Semimet Frictional Behavior

Resin-bonded metallic, semimet brake linings have sufficiently different performance characteristics that it is simpler to describe them separately. Disk brake effectiveness with semimet brake linings is virtually constant with normal usage pressures and temperatures, for speeds ranging from 50 to over 200 km/h (30 to over 125 mph). Effectiveness drops slightly below 50 km/h (30 mph).

Thermal Fade. Semimet linings tend to be nearly fade-free. When thermal fade is experienced, it occurs as a progressive loss of effectiveness with decreasing speed. Significant brake fade primarily occurs at the end of the stop.

Environmental Sensitivity. Semimet linings are prone to have a 50 to 60% loss of effectiveness after exposure to moist air for one hour or more. This becomes the limiting condition and determines the amount of power brake boost required with most semimet brake linings (most other brake lining types are limited by initial fade behavior). It also restricts the available choices for compatible drum brake linings.

Water Sensitivity. Water affects many friction materials greatly. Semimets are minimally affected unless the water is accompanied by an oil film with a thickness of 1 μm (40 μin.) or more. In that case, the frictional effect is similar to other brake linings. However, disk brakes run warm enough to dry quickly, so water effects usually are neither critical nor long lasting.

Laboratory and Vehicle Brake Evaluation

Laboratory specimen testing machines are commonly used to characterize and audit the quality, or sameness, of friction materials, using specimens from full brake linings. The advantages of using laboratory systems for evaluation include automated testing, careful control of operating conditions, and more rapid measurement of brake lining characteristics. In addition, laboratory evaluations that utilize a specimen test are less costly than full-scale brake dynamometer or vehicle experiments.

Several different laboratory machines are used to determine brake lining properties. Three commonly used laboratory test machines are described below.

The friction assessment screening test (FAST) machine was developed for rapid "fingerprinting" of friction material specimens. The FAST machine is used primarily for routine brake lining quality control testing. Although this machine reportedly has been used to perform friction material screening tests, it never has been recommended as a substitute for full-scale brake evaluations.

A friction materials test machine is also used for quality-control testing. The Society of Automotive Engineers (SAE) has designated a recommended practice (SAE J661a), used in conjunction with this machine, that is classified as a quality-control test procedure. It is used more for periodic quality-control surveillance testing, as opposed to routine production batch testing. Based on test data from the SAE J661a procedure, a brake lining friction rating specification (SAE J866a) has been used by some states to classify and regulate friction materials. However, this rating system has been shown to be clearly inadequate for meaningful comparative testing with different types or classes of friction materials. SAE J866a (revised in 1984) includes a caution against such uses.

A full brake inertia dynamometer simulates vehicle braking by mounting a complete brake assembly to a large rotating inertia and drive motor. Most are single-ended, and test a single brake assembly at a time. Brake dynamometers place the brake assemblies in closed ducts, both to expedite cooling and to control smoke and smell. Because faster cooling rates hasten testing, most dynamometer tests have much greater air flow, and resultant cooling rates, than are found in on-road testing. Consequently, brake dynamometers are used mostly for controlled wear tests, basic effectiveness tests, initial fade/recovery tests, and parking brake tests.

Full brake dynamometers are available in a range of sizes, with inertial equivalents from motorcycles to railroad locomotives. Because there are no brake dynamometer standards, many are unique. Dynamometer-to-dynamometer differences in test results can be significant, even for carefully matched linings and brakes that are tested to the same inertia loading. As a result, most brake test engineers prefer comparative brake lining test data, obtained from a single brake dynamometer, to data from different brake dynamometers.

Full brake dynamometers can closely replicate most vehicle in-service braking conditions, except for air flow over the brake and environmental conditions, such as water and dust contamination. They are therefore invaluable for brake diagnostic testing, and can be excellent for initial brake lining screening tests. However, they are not sufficient to fully evaluate brakes.

Correlation of Laboratory and Vehicle Test Results. Numerous studies have been done to determine the degree of correlation between laboratory friction material test results and actual vehicle test results. In general, the only good analog of a vehicle brake is the brake itself. Consequently, there are no specimen or scale test devices that consistently yield test data that correlate with full vehicle data. This does not mean that such laboratory tests are useless, just that they should not be used to predict field performance behavior. They can, and have, been used to screen friction materials with performance flaws, but require expertise in data analysis.

Even full brake dynamometers are difficult to correlate with on-road vehicle brake performance, unless careful instrumentation and test controls are used. It should be possible to correlate full brake dynamometer test results with on-road data without a need for questionable correction factors. Although this has been tried by many, and published by a few, it has not as yet been verified by anyone.

The testing of brakes involves evaluations under the widest possible sets of conditions, in order to find flaws and behavior inconsistencies. Friction material formulation and testing both are more of an art than a science. If accurate models of brake performance were available, then testing would be much simpler. However, each friction material formulation is proprietary, and can be unique in many respects to other materials. Consequently, brake test engineers use a combination of standard performance test procedures to ensure adequate capacity. Customer service fleet tests over the entire United States then help to determine usage and environmental stability characteristics.

Prudent brake development engineers start with friction materials that have been fully screened by laboratory tests, and then run full brake dynamometer tests to further screen the candidate brake linings and to initiate brake hardware adjustments. Only then are vehicle performance tests justified. When these are acceptable, the more difficult, costly, and time-consuming fleet and traffic tests are initiated.

Federal Braking Requirements and Other Brake Tests. As indicated, the qualification of vehicle brake systems and friction materials can involve numerous experiments to determine fade resistance, moisture sensitivity, wet friction, and other performance parameters. On new vehicles, brake performance must meet Federal Motor Vehicle Safety Standards (FMVSS) 105-75 for hydraulic brakes and 121 for air brakes. Other performance standards are determined by the vehicle and brake manufacturers. Replacement brake linings have no legislated performance standards to meet.

SAE-Recommended Practices. The SAE has developed about 20 recommended practices for checking the performance of brake linings and systems. These standards cover automobile, truck, and trailer brake system tests using both vehicles and dynamometers.

Prior to the adoption of FMVSS 105 and 121, the SAE procedures were intended to provide guidelines to brake system evaluations. The passage of FMVSS 105 as a requirement for brake system certification shifted the emphasis of these SAE procedures to the role of supplementary tests that could be used to further qualify vehicle brakes and braking systems. The majority of the SAE brake codes have been directed toward automobiles and light trucks, although some (SAE J880 and SAE J9781) have been developed for heavy commercial vehicles.

Friction material performance in vehicle brake systems can be qualified by meeting the requirements of the federal safety standards and being evaluated by the SAE recommended practices, along with brake component and vehicle manufacturer standards. For new vehicles, compliance with federal and state motor vehicle safety standards is only a starting point for the acceptance of a brake system. No federal standards exist today for replacement brake linings.

Friction and Wear of Tires

P.S. Pillai, Goodyear Tire & Rubber Company

Introduction

TIRE WEAR is a complex phenomenon that occurs in the tire footprint area--that is, the interface region between tire tread and pavement surface. The forces required to support and control an automobile act in the footprint contact area. Forces generated in the tire footprint allow the vehicle to change direction and speed of travel. Production of these action and reaction forces generates frictional work in the footprint region. The dissipation of this frictional work is the primary reason for tire wear. Factors that affect tire wear are broadly classified in Table 1.

Table 1 Parameters that affect tire wear

Tire-related factors	Operating conditions	Other factors
Tire type	Tire load	Pavement texture and condition
Tread design	Inflation pressure	Seasonal effects
Tread composition	Speed	Ambient temperature
Tire construction features	Driver vehicle interaction	
Magnitude of inertial forces	Vehicle maneuvering behavior	

Abrasion and Wear

Tire wear or tread wear refers to loss of tread rubber. Abrasion of rubber refers to the removal of rubber particles from a testpiece (a small rubber wheel, for example) when rubbed against another hard object. Thus, it would seem logical to assume that tread wear is related to rubber abrasion. However, experiments have shown that the two processes do not exhibit a one-to-one correlation. Informative review articles on rubber abrasion have been published (Ref 1, 2, 3, 4, 5).

Basic research on rubber abrasion and wear has been performed by Schallamach, Gough, Grosch, and other investigators (Ref 6, 7, 8, 9, 10, 11). Study of rubber abrasion is essentially limited to laboratory testing of model rubber specimens using abrasion machines; wear refers to tires in service. Many authors have tried to use laboratory abrasion results to predict tread wear, but have had only limited success. In the tire wear process, although te physical phenomenon is loss or abrasion of tread rubber, many factors--tire type, design and construction parameters, material properties, vehicle maneuvering behavior, driver-vehicle interaction, weather, and so on--influence wear rate. Therefore, direct wear measurements are required to rank the wear rates of different tires. The tread wear grade provided by tire manufacturers is a comparative rating based on the wear rate of the tire when tested under controlled conditions on a specified government course. Veith and co-workers have performed extensive experimental work on tire wear (Ref 12, 13, 14, 15). Veith has also published a comprehensive review of the topic (Ref 16).

Definition of Terms. Important terms related to tire wear are defined below.

- *Tread loss:* Average cumulative loss in tread depth for all the grooves in the tire, expressed in millimeters
- *Rate of wear:* Tread loss in millimeters per 10,000 km of travel
- *Tread wear index:* (Wear rate of reference or control tire)/(Wear rate of experimental tire) × 100
- *Standard wear rate:* mils per 1000 miles per 100 lbf cornering force at tire test temperature
- *Camber angle:* The vertical angle between the wheel plane and a line perpendicular to the pavement (Fig. 1)
- *Slip angle:* The horizontal angle between the tire circumferential midpoint plane and the direction of tire motion (Fig. 1)
- *Cornering stiffness:* Force per degree of slip angle
- *Test severity:* Function of tire force severity, pavement surface severity, or weather/temperature severity

- *Tire force severity:* Magnitude of cornering force
- *Pavement surface severity:* Micro- and macrotexture, blunt or harsh (qualitative ranking)
- *Weather severity:* Summer/winter temperature, rain, snow
- *Severity index gradient:* Rate of change of tread wear index with tire force severity
- *Driving severity number (DSN):* Sum of the squares of lateral acceleration per tire revolution (g_i) divided by the number of revolutions (N) normalized for vehicle weight:

$$DSN = \sum(g_i/100)^2\,(F_z F_{z,R})^2/N \qquad \textbf{(Eq 1)}$$

where F_z is the actual tire load and $F_{z,R}$ is the rated tire load.

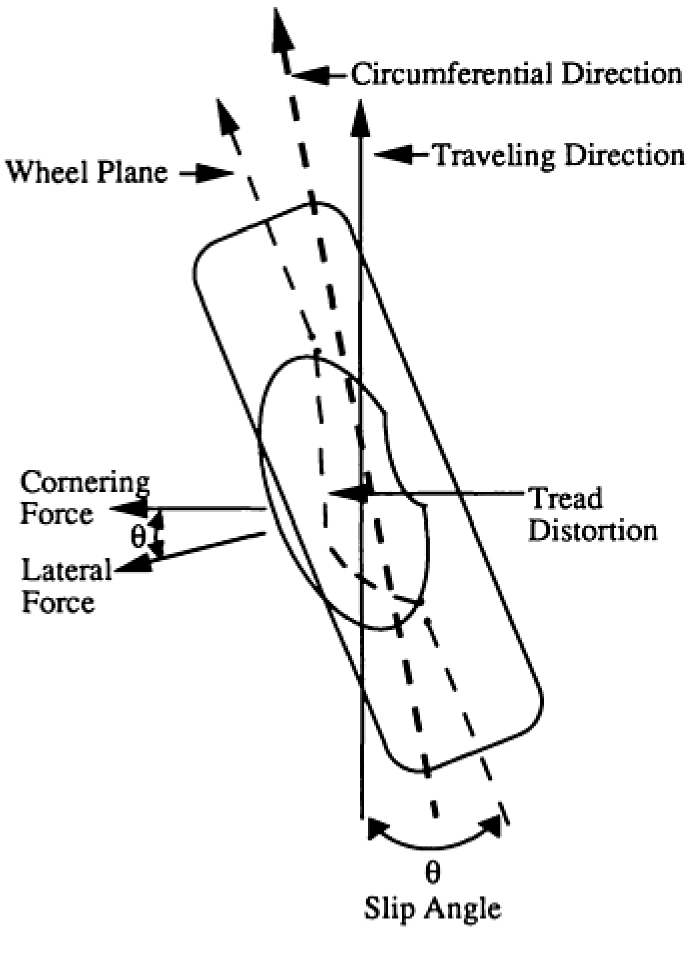

Fig. 1 Schematic showing tire footprint forces and tread distortion

Basic Mechanism. Figure 1 is a schematic of a tire making turn, the direction of motion, the slip angle, and the cornering and lateral forces are indicated. The tire is skewed to the left by the slip angle θ. The distortion of the tire footprint generates a lateral force, mv^2/R, so that the vehicle can make the turn (m is the mass on the tire, v is the instantaneous velocity, and R is the radius of curvature). The tread rubber is held to the road by rubber friction at the leading edge of the footprint. The forces acting in the footprint distort the tread area laterally. The distortion increases in magnitude as the tread element travels from the leading edge toward the trailing edge of the lateral footprint. When the local lateral distortion exceeds a certain limiting value, the frictional force cannot maintain the deflection and the tread element slides back toward the tire center plane. The tread rubber stores elastic energy while in the distorted state. This stored energy is partially converted into frictional work during the sliding domain. The dissipation of this frictional work during the cornering mode is the source of free-rolling, untorqued tire wear.

Tire Axis System. Figure 2 includes additional parameters (for example, tire forces, tire moments, and tire angles) that affect tire wear.

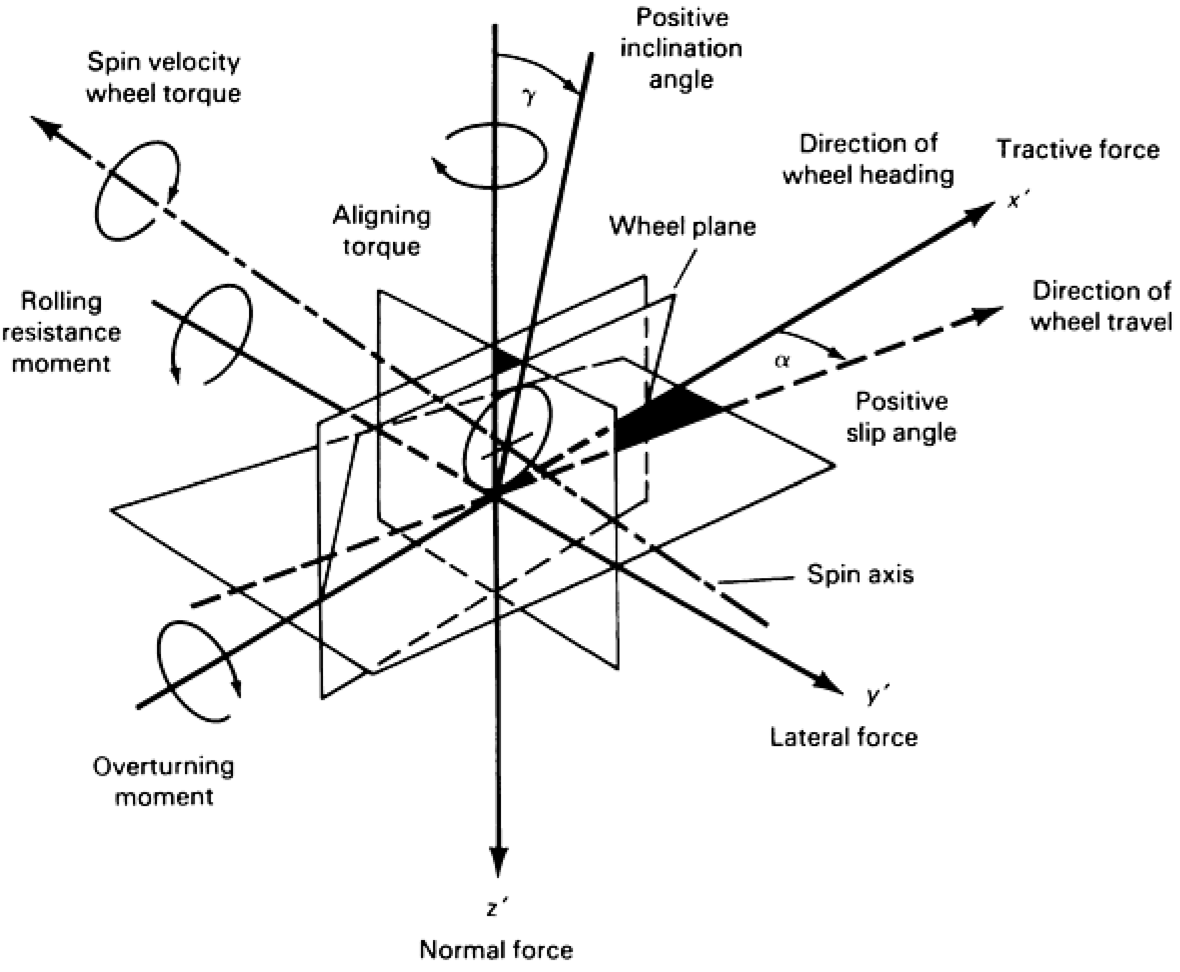

Fig. 2 Schematic showing angles, moments, and forces which comprise a tire axis system. Source: Ref 17

Tire Wear Models

Theoretical Model. Using basic principles of physics, Schallamach and Turner (Ref 18) developed an equation for even wear of tire treads in terms of average cornering force (*F*), cornering stiffness (*C*), tire resilience (*R*), and tread rubber abradability (γ):

$$A = \frac{\gamma R F^2}{C} \cdots \qquad \textbf{(Eq 2)}$$

where *A* is the wear rate per unit distance. Pulford (Ref 4) discusses some of the practical implications of Eq 2. Livingston (Ref 19) extended the Schallamach-Turner model by partitioning the total energy stored into two parts--a fraction stored in the tire body as a whole and the remainder stored in the tread--and obtained the following expression for tread life:

$$h = \left(h_0 + \frac{B}{A}\right)\exp(-Ax) - \frac{B}{A} \qquad \textbf{(Eq 3)}$$

where h and h_0 are final and initial tread height, respectively, x is distance traveled, and B and A are experimental constants.

Empirical Model. Experimental results have shown that the theoretical model expressed in Eq 2 must be modified as:

$$W = kF^n \qquad \textbf{(Eq 4)}$$

where k is a constant and the exponent *n* ranges from 2 to 4. The value of *n* depends on the slip angle, the nature of the pavement, and carbon black particles (Ref 12). The Schallamach-Turner equation (Eq 2) indicates that force is the controlling factor in tire wear. Gough (Ref 11) has also shown that cornering force is the major source of tire wear. At equivalent force levels, cornering action causes higher energy loss in tires than braking action. Experimentally, it has been shown (Ref 12) that tire wear varies exponentially, rather than linearly, with force. This is general agreement with Eq 2 and 4.

The above models explain regular wear in tires reasonably well. However, tire also exhibit irregular wear, and at present there are no good mathematical models to explain this phenomenon. According to Livingston (Ref 20), irregular wear may occur because of differences in stiffness and ground pressure from point to point in the tire footprint area. These differences result in different strain levels within the contact area, leading to different amounts of sliding from point to point. Livingston has proposed a theoretical approach that assumes differential slips for various tread elements to explain irregular wear. He suggests using finite element analysis (FEA) simulation in incremental steps.

Standard Wear Rate

Tire design and construction parameters affect the nature of the forces generated in the footprint area. As mentioned earlier, force is the dominant controlling factor in tire wear. Therefore, to compare wear rates for different tire constructions, the measured wear rate for each construction can be related to a reference force value and corrected for surface temperature variation. This corrected rate is known as the standard wear rate. Incorporating Schallamach's temperature-correction relationship (Ref 8), Veith (Ref 12) developed the following equation for the standard wear rate:

$$W^{\circ}_{50} = \frac{[W \cdot (100)^2]}{F^2[1 + \alpha(T - 50)]} \qquad \textbf{(Eq 5)}$$

where W°_{50} is the standard wear rate at 50 °C (120 °F) and 100 lb cornering force, *F* is the average cornering force in pounds, α is the temperature coefficient of wear rate, and *T* is the test temperature in degrees Celsius.

Fleet Testing and Trailer Testing

Measurement of tire wear is generally done by fleet testing. A car fitted with one type of tire is driven over specific routes representative of typical driving conditions. Test conditions, such as tire rotation, frequency of vibration, speed, straight driving, turns, and nature of pavement, are preset. The initial and final tread depths averaged over all the grooves are measured, and the total wear is calculated from the difference between the tread depth values. Based on the miles driven, an "average" wear rate is obtained. The test is repeated using tires with different variations in design, compound, materials, and so on. Results allow comparison of the wear rates of different tires. The primary limitation of this method is that the various factors that influence tread wear cannot be independently controlled.

In the trailer testing method, both cornering force and slip angle can be controlled and monitored. This method allows the researcher to directly control the magnitude of the force acting on the tire. Thus, wear rate as a function of force can be determined. Veith (Ref 12) describes a trailer test system with elaborate instrumentation for controlling test parameters and for making measurements. He used this method to study the effects of tire force, weather conditions, and pavement texture on wear rate. He also showed that wear rate is proportional to F^2, where *F* is force, which is in agreement with Eq 2. Driving severity number (*DSN*) is a concept developed by Veith (Ref 21) to arrive at a composite parameter value that combines the total effect of the three factors mentioned above. Using the *DSN*, Veith (Ref 21) quantified the tire input force and driver vehicle interaction over a test course to better explain tread wear rankings.

Effects of Load and Velocity

Veith (Ref 12) has shown that lateral force, *F*, can be expressed in terms of vehicle weight, *L*, as:

$$F = \left(\frac{L}{G}\right)\left(\frac{V^2}{R}\right) \quad \textbf{(Eq 6)}$$

where V is vehicle velocity, R is the radius of curvature, and G is acceleration due to gravity. L is equal to four times the average tire load. Combining Eq 6 and Eq 2, the wear rate can be written as:

$$W = K\left(\frac{L^2V^4}{R^2G^2}\right) \quad \textbf{(Eq 7)}$$

where K is a constant. This indicates that the wear rate is proportional to the second power of tire load and to the fourth power of vehicle velocity.

Experimental verification of Eq 7 is not straightforward. It has been found that the extent of change in W with change in L depends on how W is measured--by trailer method or by vehicle cornering. For the same change in ΔL, the corresponding change in cornering force is much smaller in the former test procedure. Therefore, change in W is higher in the vehicle cornering method than in the trailer method.

Again, the relationship between wear rate and vehicle velocity also seems to be method dependent. Veith (Ref 12) found that the effect of vehicle speed was very small in trailer testing and had a more pronounced effect in fleet testing. Experimentally, it was found that the wear rate, W, was approximately proportional to the cube of the velocity (Ref 4). It appears that there is some inconsistency between theory and experiment, as well as between different experiments, and it is thus difficult to correlate experiment with theory.

Test Severity

The major components of test severity are tire force severity, pavement surface severity, and weather/temperature severity. Biard and Svetlik (Ref 22) reported that the wear index of styrene-butadiene rubber ranged from 98 to 216 (natural rubber = 100) as severity increased. Geesink and Prat (Ref 23) found that the wear rating order of different tread compounds changed with test severity. Veith (Ref 12, 13) systematically studied tread wear as a function of the three severity factors listed above.

Tire Force Severity. Force severity was controlled by different vehicle cornering and braking maneuvers. Miller *et al.* (Ref 24) have shown that the cornering wear rate is about seven times higher than the braking wear rate. These results confirm the previous assertion that cornering force is the most important variable affecting tire wear.

Veith (Ref 12, 13) varied tread composition by using different types of carbon black and determined the tread index as a function of cornering force. Severity index gradient was defined as the rate of change of wear index with force severity. This experiment led to the conclusion that carbon black of smaller particle size provides good wear resistance at high severity conditions. Studebaker (Ref 25) and Dannenburg and Amon (Ref 26) also support this finding. As radial tires became popular, the wear rating of radial construction versus bias construction was measured. It was found that as force severity increases, the radial construction has a higher wear index than the bias construction. In other words, radial tires have higher wear resistance than bias tires.

Pavement surface severity is a combination of micro- and macrotexture and is qualitatively ranked as harsh or blunt. Lowne (Ref 27) has shown that pavement texture is important in determining wear rate. The wear ranking of tread compounds is not independent of the surface texture of the pavement. For example, a compound that is superior to another compound on a blunt surface can become inferior on a harsh surface. Veith (Ref 13) observed similar ranking reversals in testing of two different tread compounds on blunt and harsh surfaces. This sort of ranking reversal has also been observed in laboratory abrasion experiments by Schallamach (Ref 28), Kragelski and Nepomnyashchi (Ref 29), and Pulford (Ref 30). Schallamach explains this behavior by invoking the tensile tear mechanism and/or physical property degradation of rubber, depending on the nature of the abrading surface.

Weather Severity. Tire surface temperature, ambient temperature, rain, and snow affect wear. Wear rate increases as temperature increases. Veith has studied this phenomenon extensively (Ref 13, 16). The literature presents conflicting results with regard to wear rate on wet versus dry pavement.

Effects of Various Factors: Experimental Design Study

Veith (Ref 14) conducted and extensive study of the effects of multiple levels of five design factors on tread wear (Table 2). The design details, the tread wear testing, and the regression analysis are presented in Ref 14. The factors in order of importance for superior wear resistance are tire type, tread loss modulus, and tread pattern. Radial tires had better wear resistance. Similarly, as the loss modulus increased, wear resistance increased. Tires with higher groove volume and aspect ratio showed poor wear resistance.

Table 2 Effects of tire-related factors on tire wear rate

Parameter	Level	Transformation of level		Change in wear rate[a]
		From	**To**	
Tire type (ply)	Bias	Bias	Radial	-100
	Bias belted			
	Radial			
Aspects ratio	60	60	78	+39
	70			
	78			
Groove void fraction	0.16	0.16	0.43	+46
	0.43			
Tread pattern	Circumferential	Circumferential	Block	-7
	Block			
Tread loss modulus	0.84 MPa (122 psi)	0.84 MPa (122 psi)	1.37 MPa (200 psi)	-15
	1.37 MPa (200 psi)			

(a) Minus sign represents an improvement in wear rate; plus sign represents a decline in wear rate:

Veith and Chirico (Ref 13) also studied carbon black in a separate experiment. At high severities, carbon blacks with high structure and surface area exhibited better wear resistance than those with normal structure. The rate of wear passed through a minimum as a function of carbon black level at each severity. Wear rate increased with increased oil content. Some crossover results were obtained as the severity level changed from high to low.

Tire Conceptual Model

A tire is a composite deformable structure. Under load, each tire component deforms. The magnitude of these deformations varies from component to component, depending on component stiffness. The different deformations generated in each component cause interfacial stresses, leading to a complex stress distribution in the footprint area. Oblizajek and Veith (Ref 15) discussed a detailed experimental setup to measure the footprint stress distribution and mechanical properties of tire components.

The mechanical properties discussed in Ref 15 can be used to characterize wear using the Gough model (Ref 11, 31). The Gough model considers the tire tread band as a beam and the carcass as an elastic foundation. Tread/belt transverse flexural rigidity. *EI,* and carcass foundation stiffness, *K,* are introduced in this model. The flexural rigidity is a product of Young's modulus, *E,* and the moment of inertia, *I.* The effects of different combinations of *EI* and *K* values are discussed in Ref 11. It is reported that tire wear improves as the pairs of *EI* and *K* values change in the following order: high *K,* low *EI;* high *K,* high *EI;* low *K,* high *EI.* Using composite theory, Walter *et al.* (Ref 32) developed a method to calculate the tire component stiffness parameters in different directions.

Further refinement of the Gough model introduced tread band transverse shear modulus, *G,* as an additional important parameter to explain wear resistance. The modified tread band transverse stiffness incorporates both *EI* and *G* (Ref 31). Oblizajek and Veith (Ref 15) have shown very good correlation between these mechanical properties and tread wear over a wide range of tire construction.

Coefficient of Friction of Rubber. Providing a specific value for the friction coefficient of rubber is impossible because there is no one value for the coefficient of friction of rubber against a specific surface (asphalt, concrete, glass,

and so on). Friction is dependent on a complex system of parameters (that is, normal force, sliding and rotating speed, surface roughness, surface lubrication, and temperature). Grosch (Ref 33) has conducted extensive experimental studies of rubber friction over a wide range of parameters and conditions. It is postulated that the total frictional force, F_t, is given by the equation:

$$F_t = F_a + F_h + F_v \quad \textbf{(Eq 8)}$$

where F_a, F_h, and F_v are the adhesive, the hysteretic, and the viscous components, respectively. In addition, the magnitude of the friction force depends on the contact area. Muhr and Roberts (Ref 34) have published a review of rubber friction and its relation to wear. Despite all of the experimental work done or rubber friction to extrapolate data from the laboratory results, determining the actual tire tread wear rate in the field is still not easily possible.

Future Outlook

Tire tread wear is a result of dissipation of frictional work generated in the footprint area. Cornering force is the primary factor responsible for tire wear. Reasonable correlation between tire component mechanical properties and tread wear has been established by statistical methods. However, this approach has its limitations. Although much research has been directed toward gaining an understanding of tire wear, most of it so far has been empirical. More research is needed to establish a precise relationship among composite properties, material properties, and tire wear.

Friction and Wear of Aircraft Brakes

E.M. Tatarzycki and R.T. Webb, Aircraft Braking Systems

Introduction

AIRCRAFT BRAKES are designed to stop an aircraft through the conversion of kinetic energy into heat by the mechanism of friction. Aircraft brakes are composed of multiple disk pairs, which are commonly referred to as the brake heat sink. Unlike an automotive brake, which consists of a single piston, a single rotor, and two brake pads, the majority of aircraft brakes use full-circle rotors and stators (Fig. 1). Brake housings normally contain several pistons for applications of the normal force needed to develop the brake torque. Large commercial transport aircraft brakes must be capable of absorbing up to 135 MJ (100×10^6 ft · lbf) of energy. The high levels of torque developed to stop an aircraft require the conversion of large amounts of kinetic energy into thermal energy over a short period of time. This energy conversion process produces very high energy fluxes at the multiple friction interfaces, resulting in high temperatures and stresses in the brake heat sink.

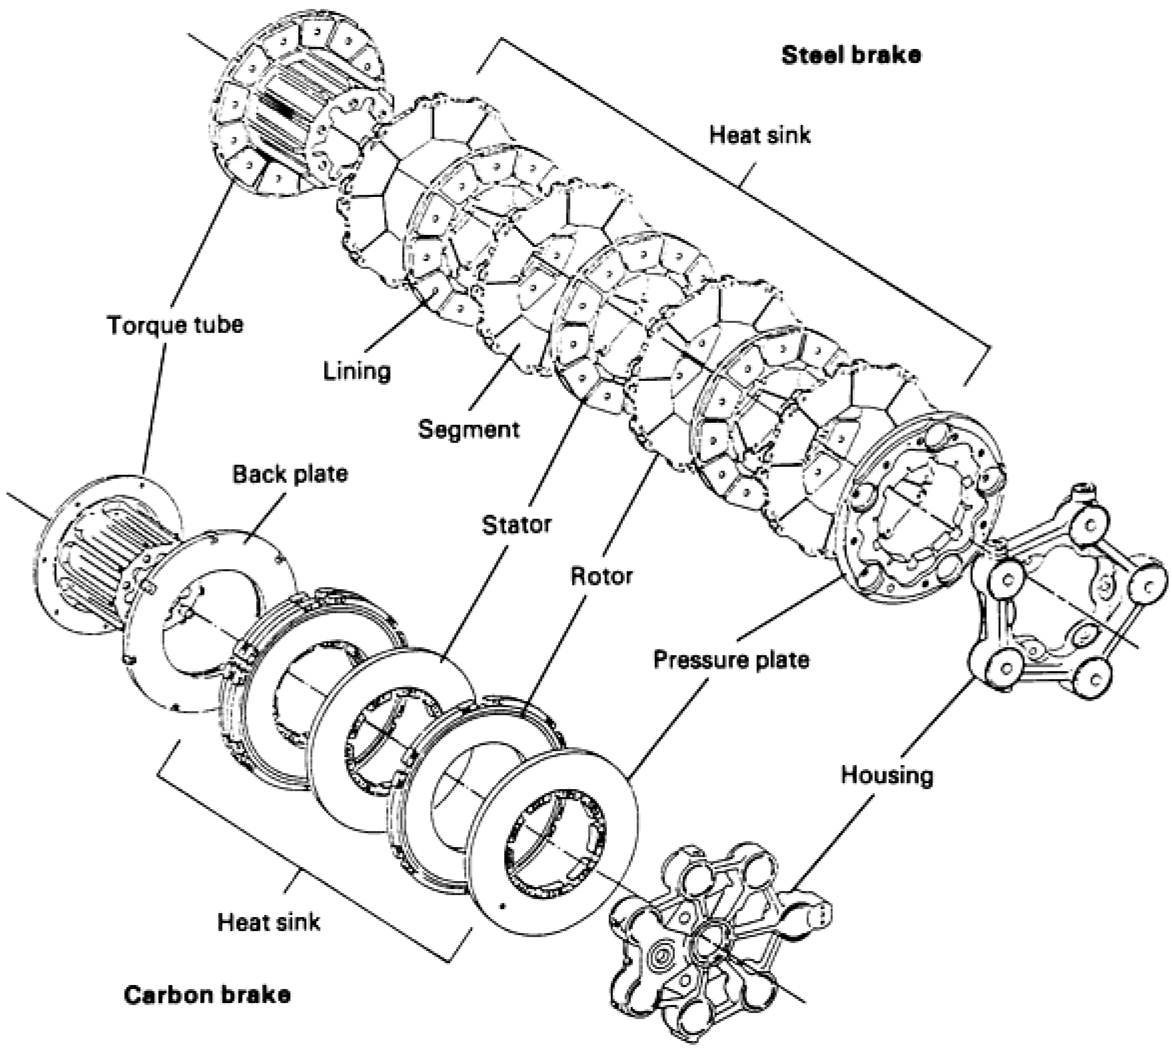

Fig. 1 Illustrations of steel and carbon aircraft brakes

The friction and wear characteristics of the friction materials used in aircraft brakes are influenced by internal factors (such as friction-material composition and heat sink mass) and external factors (such as the amount of kinetic energy absorbed by the brake, the surface velocity of the friction interfaces, and aircraft deceleration requirements). Simply put, these factors control the temperature at the interface and the normal and tangential forces of the friction material.

Aircraft Friction Materials

Three basic friction materials are presently being used in the aircraft brake. These include:

- Sintered metal friction materials
- Carbon-carbon composites
- Organic materials

The sintered metallic friction material is probably the most widely used in aircraft brakes. The steel brake heat sink consists of a sintered metallic friction material bonded to a steel supporting backing plate. The steel brake has a higher wear rate, is heavier, and has a lower cost per brake landing compared to the carbon brake. The carbon/carbon composite friction material is the latest technology. The carbon brake is lighter in weight, has excellent high-temperature performance, has a low wear rate, and has a higher cost per brake landing. Organic brake linings are used on older and

smaller aircraft and in helicopter rotor brakes. Most of the work being done in this area is aimed at replacing the existing asbestos-based linings with nonasbestos materials and will not be discussed in this article.

Steel Brakes

The metallic friction materials are primarily fabricated into two final forms. The current designs dictate that the metallic friction material be bonded into metal cups. These linings, as they are commonly called, are then riveted to a carrier disk. The other form is called a full-sintered disk on which the friction material is bonded directly to the carrier disk.

The steel brake is composed of multiple pairs of rotors and stators (Fig. 1). In this type of brake, the stators carry the metallic friction material and the rotors are composed of a high-strength high-temperature steel, commonly called the opposing surface. Some designs have the rotors carrying the metallic friction material. The opposing steel typically will last two to three times longer than the metallic friction material lining. The selection of the metallic friction material influences the brake design and must be carefully considered in order to obtain optimum dynamic performance, friction coefficient, stability, and wear rate of the friction pair. The system dynamics, which includes brake, wheel, tire, strut, and hydraulics, is also greatly influenced by the selection of the friction material.

Chemistry. The metallic friction materials are blends of various metallic and nonmetallic powders. The mixtures are primarily blends of copper and iron with one or the other being predominate in the composition. The base matrix of either iron or copper is modified by the addition of graphite, in natural or synthetic form; silicon as an abrasive; and modifiers such as high-temperature lubricants (for example, molybdenum disulfide). The size and shape of the powders can influence the final product. Proprietary materials may be added to control brake vibration, matrix strength, and wear.

Processing. The metallic mixture is then sintered in a furnace to form a metal-matrix composite. The sintering process takes place at high temperatures and sometimes under pressure. The required final density of the metallic matrix is attained by hot or cold working of the lining. The choices made in the processing of this matrix can greatly affect the dynamic performance and wear life of the friction pair. The bond of the friction material to the steel cup or core is critical. If the sintered matrix does not bond, then the matrix can spall and leave large areas void of friction material. The bonding of the matrix to cup or core is controlled by the base metallic elements (iron and copper) and any devices that might be added to the design to enhance matrix-to-carrier bond strength.

The copper-base metal matrix can attain a good bond to the carrier if sintered at an optimum temperature, time, and pressure. The iron-base metal matrix sometimes requires a screen welded to the cup bottom to supplement bonding. The iron-base metal matrix relies on a mechanical bond occurring in the open area of the screen.

Friction Material Selection. Choice of friction material determines the friction coefficient and the brake design. The iron-base matrix tends to have a lower coefficient. This requires the brake to have large-diameter pistons to achieve specific design goals (such as stopping distance, which is a critical parameter in aircraft certification). The copper-base matrix tends to have a higher coefficient. This would require smaller pistons and result in a lighter housing.

Thermal Properties. The thermal and strength properties are influenced by the chemistry, particle shape, and particle size of the friction material mixture. For a stator-rotor friction pair, the most significant parameter is the temperature at the friction interface. Typically, the lower the interface temperature, the better the brake wear life. This temperature is influenced by the thermal conductivity of the lining and opposing steel surface, the thickness of each disk, and other boundary conditions. It is desirable to design a friction pair such that the heat is conducted away from the interface quickly.

Balance. The correct distribution of mass among the various brake members is crucial for optimum dynamic performance and balanced disk wear. The specific distribution of mass in the brake is very dependent on the nature of the friction mix. Each interface of a multiple-pair brake does not perform equally. Typically, the greatest wear takes place on surfaces that are nearest the pistons. Therefore, the friction pairs are normally of greater axial thickness closer to the pistons. Mass balancing of the brake stack components is done so that the friction interfaces all wear out at the same time.

Brake wear is normally measured by the length of a steel pin (wear pin) extending from the pressure plate through the housing. If a brake has a 25 mm (1 in.) wear pin, this means that 25 mm (1 in.) of wearable material is left in the brake stack. Brake wear is usually expressed in units of mm/face/stop. In subscale dynamometer evaluations, weight-loss measurements are of primary importance.

The wear mechanism taking place at the friction surface is very complex and not fully understood. After the first few stops, both surfaces form a film, sometimes referred to as a layer of glaze, at the contact surface. This film is mainly an oxide, the mechanical and tribological properties of which are different than the parent materials. The film thickness varies over the surface. The combination of thickness and properties controls the resulting coefficient and wear rate of the brake.

Wear Mechanism. An aircraft brake is expected to operate over a wide range of energy inputs. These varying energies control the temperature at the friction interface. During low energy, that is, low interface temperature, the wear is characterized by abrasive wear. Abrasive wear occurs when hard particles cut grooves across the opposing surface and displace material. When brake energies are higher, the interface temperatures are also higher and an adhesive type of wear takes place. Adhesive wear occurs when surface asperities, bonded together under localized high temperatures and pressures, shear apart during sliding of the surfaces. The wear debris may become trapped between the surface and contribute to abrasive wear.

Wear Rates. Figure 2 shows wear rates based on normalized stack loading and average energy flux (AEF). For an aircraft to attain 1000 stops (a stop is equivalent to a landing), assuming a five-pair brake with a 50 mm (2 in.) wear pin, wear rates of 0.0025 mm/face/stop (0.0001 in./face/stop) would be required.

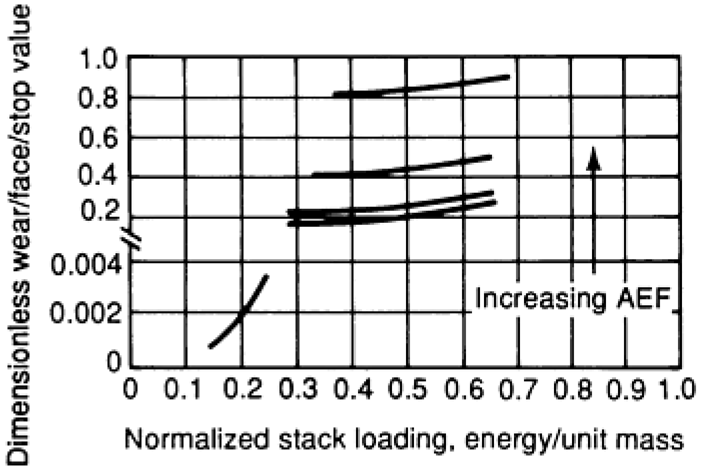

Fig. 2 Typical wear rates for a steel brake based on stack loading and average energy flux (AEF)

When aircraft taxi out to the runways, they normally start and stop along the way. These small stops are referred to as taxi stops and snubs. During a snub an aircraft does not come to a complete stop. Brake life typically is measured by the number of landings, and this would include any taxis and snubs required to maneuver the aircraft. For steel brakes, the wear that takes place at these low energies is not as significant as the main landing wear and is normally considered as being part of the main landing stop. In contrast, the taxi wear in carbon brakes accounts for a large portion of the brake wear.

Aircraft brakes are designed to handle one rejected take-off (RTO) stop (the wear rate is normally one hundred to one thousand times greater during an RTO stop than during a service stop). After an RTO stop, the brake and wheel are normally scrapped. In recent years the worn RTO has become an important issue. Because RTO wear on a worn brake stack in normally at a higher rate than wear on a new stack, some aircraft have been mandated by the Federal Aviation Administration (FAA) to limit the brake life to ensure that there is sufficient wear material in the brake to perform a worn RTO.

Brake Design. The selection of the metallic mix can influence the brake design in many ways. A friction material with a low friction coefficient will require larger pistons to supply a large clamping force (normal force) in order to achieve the high torque required to attain stopping distances. The required heat-sink mass is normally determined by how much energy the brake must absorb during the RTO stop or by some other critical condition. Typically, new brakes with metallic linings are designed to be loaded in the 750,000 to 900,000 J/kg (250,000 to 300,000 ft · lbf/lb) range for the RTO stop. The required aircraft deceleration is also influenced by mix selection. The deceleration rate controls the

average energy flux at the interfaces, and different types of mixes have differing limitations. The limitations on AEF determine the amount of rubbed area required in the brake.

Coefficient of Friction. In general, metallic friction materials exhibit a consistent coefficient of friction over a broad range of loadings, whereas carbon friction materials exhibit a wider band of coefficient over the operating spectrum of the brake. The balance coefficient is influenced by the past service history of the friction material, the loadings, and the design of the opposing surface. Normally, the brake coefficient decays during the first several landings when starting with new friction material. This decrease in coefficient is usually attributed to formation of oxides and stabilization of the surface film.

The friction coefficient is also affected by the energy flux and the total loading on the brake (Fig. 3). If a brake design requires a high energy flux, the coefficient must then be accounted for. Normally, as the energy flux is increased, the average coefficient decreases, and thus the brake clamping forces must be of sufficient magnitude to ensure that the required deceleration rate is met.

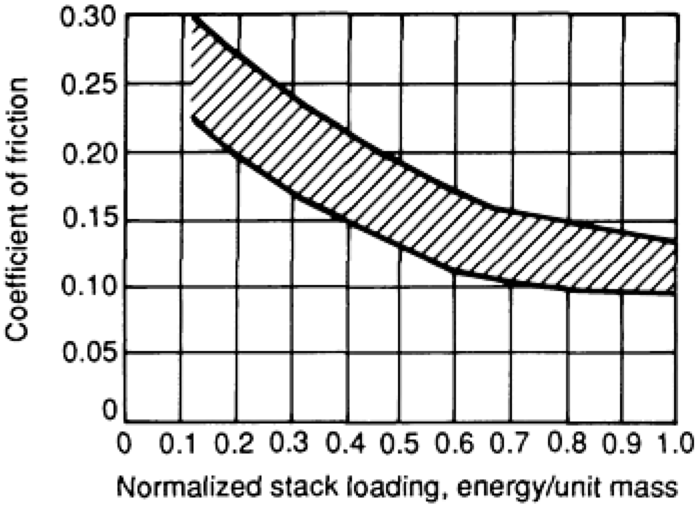

Fig. 3 Typical range of friction coefficients for a steel brake based on stack loading

The brake loading is another parameter that changes the average coefficient during a stop. The requirements of the RTO stop normally influence the brake design, and lower friction coefficients due to higher loading and surface velocity must be considered. Coefficients are also influenced by the material and design of the opposing metal surface. The majority of the steel brakes use AMS 6385C (plate), AMS 6302C (forging), or Timken 17-22AS for the opposing surface.

Spalling. The metallic friction material is exposed to high stresses and temperatures. During the extended use of an aircraft brake, the linings wear thinner and the friction material oxidizes; both factors potentially lower the matrix strength of the friction material. The high stresses encountered during stopping may spall all the friction material. The loss of large chunks of friction material reduces the rubbing contact area, thereby reducing brake torque. Once a lining spalls, the metallic cup that holds the friction material can warp. In severe cases, the rivet could fail and deline the face of one disk. In order to eliminate the potential for matrix spalling, minimum lining thicknesses have been established and friction materials with enhanced matrix strength have been developed.

Vibration. Typically, a metallic friction material that has a longer wear life also tends to cause brake vibration. It has been determined that a friction material with an increasing coefficient during a stop will tend to make the braking system unstable and cause vibration (Fig. 4). Proprietary additives and changes in the basic constituents of the friction material are made to produce a "smooth" friction material. Severe brake vibrations can cause the strut to vibrate, possibly leading to strut failure; therefore, such vibrations must be accounted for and remedied.

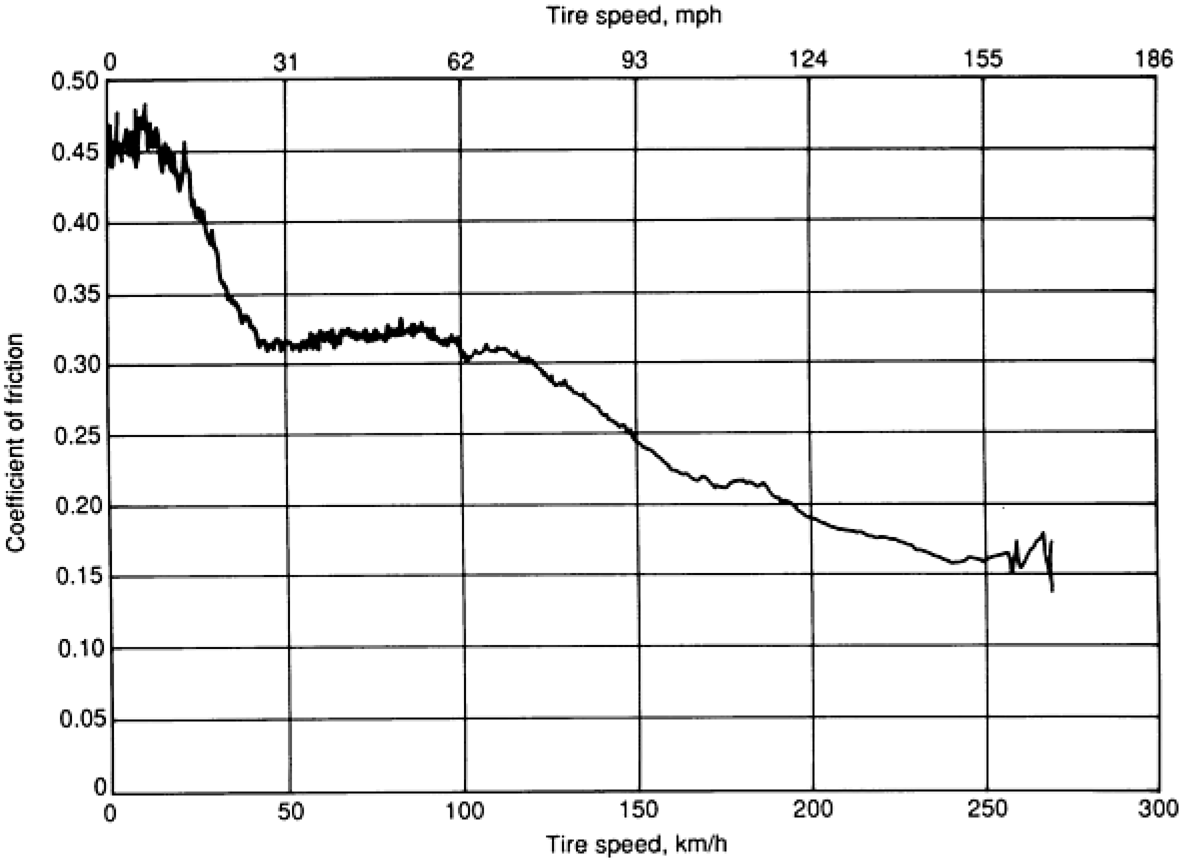

Fig. 4 Variation of friction coefficient versus tire speed during a single stop

Service Life. The aircraft industry is constantly striving to produce longer wearing brake materials. Typically, large commercial jets get around 1000 landings on a brake stack before refurbishment. The individual brake components should be balanced so that they wear evenly. Uneven wear can cause problems, such as spalling and delining.

Carbon Brakes

Raw Materials. Carbon-carbon friction materials are composites comprised of high-density carbon fibers embedded in a carbon matrix. At the present time, all the carbon fibers used in carbon aircraft brakes are made from two precursors: polyacrylonitrile (PAN) or pitch. Fiber properties are normally controlled by the manufacturing process of the fiber and are beyond the scope of this article. Such information, however, can be found in the articles "Carbon Fibers" and "Processing of Carbon-Carbon Composites" in *Composites,*Volume 21 of *ASM Handbook.*

Carbon fibers can be woven, knit, spun, and generally handled like most textile threads, but with more difficulty. In brakes, woven fabrics, short-length yarns, chopped fabrics, and woven three-dimensional preforms are used. Each manufacturer has its own preferences; thus the entire system--reinforcement and matrix--can be designed to produce specific performance.

The carbon matrix can be established in many ways. The most common is by the deposition of pyrolytic carbon directly onto the surfaces of the pores and voids within the disk. This technique is called the chemical vapor infiltration (CVI) or chemical vapor deposition (CVD) process. The infiltration or deposition is carried out in a reactor (furnace) under vacuum, high temperature, and the flow of a hydrocarbon gas. Another way to achieve a carbon matrix is to mold the fibers with a resin, such as phenolic, and convert the resin to carbon by charring at temperatures ranging from 540 to 815 °C (1000 to 1500 °F). Subsequent impregnation as with resin, pitch, or resin-pitch blends followed by a char cycle can also be carried out.

Processing. Carbon-carbon composites are porous because of the nature of the densification process. The conversion of phenolic resin to char results in porous, glassy carbon. The CVI process relies on the ability of the gas to infiltrate the maze of fibers or partially densified composite to deposit a carbon, which some researchers have categorized into three groups: isotropic, smooth laminar, or rough laminar. As the infiltration proceeds, many of the interior surfaces become inaccessible to the gas. These remain inaccessible and become permanent voids. Consequently, a multiple-step densification cycle is necessary to reduce the porosity and to achieve acceptable densities, usually in the 1.70 to 1.85 g/cm^3 range.

Processing may also include heat treatment at temperatures ranging from 1650 to 2800 °C (3000 to 5000 °F). Such a heat treatment is called graphitization and is used to control the properties of the carbon. For example, a fully graphitized carbon (graphite) will have a crystalline form, have an atomic lattice spacing of 0.3359 nm (3.359 Å), offer little resistance to indentation (making it soft), have a high coefficient of friction, and will exhibit high wear. An ungraphitized carbon will be amorphous in nature, have an atomic lattice spacing of 0.344 nm (3.44 Å), show high resistance to indentation (making it hard), produce a low coefficient of friction, and exhibit low wear. By selecting the appropriate raw material constituents, quantity of each constituent, specific process, and heat treatment temperature, it is possible to engineer a carbon for a range of friction coefficients and wear rates.

Physical Mechanical, and Thermal Properties. Carbon-carbon composites used in brake applications are unique because a single material serves as the friction surface, the heat sink, and the structural member of the brake. Consequently, this family of materials must have a wide range of properties. Densities must be high enough to enable the brake to absorb the high kinetic energies expended by the largest transports, yet low enough to be considered as a light-weight aircraft material. Its surfaces must produce a suitable rubbing aggressiveness to stop a large aircraft, yet maintain uniformity in friction over a wide range of temperatures. As a structural member, the carbon must exhibit high strength at both room and elevated temperatures.

The following properties are considered to be important for carbon brake performance:

- Density
- Porosity
- Thermal conductivity
- Specific heat
- Tensile strength
- Flexural strength
- Compressive strength
- Shear strength
- Impact strength

Coefficient of Friction. Many factors affect the coefficient of friction in a carbon brake. These factors can be grouped into two categories: overall brake design and actual carbon in the heat sink. In the brake design category, increasing the number of rotors will increase the coefficient as will a smaller size piston. The influence of carbon on the coefficient is complex. Studies conducted by the brake manufacturers have remained proprietary, but some generalities can be discussed. The PAN-base fibers will produce a different coefficient than pitch-base fibers. How different these coefficients will be is determined by processing factors. Fiber direction also determines the magnitude of coefficient. Some studies have shown that fibers in the circumferential direction produce a higher coefficient. The hardness or softness of the matrix also changes the coefficient; a harder matrix results in a lower coefficient.

The requirements for the RTO normally determine the adequacy of the brake design. A sufficiently high coefficient is needed to stop the aircraft. Proper selection of raw materials and processing conditions will determine the coefficient under RTO conditions as well as under the other energy conditions. Normally, the highest coefficient occurs at taxi conditions; the lowest occur at RTO energies. Figure 5 shows a typical variation in coefficient from taxi to RTO energies.

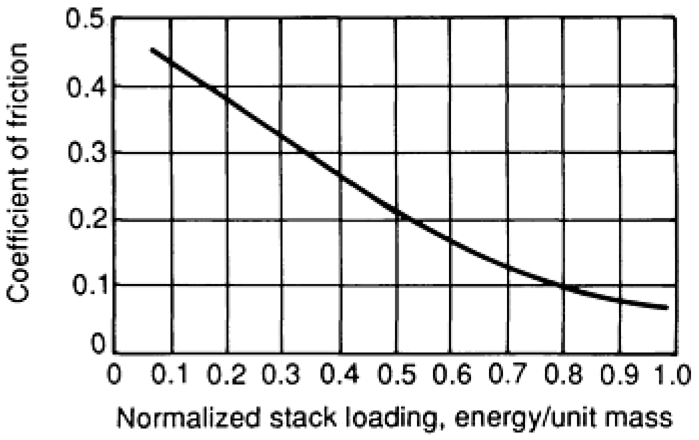

Fig. 5 Variation in coefficient of friction of carbon brake from taxi (left side) to RTO (right side) energies

Brake Wear. Carbon aircraft brake wear characteristics depend upon the raw materials and the specific processing parameters used during fabrication as well as the operating conditions of temperature, rubbing velocity, contact pressure, and prior braking history. Published information on the wear of carbon brakes is sparse, primarily because of the highly competitive nature of the aircraft brake business. Consequently, brake wear will be discussed in terms of possible underlying mechanisms rather than published scientific data.

Aircraft brakes operate under a wide range of energy conditions. Typically, an aircraft will taxi out to the runway, making several braking snubs (slowdowns) and complete stops along the way. After a successful take-off and flight, the landing occurs. Landings are classified into three typical categories:

- Service energy
- Normal energy
- Overload energy

Service energy is the lowest, and overload energy is the highest. Magnitude of energy is determined by the load the aircraft is carrying. The highest energy an aircraft will experience is during RTO.

Wear tests in the laboratory are conducted so as to simulate the conditions experienced by the actual aircraft. Taxi snubs, taxi stops, and landings are conducted in combinations called taxi/landing cycles, and wear is measured after several hundred of these cycles. Thickness loss as well as weight loss are measured. This technique enables engineers to compare different materials in the same brake run under the same conditions. In order to understand wear in engineering terms, it is necessary to run special tests at single energies. For example, 100 stops may be run at taxi energies, 100 more at service energies, 50 more at normal energies, and 20 at overload conditions. After each condition, the brake is disassembled and wear measurements taken. This approach enables the determination of which conditions result in the highest and the lowest wear. Figure 6 shows such data incorporated into a curve. Unlike a metallic brake, a carbon brake experiences the highest wear during the taxi condition, the lowest during the service condition.

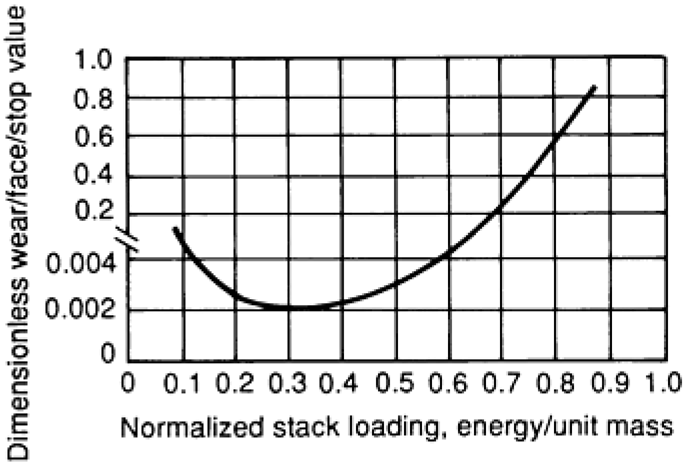

Fig. 6 Variation in wear of carbon brake from taxi to RTO energies

Each of the three energy ranges has its own wear mechanism. The taxi region exhibits the highest wear, and mechanical abrasion predominates. In the mid-energy (service energy) region, wear is lowest because a thin film protects the substrate. The third region occurs when temperatures are sufficiently high to produce oxidation of any debris or substrate (fiber or matrix). Oxidation usually occurs during overload and RTO conditions.

PAN-base fibers wear differently than pitch-base fibers; these differences are associated with fiber processing as well as composite processing. A harder matrix will wear less than a softer one. Studies have shown that circumferentially oriented fibers have high wear and a high coefficient of friction.

Wear Mechanism and Wear Debris Analysis. The worn surfaces of the carbon materials have bands of different reflectance when observed via macro examination. Debris material occurs in both bright and dull bands. The observed banding on the wear surface of the composite is related to variations in reflectance; these variations are thought to be related to differences in the character of the wear debris. The bright bands consist of a thin film of debris with a polished appearance that produces a high reflectance. The dull bands have a high number of fissures or shallow grooves and scratches in the longitudinal fiber bundles, both of which are indicative of fiber removal caused by abrasion. The debris material in the dull bands does not produce a high reflectance and appears less dense (more porous) than the bright bands. The debris in the dull bands is particulate and is comprised of fibers and matrix. This debris does not form a film, but fills in the original porosity, mainly in the matrix, and is found primarily under low-energy conditions.

The debris in the bright band consists of a thin film (up to a few micrometers thick) that is smeared over fibers and matrix and also fills in the pores. The bright bands appear to be denser (less porous) than the dull bands. The wear debris film is grooved, whereas the fibers and matrix are not. This indicates that the wear debris film is protecting the fibers and matrix from abrasion.

The thin film of wear debris is amorphous in character and is comprised of both fibers and matrix. High-energy braking conditions produce a high coverage of wear debris (film), which may result in a low coefficient of friction and low wear rate. More detailed information on wear debris analysis can be found in the article "Lubricant Analysis" in this Volume.

Moisture Problems. Carbons and graphites have an affinity for moisture. These materials adsorb moisture; that is, water molecules are attracted to their exterior and interior surfaces. Consequently, the presence of moisture significantly reduces the coefficient of friction. When a brake is sitting for a period of several hours, the rubbing surfaces will adsorb moisture from the air. Thus, when a brake stop is initiated in this condition, the stopping power is significantly reduced because of the low coefficient. This is typically referred to as "morning sickness." As rubbing continues through the stop, the moisture evaporates and the coefficient returns to its normal dry value.

Oxidation. Carbons and graphites are also subject to oxidation at elevated temperatures. Typically, the threshold of oxidation is considered to be 430 °C (805 °F). Technically there is oxidation at this temperature, but it is so low that it is considered to be negligible. Other than taxi conditions, the operating temperatures of a carbon brake will range between

500 and 1000 °C (930 and 1830 °F) during landings; under RTO energies the temperatures exceed 1300 °C (2370 °F) and oxidation becomes a significant factor. In order to keep the disks from deteriorating, an oxidation inhibitor is applied to the outer and inner diameters of each carbon brake disk. Inhibitor is not applied to the wear surfaces because it would alter the friction characteristics of the carbon.

Friction Coefficient Variability. As stated previously, friction coefficients have a larger range over the operational spectrum of the aircraft when compared to the friction coefficients for steel brakes. This coefficient range has implications for brake control (antiskid) system design. In the carbon friction material, friction coefficients can vary by factors of 3 or more over the operation range of the brake. Therefore, the brake torque can vary by a factor of 3 or more. Carbon processing and brake frame design must take this friction coefficient variation into account.

Vibration. An aircraft wheel and brake is a system with multiple degrees of freedom that is subjected to high dynamic loads. This high dynamic loading is transient in nature and can be an exciter of vibration.

In a carbon brake, the most critical vibration mode is known as whirl. This mode consists of an accordian-type action of the brake disks combined with an orbiting motion of the brake structure about the axle (Fig. 7). The torque output and friction coefficient of the brake, as functions of velocity and brake pressure, are significant parameters in determining whether or not whirl motion will occur and, if it does occur, the severity of the vibration. Severe whirl can result in damage to the carbon brake disks and other wheel/brake hardware.

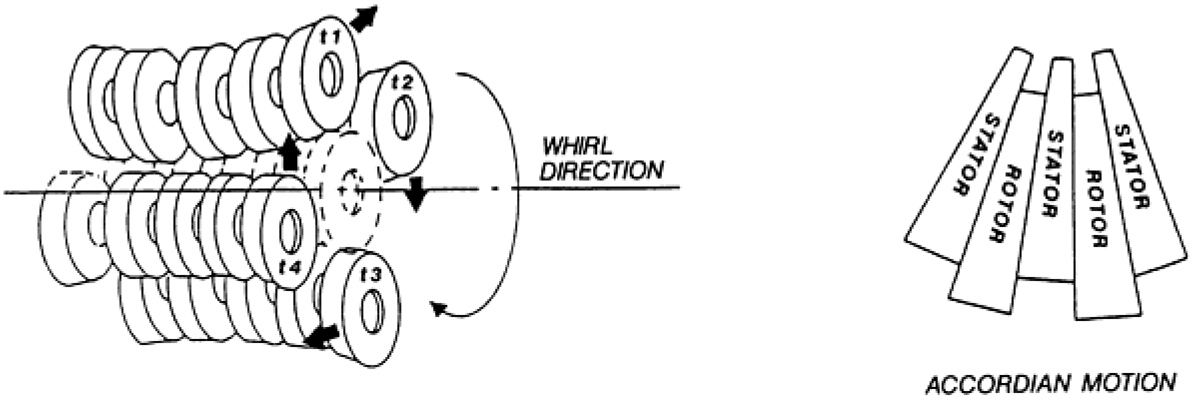

Fig. 7 Carbon brake vibration

There are two basic approaches that can be taken to control whirl vibration. First, carbon friction coefficient characteristics are engineered in such a way that the brake coefficient, at a given velocity and brake pressure, remains low enough to minimize the potential for the whirl vibration. Second, the aircraft wheel/brake is designed to incorporate the required stiffnesses and damping characteristics. Adequate stiffnesses and damping, combined with favorable friction coefficient characteristics, will ensure the stability of the aircraft wheel/brake structure at given dynamic conditions.

Testing

Friction material testing is conducted on either direct-connected dynamometers or on landing wheel dynamometers. Typically, new friction materials are screened in subscale brakes on direct-connected dynamometers. Once a potential material has been selected, then full-scale brakes are tested on landing wheel dynamometers which use an aircraft tire and wheel. Full-scale brake testing is very expensive and therefore limited. During aircraft wheel and brake qualification testing, the full-scale brake is run through numerous tests before any aircraft testing is done.

Test Requirements. Generally an aircraft brake must pass testing standards set up by the military or FAA. The military requirements are outlined in MIL-W-5013, and the FAA requirements are continued in TSO-C26. The Society of Automotive Engineers (SAE) also publishes an Aerospace Recommended Practice (ARP) for aircraft wheels and brakes (ARP 597). The airframe manufacturers also specify extensive supplemental qualification requirements that must be met before the brake can be qualified for service.

Wear of Jet Engine Components

J.D. Schell and K.P. Taylor, General Electric Aircraft Engines

Introduction

A JET ENGINE is a sophisticated piece of machinery with many moving parts; the potential for wear problems exists whenever moving parts come into contact or unintended motion occurs between stationary contacting parts. As for any system, wear in jet engines can be controlled through proper design, material selection, and lubrication. A schematic cross section of a typical jet engine is shown in Fig. 1. The major engine subsystems consist of the fan, the high-pressure compressor (HPC), the combustor, the high- and low-pressure turbines (HPT and LPT), and the exhaust nozzle. The engine design contains one nonrotating system and two concentric rotating systems. The nonrotating (stator) system is made up of structural frames and casings. The low-pressure rotating system consists of the fan disk(s) and fan blades, the LPT disks and turbine blades, and a connecting shaft. The high-pressure rotating system consists of the HPC disks/spools and compressor blades, the HPT disks and turbine blades, and a connecting shaft.

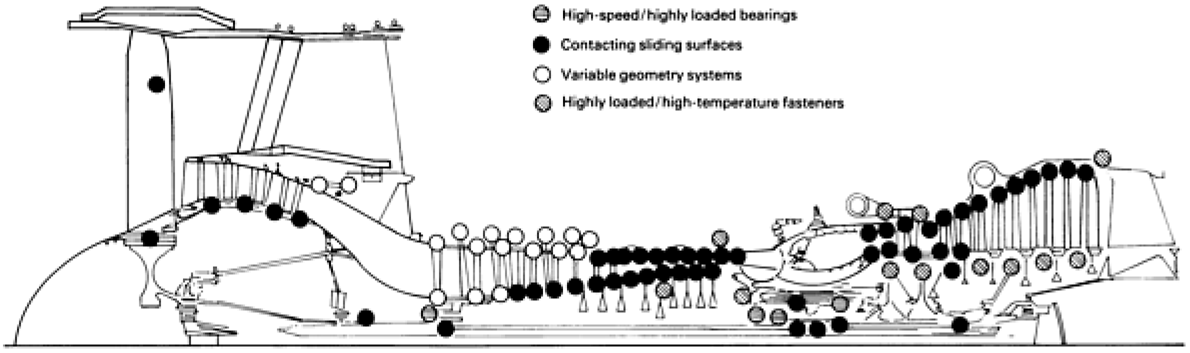

Fig. 1 Jet engine cross section showing important subsystems and potential areas of wear

Operating environments vary widely between different sections of the engine and depend on where the engine is in its mission. Temperatures may vary from subzero to above 1095 °C (2000 °F), rotational speeds may climb to more than 15,000 rev/min, and contact loads may range from a few psi to local hertzian stresses well beyond 1720 MPa (250,000 psi) in rolling-element bearings. The relative motions of components may be unidirectional sliding of rotating parts on stators, oscillatory sliding varying from a few thousandths of an inch up to several tenths of an inch, or vibratory motion resulting in impact between components. Components also may be subjected to ingested particle impacts.

The wide variety of operating conditions results in a wide variety of materials used to meet the design needs of the engine. Aluminum and titanium alloys, plastics, and resin-matrix graphite composites are frequently used in the fan and the engine nacelle. The HPC uses titanium alloys, nickel-base superalloys, such as Inconel 718, and steels, such as M152, 17-4PH, and A286. The combustor requires heat-resistant nickel or cobalt alloys, such as Hastelloy X or Haynes 188, and stainless steels for fuel tubing. The turbine sections rely on cobalt and nickel superalloys, such as Inconel X750, MAR-M-509, René 77, René 80, René 125, and advanced directionally solidified and single-crystal alloys. Often the design demands on materials for jet engine components will not permit substitution of materials for wear purposes, so a number of surface coatings and treatments are employed for wear protection.

The different operating environments and types of materials in each section of the engine result in a variety of wear types, including fretting, impact, adhesive, high-speed and oscillatory sliding, oxidational, ingested particle erosion, and abrasive wear. High-speed sliding wear occurs in rotating gas path seals. Impact wear can occur in loose part assemblies or blade midspan or tip shroud interlocks. Fretting wear is frequently seen in blade dovetails. Erosion occurs when dirt and sand particles are ingested with the air through the fan and compressor. Bearings and gears can experience rolling contact fatigue. High-temperature components can experience oxidational wear. This article will discuss some of the most significant of these wear problems in relation to specific jet engine components.

Gas Path Seals

A major area of wear in jet engines involves gas path sealing. Such seals include blade tip seals, labyrinth seals, and leaf and spline seals. Blade tip and labyrinth seal problems are concerned with clearances between rotating parts and their adjacent stators. Engine efficiency is significantly affected by the amount of gas leakage over blade tips or through labyrinth seals. In an ideal engine, the blade tips or labyrinth seal teeth would maintain minimum clearance with the adjacent stator surfaces at all points in the engine cycle. In practice, the rotor parts and stator parts experience differential growth rates because of thermal gradients in the engine and much larger mechanical growth of the rotor than the stator because of centrifugal forces. The results of these differences are depicted in Fig. 2. When the rotor and stator diameters are plotted against time after the throttle is applied for takeoff, they are seen to experience a period of interference (pinch point in Fig. 2) that causes wear. The issue can be further complicated by the stator going out of round (Fig. 3).

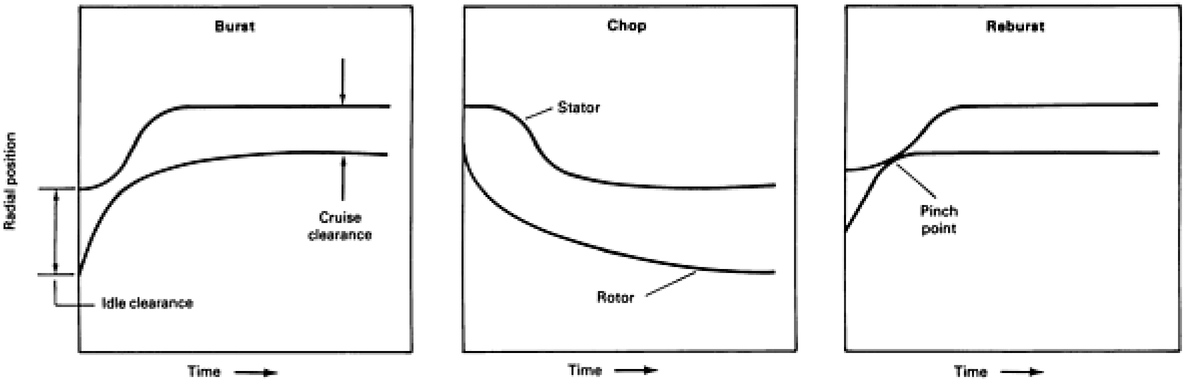

Fig. 2 Rotor and stator growth rates as a function of time and engine throttle movements

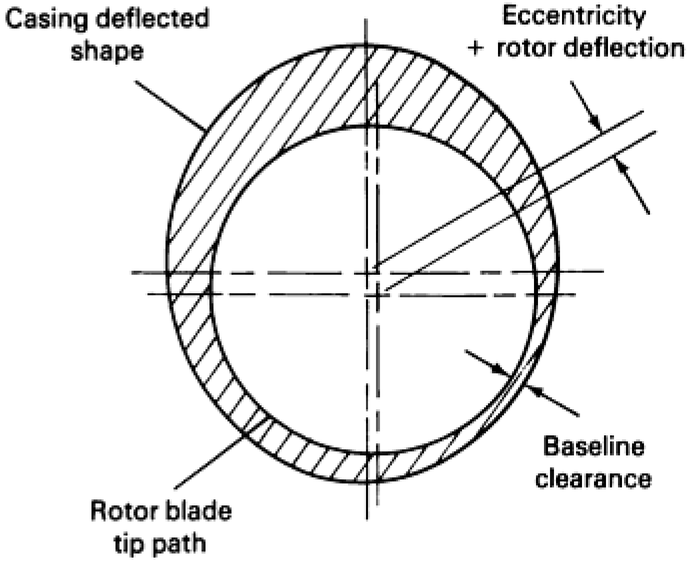

Fig. 3 Clearance change caused by rotor/stator eccentricity or maneuver deflections

Both design and material approaches are employed in combating wear of blade tips. One design approach, known as active clearance control, applies heating or cooling to the stator to achieve a better match of the thermomechanical responses of the stator and rotor. A second design approach for the out-of-round condition involves local arc grinding to remove casing material in the areas where minimum radii would occur. A materials approach that has been used in recent years is called passive clearance control. The casing is made of an alloy with a low coefficient of expansion, such as IN909, to achieve a more favorable overall thermal transient response match of the rotor and stator diameters. The most commonly used materials approach involves the application of an abradable material to the stator. The abradable material wears preferentially in a limited arc when the stator is out of round or when the rotor moves off center. This results in local clearance increases during rotor/stator interferences instead of wearing the rotor and causing a 360° clearance increase. An alternative materials approach is to apply an abrasive to the rotor, which machines the stator material, thus achieving the same result.

The materials used for the abradable stator seals or abrasive rotor coatings vary by location in the engine. Abradables can take several forms, including bonded elastomers, braze-attached sintered porous metals or honeycomb cells, or thermal spray coatings. Some of the more commonly used abradables are listed in Table 1. These materials are designed to wear in preference to the opposing blade tip or seal tooth. They rely on low densities created by included porosity or friable structures with weak bonding between constituent materials. Bill and Wisander (Ref 1) have provided a model for friable abradable seal materials. In practice, however, wear usually occurs on both surfaces, necessitating periodic overhaul.

Table 1 Commonly used abradable seal materials

Type of seal	Material
Fan and booster seals	Phenolic/carbon microballons
	Aluminum
	80/20 nickel-graphite
	Porous Teflon
	Aluminum-silicon/polyester
	Ni-Cr-Al/bentonite
High-pressure compressor seals	Nickel-graphites (75/25, 80/20, and 85/15)
	Nickel-aluminum
	Aluminum
	Aluminum bronze/nickel-graphite
	Ni-Cr-Al/nickel-graphite
	Ni-Cr-Al/bentonite
	Hastelloy X open-faced honeycomb
	FiberMetal
High-pressure turbine seals	Co-Ni-Cr-Al-Y
	Bradelloy (Hastelloy X honeycomb + braze/nickel-aluminum

The abrasive materials approach has been used with success on rotating parts, allowing them to machine their own clearances and minimizing rotor wear. The most commonly used abrasive is plasma spray aluminum oxide on seal teeth or rotor lands. Figure 4 shows a sector from an HPC rotor with two sets of seal teeth coated with plasma spray aluminum oxide. The most common mating stator seal material for such applications is open honeycomb (Fig. 5). Commonly used abrasive coatings for clearance control in jet engines include:

- Plasma spray aluminum oxide
- Entrapment-plated cubic boron nitride (Borazon)
- Entrapment-plated aluminum oxide

The abrasive coatings approach is usually combined with honeycomb or an abradable seal to improve the overall wear system for both surfaces.

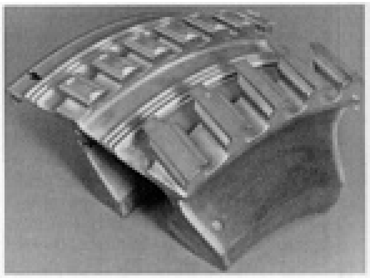

Fig. 4 High-pressure compressor disk with seal teeth coated with plasma spray aluminum oxide between stages. Arrow indicates location of coated seal teeth.

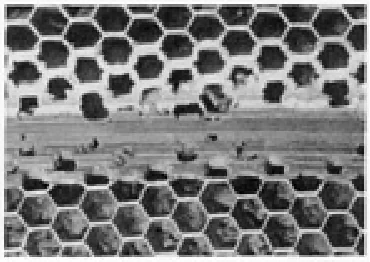

Fig. 5 Open-faced honeycomb seal showing cutting by seal teeth

Blade Midspan Stiffeners and Tip Shrouds

Some fan, HPC, and LPT rotating airfoils (blades) require the use of either a midspan stiffener or a Z-notch tip shroud (often called interlocks) to prevent mechanical flutter of the aerodynamically loaded blades. These must be designed so that the blades are sufficiently loose to allow easy assembly, but lock up into a solid stiffening ring as aerodynamic loads are imposed on the blades, causing them to untwist along the blade stacking axis. These two requirements result in a combination of impact and sliding as the interlocking contact surfaces engage and rotate into position to form the solid stiffening ring.

The impact loads imposed on the contact surfaces can be on the order of 7 to 70 MPa (1000 to 10,000 psi) and can cause severe wear damage to most materials suitable for use as blades. Therefore, it is common practice to apply a wear material to the interlock contact surfaces. These wear treatments are usually coatings on the order of 0.13 to 0.25 mm (0.005 to 0.010 in.) thick or welded hardfacing deposits up to 2.5 mm (0.100 in.) thick. Much care must be taken in the design and assembly of alignment tolerances for interlocks to prevent excessive wear, chipping, or spallation of even the most successful wear treatments on the interlock contact surfaces.

The materials used for fan and HPC blades with interlocks are usually titanium alloys, which have poor wear properties. Most fan blade and HPC interlocks use thermal sprayed WC-Co coatings or brazed-on WC-Co powder metallurgy wear pads to prevent excessive wear. The most widely used coating is Union Carbide's LW1N40, applied using a detonation gun (D-gun). Recent advances in thermal spray coatings have allowed the use of high-energy plasma spray WC-Co coatings, which hold promise for direct substitution, or high-velocity oxyfuel (HVOF) sprayed WC-Co coatings on titanium alloy interlocks. The WC-Co coatings are successful in the titanium alloy interlock applications because of the high wear resistance of the tungsten carbide, adequate fracture toughness because of the cobalt matrix, high adherence on the titanium alloy substrates, and a good match in coefficient of thermal expansion with the titanium alloy substrate materials. The typical range of temperatures for fan and HPC interlocks may vary from subzero to 95 °C (200 °F) in the fan and from about 40 to 260 °C (100 to 500 °F) in the HPC. Fortunately, WC-Co coatings appear to retain sufficient low-temperature ductility and high-temperature oxidation resistance over these temperature ranges. The formation of a wear glaze at the contact zones contributes to the good wear resistance of the WC-Co in these interlock applications.

The LPT blade materials are typically nickel-base superalloys, such as René 77 or René 125, which usually possess fairly good sliding wear resistance. However, they have inadequate wear resistance in the combined impact and sliding wear environment of LPT blade interlock contact surfaces. Typical use temperatures for LPT interlocks are 540 to 925 °C (1000 to 1700 °F), so the oxidation properties of the alloys under the existing wear conditions also play a significant role in their wear resistance. Typical wear coating compositions applied by thermal spraying or weld buildup that are used for LPT blade interlocks include:

- Tribaloy 800 (plasma sprayed, welded, HVOF)
- Cost Metal 64 (welded)
- Chromium-carbide/nickel-chromium (plasma sprayed, HVOF, D-gun)

Most of these alloys are cobalt based for good wear resistance and benefit from the formation of cobalt oxide and/or spinel wear glaze films.

Tribaloy 800 and Coast Metal 64 are the most commonly used LPT blade interlock coatings at GE Aircraft Engines. Tribaloy 800, applied by thermal spraying or tungsten inert gas (TIG) welding, provides excellent wear resistance and oxidation resistance to about 840 °C (1550 °F). Above this temperature. TIG-welded Coast Metal 64 provides better wear and oxidation resistance than Tribaloy 800. In general, wear coating performance for LPT blade interlocks correlates to the chromium content and use temperature, with better performance at elevated temperatures for coatings with higher chromium contents and better performance at lower temperatures for coatings with lower chromium contents.

Mainshaft Bearings

The materials traditionally used for gas turbine mainshaft bearings are 52100 and M50 steels. More recently, powder metallurgy (P/M) bearings and case-carburized M50NiL steel, a modified M50, have been introduced as race materials. Several factors have contributed to this recent trend. Newer gas turbine mainshafts operate at higher speeds. This has pushed the bearing DN values (bore diameter in millimeters times shaft revolutions per minute) well past 2 million, which increases race hoop stresses and the hertzian contact stresses between rolling elements and the races.

The higher hoop stresses can cause fracture of the 52100 or M50-type races because they are through-hardened materials, typically in the 50 to 60 HRC range, and thus have low fracture toughness. At high DN values, this can become a fracture reliability problem for a statistically significant number of these bearings. The higher hertzian stresses, approaching 2400 MPa (350,000 psi) for a 2.5 million DN mainshaft bearing outer race, also can cause significant reductions in rolling contact fatigue life. This is undesirable, because changing a mainshaft bearing requires costly disassembly of the engine.

Bearing races made from the new P/M alloys and forged low-carbon alloys with carburized surfaces do not have these shortcomings. These materials are designed for high DN use and require special manufacturing processes. GE Aircraft Engines has concentrated on a variation of M50 steel with reduced carbon and increased nickel to improve fracture toughness. The race is then carburized to produce a fine dispersion of carbides for high hardness. Compressive residual stresses are frozen in to the raceway surfaces to improve rolling contact fatigue, while the low hardness (<50 HRC) rare core material remains tough to deal with high hoop stresses.

This M50NiL material with its finely dispersed carbides, as well as the fine-grained (to improve fracture toughness) P/M race materials, can suffer from a low tolerance to wear. Wear can occur at the ball cage guide lands under marginal lubrication conditions even for "normal" bearing cleanliness operation. The rolling-element cage shoulders are silver plated, which provides solid lubrication and low friction to prevent wear when direct metal-to-metal cage skidding occurs on the cage guide land of the race. This works quite effectively for 52100 and M50 steels. However, the P/M and M50NiL steels sometimes experience rapid wear under similar operating parameters.

Research by Budinski (Ref 2) has shown that the size, distribution, type, and volume fraction of carbides in tool steels can significantly alter their abrasive wear resistance, with coarser carbide grains having better resistance than finer carbide grains. Thus, it has been suggested that the coarser carbide stringers in M50 or 52100 forged bearing races can adequately resist the initiation of abrasive wear, while the very fine; evenly dispersed carbides in M50NiL or P/M bearing races cannot.

The abrasive particles found in the bearings originate in the oil supply system. Sump castings, abrasively cut tubes, and grit-blast-cleaned parts in the bearing lubrication system all likely contain very fine alumina or silicon carbide contaminant particles. Most of these are removed during cleaning prior to assembly or by in-line filtering, but some of the finer particle (<50 μm) get through to the bearings even under the most stringent clean-room assembly conditions. Once inside a bearing, contaminant particles can become embedded in the silver plating on the ball cage shoulders, where they protrude, causing abrasive wear to initiate during transient cage shoulder/race guide land contacts. The abrasive particles soon become "capped" with race transfer material, and adhesive wear ensues.

The high differential sliding speeds between the orbiting cage and race cause frictional heating, local oxidation, and carburization by oil coking of the thin metallic transfer layers. Thus, a very hard abrasive transfer layer results and the wear process accelerates. These deposits also increase friction. Therefore, when cage-to-cage encounters occur, a more severe rebound force results from the skidding contact, generally increasing the cage orbiting and number of skid contacts and producing further wear.

Combustor and Nozzle Assemblies

These engine components are subjected to a variety of severe wear environments. Combustor hardware includes fuel nozzles, swirlers, and cowl damping wires, which experience relatively high temperatures (540 °C, or 1000 °F, and up) during operation. Exhaust nozzle assemblies are characterized by many parts, such as pins, bushings, links, and overlapping flaps, which aid in motion of the nozzle to control engine thrust. Some of these nozzle parts are directly in the hot gas stream and experience temperatures up to 815 °C (1500 °F); others are bathed in bypass cooling air and remain relatively cool (approximately 315 °C, or 600 °F). Combustor and nozzle assemblies experience large amounts of vibration from turbulent air flows both inside and outside the engine. This vibrational/impact wear can cause significant material removal as well as high-cycle fatigue of some components. The combined effects can cause liberation of hardware; in the case of the combustor, this will in turn cause severe damage to downstream components, such as turbine nozzles and blades.

The majority of wear problems in both of these assemblies is cause by vibration and impact. Because of the elevated temperatures in the combustor, oxidational wear occurs as scales are formed and subsequent chipped off by impact. Contact pressures between parts are nominally low, but can be aggravated by high-frequency impacts, which may locally yield the materials. Oscillatory sliding (galling) wear sometimes occurs on exhaust nozzle flaps as they are actuated during mission cycles over several hundred accumulated flight hours.

The design of these components addresses temperature and fatigue concerns. Both combustor and exhaust nozzle hardware are made from heat-resistant superalloy sheet materials, such as Hastelloy X, René 41, or Haynes 25. Because these materials vibrate in the turbulent hot gas stream, high-cycle fatigue life at elevated temperature is important. The cooler sections of the exhaust nozzle sometimes use high-temperature titanium alloys, such as Ti-6Al-2Sn-4Zr-2Mo, to reduce engine weight and maintain mechanical properties at elevated temperature. Many pins and bushings are manufactured from steel alloys, such as 17-4PH and A286. Coatings can be applied to problem areas on specific components, but they must withstand the application temperatures and not degrade the mechanical properties of the base alloy to unacceptable levels. Therefore, specification of the material and/or coating can be a complicated process.

In general, cobalt-base alloys, such as Haynes 25 and Haynes 188, tend to perform best at temperatures above 540 °C (1000 °F) in both sliding and impact wear. Some nickel-base alloys, such as René 41, also possess good wear resistance at high temperatures. Effective coatings for wear problems in these temperature regimes include Tribaloy 800 and chromium carbide/nickel chromium. Tribaloy 800 derives its good elevated-temperature wear resistance from a hard Laves phase in a cobalt-base matrix. This matrix produces a cobalt oxide, which provides lubricity to the interface. Chromium carbide/nickel chromium derives its good performance chiefly from the hard carbide phase and the formation of favorable oxide wear glazes. Cooler titanium components in the exhaust nozzle generally have poor wear resistance and almost always require coatings for mating parts in relative motion. Here, the coating of choice is generally WC-Co, which again derives its wear resistance from the hard carbide phase. Oxidation of the carbide limits use of this coating to temperature regimes below 480 °C (900 °F). Because of the aggressive nature of the carbide, both mating surfaces should be coated. The steels used in the actuation systems for the nozzle flaps are usually ion nitrided to develop a hard case layer on the surface (hardness of up to 72 HRC can be achieved). For a particularly severe wear environment, ion nitriding may not provide sufficient wear protection, and chromium carbide or tungsten carbide coatings may be required.

Dovetails

Aircraft engines utilize bladed rotors in the low-pressure fan and the high-pressure compressor to generate thrust and provide the required air compression ratios for proper fuel combustion to drive the turbine sections. These airfoils are attached to their respective disks on the rotor by dovetails (Fig. 6). As the rotor speed increases, the disk posts grow and open while the mass of these blades is forced radially outward by centrifugal forces. These forces result in relative motion between the blades and the disk under very high normal stresses, reaching localized peak loads of up to 930 MPa (135 ksi) in the fan.

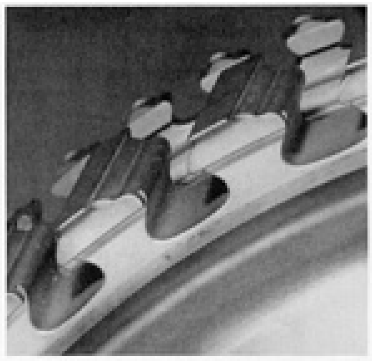

Fig. 6 Front-stage HPC rotor disk showing dovetail disk slots and pressure faces

Superimposed on some stages of the high-pressure compressor are high-frequency, low-amplitude vibrations caused by local aerodynamic effects from vane or strut positions relative to the rotating hardware. The combination of contact stress and high-frequency motion admits a large amount of mechanical work into the metal surface. Temperatures for dovetails range from subzero (fan) to close to 650 °C (1200 °F) (rear compressor). The combination of these factors creates wear problems for critical rotating hardware.

Fan and front-stage compressor blades and disks are manufactured from titanium alloys; middle- and rear-stag compressor rotor materials included steel (A286) and nickel-base alloys (Inconel 718). Rear-stage components rarely exhibit wear; however, titanium alloys have notoriously poor wear resistance when unprotected. Any cause of surface damage, such as wear, must be minimized because of the surface sensitivity of titanium in relation to high-cycle fatigue crack initiation.

Most jet engines in service use a titanium protection system comprising a thermal spray coating and a solid film lubricant on the blade dovetail. Most disk and spool dovetail slots cannot accommodate a thermal spray coating in the disk slots because they are relatively small, but the largest fan disk slots use the same coating system as the blade dovetails. The coating of choice is a relatively soft copper-nickel or copper-nickel-indium alloy applied by air plasma spraying. The thermal spray coating is subsequently dry film lubricated with molybdenum disulfide in an organic resin binder that is oven cured for strength and adhesion. The solid film lubricant provides a low coefficient of friction to prevent galling, allow part seating, and delay the onset of wear produced by metal-to-metal contact. Coating thicknesses range from 0.05 to 0.28 mm (0.002 to 0.011 in.) for the thermal spray and 0.025 to 0.075 mm (0.001 to 0.003 in.) for the cured lubricant.

Titanium galls readily in contact with other metals in relative motion, even against the soft thermal spray coating, so solid film lubricant life is important. Unfortunately, copper-nickel and copper-nickel-indium alloys and MoS_2 can oxidize above about 315 °C (600 °F), while the organic binder breaks down and loses strength at such temperatures, resulting in higher friction coefficients, increased shear forces, and wear. Improved dovetail coatings for the 315 to 540 °C (600 to 1000 °F) range need to be developed, as new high-temperature titanium alloys are being specified farther back in the compressor

Compressor Airfoil Erosion

The introduction of underwing-mounted jet engines has brought with it the problem of the ingestion of materials left on airport runways. Sand and dirt are used during winter months to improve traction on snow-covered runways. This grit is easily ingested by the engine when the snow melts and evaporates. Because the current "hub-and-spoke" airline system produces many takeoff/landing cycles in a short time, compressor blades and vanes erode rapidly from these contaminants. Erosion is also prevalent in helicopter engine compressor because of the harsh unpaved environments in

which they operate. Helicopter engines have particle separators to eliminate very large grit sizes, but finer grit sometimes enters the compressors. This particle ingestion is severe enough to cause erosion of titanium-, nickel-, and steel-base materials to various degrees.

Erosion occurs by two distinct mechanisms: high-impingement angle and low-impingement angle. High-impingement-angle erosion is characteristic on the front stages of the high-pressure compressor when large ingested particle strike the leading edges of the rotating blades. In the most severe form of this type of erosion, the leading edge can be deformed by burring or plastic deformation. Otherwise, high-angle-impingement attack usually results in blunting of the leading edge. Both changes in leading edge profile cause aerodynamic flow problems that reduce compressor efficiency and increase fuel consumption.

Low-impingement-angle erosion is characteristic on the rear stages of the high-pressure compressor. As the ingested material swirls through the compressor, it becomes fragmented and centrifuged radially toward the casing. This results in glancing impacts by angular, sharp grit near the trailing edge of the airfoil and along the tip. The loss of airfoil material causes thinning of the trailing edge and opens tip clearances near the casing, reducing compressor performance. Figure 7 illustrates the mechanism of low-impingement-angle erosion

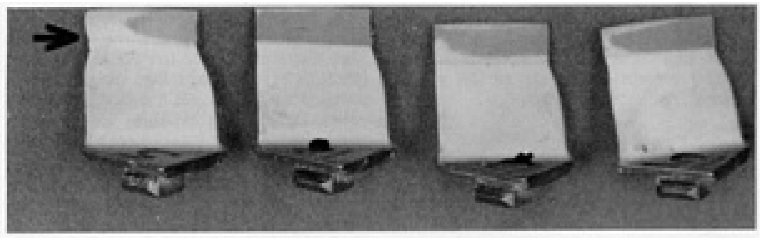

Fig. 7 Rear-stage compressor blades illustrating the low-impingement-angle erosion mechanism. Arrow indicates lost erosion coating on blade trailing edge.

Protection of individual blades has historically consisted of coating those airfoil surfaces most affected by erosion: the leading edge, across the concave surface, and back to the trailing edge in the tip region of the blade. Based on field experience, coating practice has been modified to include wrapping the coating around the leading edge and extending the coating down the airfoil surface in the direction of the dovetail. Coating materials of choice are those with higher hardness than the impinging grit, such as carbides and nitrides of titanium, tungsten, and chromium. These coatings can be applied by processes such as physical vapor deposition (PVD), D-gun, or HVOF thermal spraying to maximize their density and hardness.

The chosen coating system must not affect the mechanical properties of the base alloy, such as high-cycle fatigue resistance. Blade airfoils pass through several resonant frequencies during an engine cycle. Degradation of fatigue strength by the coating could cause cracking and liberation of the blade tip, producing more damage downstream. The coating system must also exhibit excellent adhesion to resist spallation and produce a very smooth surface finish for compressor efficiency. Any coating-induced surface defect will cause unacceptable turbulence, which can disrupt the axial flow through the compressor. Coating thicknesses are relatively thin, typically less than 0.025 mm (0.001 in.) for PVD coatings and 0.050 to 0.075 mm (0.002 to 0.003 in.) for D-gun and HVOF coatings. Coatings must remain thin so that they taper smoothly to the uncoated blade, without a sharp step that would cause compressor airflow turbulences.

Some helicopter engine compressor are constructed from one-piece blade and rotor components, called blisks. These components do not allow for the coating of individual airfoil surfaces, because the blades are an integral part of the disk (Fig. 8). Blisks also have twisted airfoils in the direction of the stacking axis, making them difficult to coat using a line-of-sight process such as thermal spray. Leading edges are extremely thin, sharp, and prone to severe burring and blunting under particle impingement. Development of non-line-of-sight erosion coatings for difficult geometries such as these is required to maintain helicopter performance.

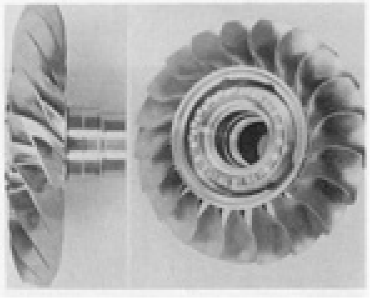

Fig. 8 Front-stage helicopter engine compressor rotor blisk

Discussion and Summary

Jet engine designs push components to their limits for mechanical strength and temperature capability. New engine designs for commercial airplanes and military fighter jets introduce new requirements for thrust and performance. The fact is that the hotter the combustion in the engine, the more powerful and efficient the engine becomes. Advances such as new superalloys, improved cooling flow designs, and thermal barrier coatings were developed to stretch the capabilities of these components and to take advantage of the thrust and efficiency gains associated with increased combustion temperatures.

A second method of generating more thrust is to increase the size of the fan and thus of the turbine required to drive it. Increased size results in larger structures with more thermal movement. Relative motion and vibration are also expected to increase with these new designs.

To accommodate size increases without substantially increasing weight, lighter materials are being developed with similar strengths to handle these more demanding conditions of temperature and loading. These advanced materials include ceramics, organic-matrix composites, metal-matrix composites, ceramic-matrix composites, and intermetallics. Each class has its own property challenges that must be overcome before it can be incorporated in engine designs. For example, composites utilize second phases to improve properties lacking in the matrix material, such as tensile strength and ductility. Intermetallic and ceramic materials can be very sensitive to any type of surface defect that may cause brittle fracture, including wear or erosion.

These advanced mechanical designs and material systems provide research opportunities in the field of tribology. The effects of increased temperature, of increased motion and vibration, and of second phases in composites on the wear process require further investigation.

Wear of Pumps

William D. Marscher, Dresser Pump Division, Dresser Industries

Introduction

TURBOMACHINERY such as a pump is susceptible to loss of surface material from component parts by four basic mechanisms:

- Corrosion that causes pitting or the formation of surface layers of corrosion products prone to later removal
- Rubbing or sliding wear or surface fatigue in bearings and in close running clearances between stationary and rotating or sliding components
- Erosion caused by solid particles in the flow stream that scrub on flow-path surfaces or that jam in close clearances
- Erosion caused by high-frequency impact damage from liquid cavitation bubble formation and collapse in the flow stream of locations where the static pressure is locally reduced below the vapor pressure

Pitting corrosion is beyond the scope of this article. The rubbing wear, particulate erosion, and cavitation erosion mechanisms are discussed separately below. Each discussion focuses on specific components subject to the given form of wear and includes:

- The effects of wear on overall pump performance
- The relationship of the wear mechanism to relevant design parameters and environmental variables
- Specific defenses that minimize the rate of material loss, and hence extend the life of the pump, or that affect the choice of a specific pump

The pumps discussed in this article are primarily heavy-duty industrial types, including single-and multistage centrifugal, single-stage axial flow, reciprocating, and positive-displacement progressive cavity pumps, such as screw pumps.

Rubbing Wear

Centrifugal and Axial Flow Pumps. Rubbing wear in centrifugal and axial flow pumps occurs in the following components, illustrated by the multistage pump in Fig. 1:

- Impeller neck ring or wear ring annular seals, which are located in a minimum clearance area in the impeller/casing wall clearance gap to prevent leak-back of the high-pressure impeller discharge flow to the lower-pressure impeller inlet, or "suction"
- Interstage bushing or diffuser bushing annular seals, which separate the inner diameter of the backside of one stage from the inlet area of the following stage
- Axial thrust-balancing devices, such as drums with a radial annular seal or disks with an axial face seal. Such balancing devices separate multistage discharge pressure acting on one cross-sectional area from suction pressure acting on another cross-sectional area in order to oppose the accumulated axial thrust of the various pump stages. In the drum type, which is generally preferred because of its dynamic stability, if the original running clearance opens up sufficiently, parasitic leakage becomes unacceptable, and pressure values on each side change to the point that thrust-balance may no longer be possible
- Sealing between the casing fluid and the outside environment, such as "pressure-breakdown" bushing labyrinth seals, pump packing, and mechanical seals. Such seals are eliminated in magnetic-drive pumps, canned motor pumps, and most other types of hermetically sealed pumps

- Flexible couplings involving potentially sliding teeth or splines, such as gear couplings
- Bearings, including plain journals, fixed pad, tilting pad, and rolling-element bearings

These components represent the closest clearance locations within a centrifugal pump and, even in an upset condition in which one or more of them is rubbing, prevent the rotor from contacting at other locations. This same principle prevents excessive bending deflection of the rotor, such that shaft lateral steady deflection or lateral vibrations cannot induce sufficient bending stress to result in fatigue failure of the internal shaft (Ref 1). Of course, a serious metallurgical defect or machining imperfection that causes a stress concentration is always a potential failure source, whether or not there is a vibration problem.

It is common for a centrifugal pump to experience wear in one or more of the locations listed above. The goal of the pump designer and pump user should be to minimize rather than prevent rubbing wear at close clearances, so that the original clearances are at most tripled during intervals between pump overhauls. Therefore, the effects of up to three times increased clearance at all potential rubbing locations on hydraulic performance degradation must be accounted for in pump design. Generally, roughly one to two points of efficiency and 0.5 to 1% of head are lost when running clearances throughout a pump are doubled.

The predicted rotor dynamic behavior of the pump as clearances change is also critical to pump design. Multistage pump vibration can increase by a factor of 30 if the natural frequency of a shaft becomes equal to the frequency of a strong excitation force, such as residual imbalance at running speed, because this results in a resonance (Ref 2). Therefore, as a minimum, the designer must ensure that natural frequencies do not change sufficiently to cause a resonance within a range of clearance change of up to a factor of three. Otherwise, shaft vibration will exceed the running clearances, and rapid wear will result.

This can pose a significant problem for flexible shaft designs with a large number of stages, because the natural frequencies of such rotors depend strongly on the clearance of the annular seals through the workings of the "Lomakin effect" (Ref 3, 4). This effect causes a nonuniform pressure buildup through leakage velocity variation, as expressed by Bernoulli's equation. This tends to recenter the shaft if it moves off-center and therefore contributes to the supporting stiffness and thus the natural frequency of the rotor. The Lomakin in effect is illustrated in Fig. 2.

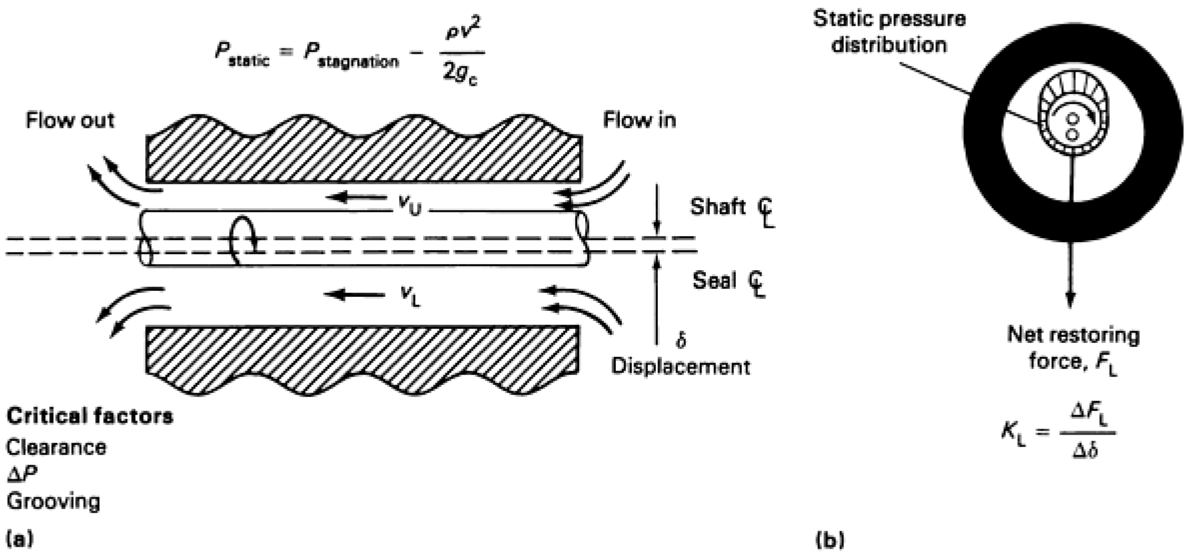

Fig. 2 Schematic showing principle of the Lomakin effect. (a) Longitudinal view of cross section. (b) End view

Even if the designer has been careful to avoid vibration-related wear problems, pump life can still be dramatically reduced unless the user (1) runs the pump within the proper flow range and (2) monitors pump vibration. The first concern is illustrated by Fig. 3, which shows a typical plot of vibration versus flow rate. Although common sense suggests that the less flow required of a pump, the less it will vibrate and wear, Fig. 3 shows that the opposite is true. The angles of the impeller and diffuser vanes of a pump can be designed to match the flow inlet and exit angles at only one particular flow rate, called the best efficiency point (BEP).

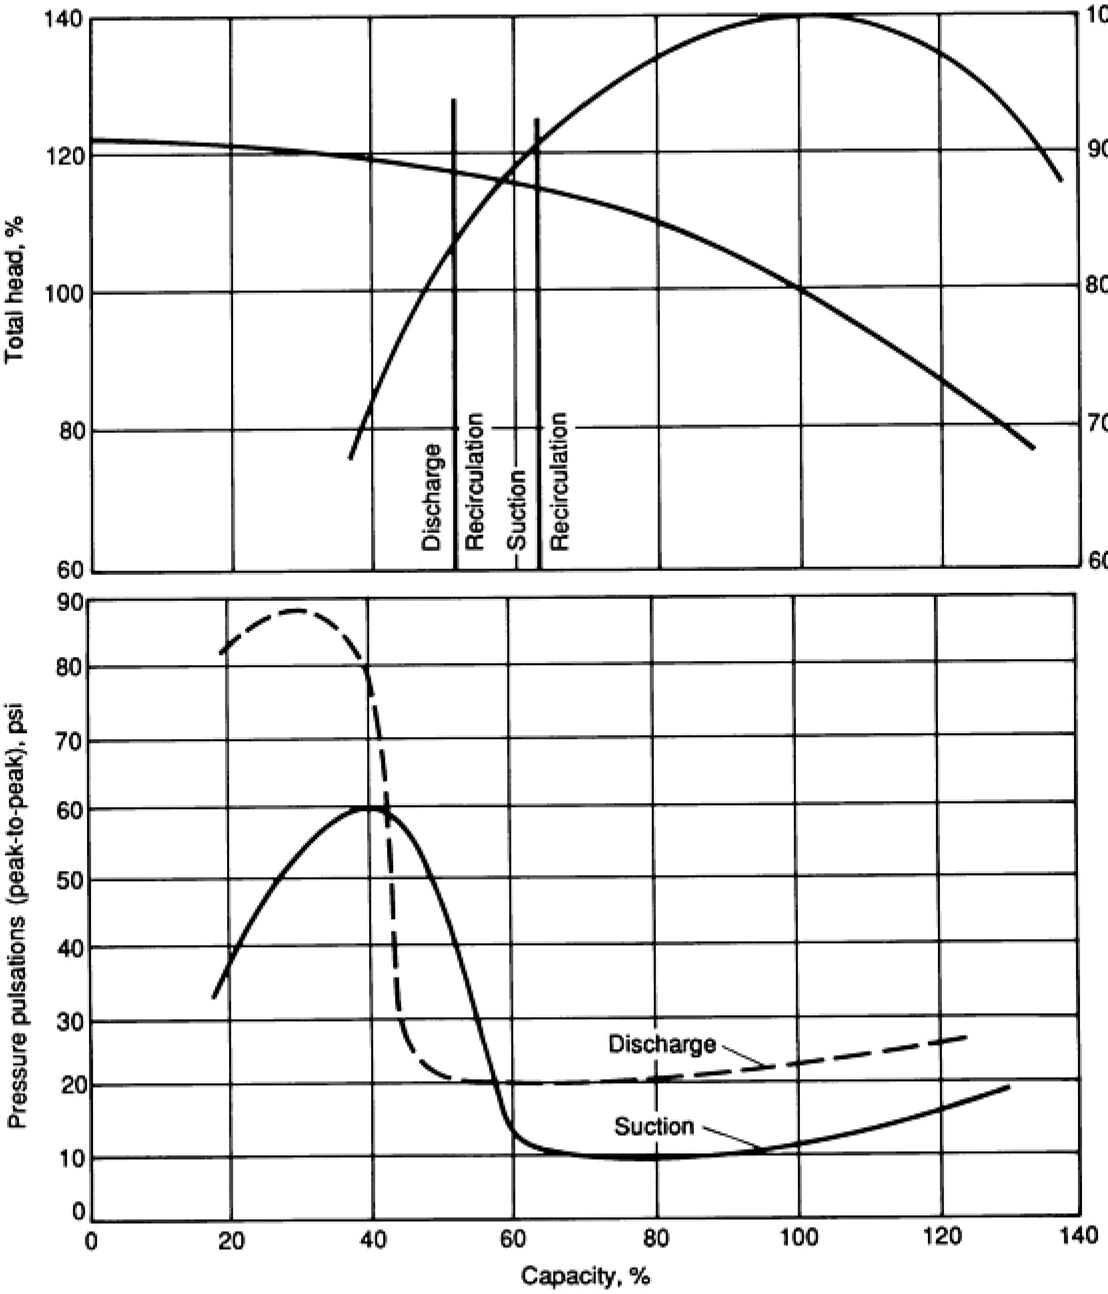

Fig. 3 Dependence of pump vibration on flow rate

The user should select a pump whose BEP is close to the expected flow requirement of a particular system, because other flow rates, higher or lower, lead to a mismatch in flow-to-vane angles and result in potentially large steady and oscillating radial loads on the pump rotor (Ref 5). If the flow mismatch becomes great enough, stalling can occur (as on an airplane wing with too high an angle of attack), leading to formation of regions of recirculating flow and an associated increase of shaking forces (Fig. 3). This is known as onset of recirculation and usually occurs first at the pump inlet or "suction" (Ref 6, 7). The minimum continuous flow of a pump should be set to avoid operating at or below this flow for extended periods of time. This sometimes requires installation of a minimum flow recirculation loop, with a valve that automatically opens when flow drops below the recirculation onset flow.

Another approach that is less wasteful than discharge throttling is to reduce pump flow as required by using a variable-frequency drive (VFD) on the pump motor to reduce operating speed. If VFDs are used, careful design of the support structures for vertically mounted pumps is essential to avoid resonances between the speed range and the structural

natural frequencies, several of which are likely to be in the speed range (Ref 8). If throttling rather than VFDs is used, other vibration problems associated with the recirculation phenomena discussed above are possible (Ref 9).

It is also important that the user monitor pump vibration levels, allowing early identification and repair of vibration problems that may accelerate wear. Various "condition monitoring" and "predictive maintenance" systems are marketed for this purpose. Figure 4 gives limits of overall vibration as a function of running speed (Ref 10). Vibration above these limits can be expected to accelerate wear at a rate such that vibration at double these limits will result in up to 10 times the rate of wear. Halving these limits generally has little or no effect, however, because at these levels no running clearance contact should have yet occurred; therefore, reducing vibration further has no impact on rubbing wear (Ref 1). Experience suggests that contact can be expected to begin, on average, at about one and a half to two times the recommended vibration limits.

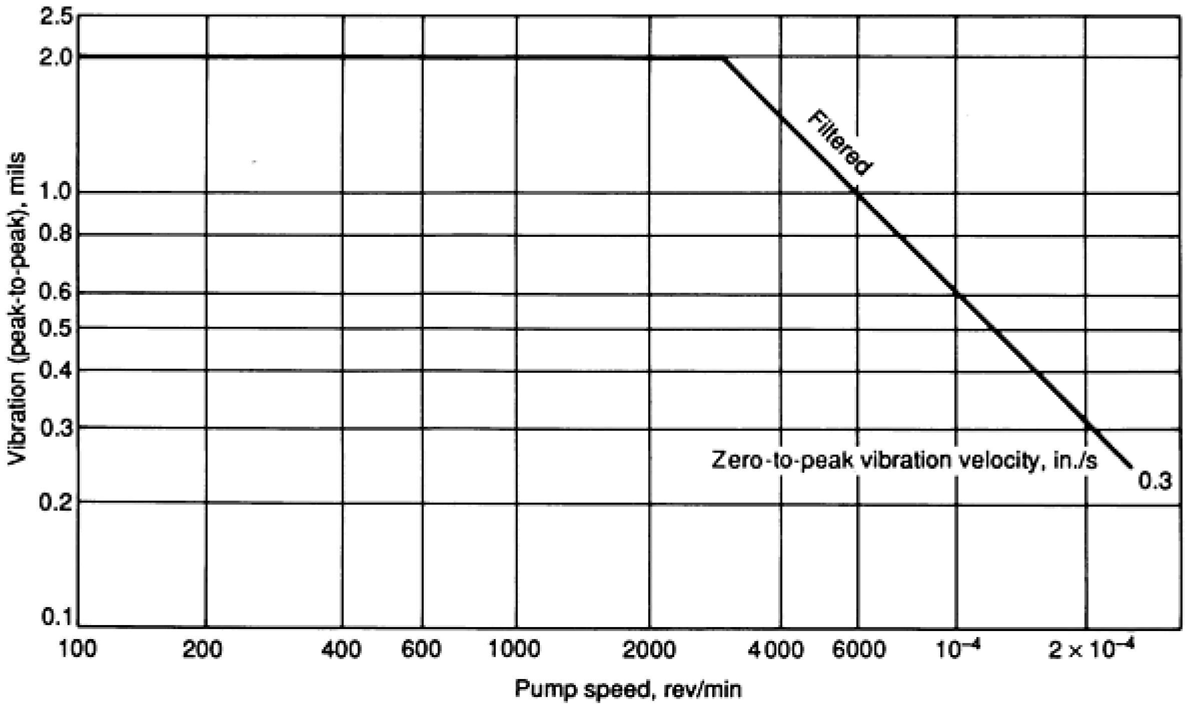

Fig. 4 Allowable vibration as a function of running speed. Adapted from Ref 10

Despite the best efforts of the designer and the user, it is likely that the occasion will arise when close clearances contact and rub. Of key importance when such contact takes place is that no galling wear occur, because this can seize the pump and cause severe damage to the rotor system or drive train by overtorque.

Galling can be resisted in several ways. Opposing material pairs can be selected from "adhesive compatibility charts," such as the one shown in Table 1, which identify those combinations with the least chemical attraction. This selection process is aided by heat treating the opposing parts so that they have a Brinell hardness difference of at least 50, which encourages wear of the softer material rather than adhesion and resultant part-to-part material transfer (Ref 11).

A second method of discouraging galling is to machine grooves in one or both of the close-clearance components, so that as wear takes place the debris can collect somewhere other than at the close running clearance. This also promotes rapid heat transfer at rubbing interfaces, keeping parts cool and hard. Local surface temperatures can become very high even with grooving, because of the flash-temperature effect, but such temperatures decay in short distances and do not result in

galling if surface heat removal is effective (Ref 12). Grooving the surfaces results in a design compromise, however. Although grooving reduces clearance leakage, it also reduces the beneficial shaft support provided by the Lomakin effect.

Another way to assess galling potential is with a measure number for the contact stress required for cold welding and subsequent material pullout for a material mated against itself. This is called galling threshold load and is tabulated in reference handbooks for various engineering materials. Generally, austenitic and precipitation-hardening steels have very low galling threshold loads, on the order of 15 MPa (2 ksi). On the other end of the scale is Nitronic 50, Nitronic 60, and Waukesha 88, with values of about 350 MPa (50 ksi).

In open-impeller (that is, no shroud encloses the blade passages) and axial flow pumps, such as those used in water-flood service, the impeller or propeller blades interface directly with the casing across a narrow blade-tip clearance instead of with wearing rings. The same considerations apply regarding use of compatible materials with reasonable hardness differences. For large-diameter propellers, materials should also have relatively low friction coefficients, so that sudden rubbing contact does not cause overtorque of the pump shaft or drive train. Materials selected using the compatibility chart (Table 1) generally have low friction coefficients. Typical performance loss due to blade tip wear in unshrouded impellers and propellers is about 1% efficiency and head loss for each percent of blade height removal. Open or semiopen impellers are often used for abrasive slurry service, particularly in the paper industry, as discussed below in the section on particulate erosion.

Coupling tooth or shaft spline wear is typically a reliability problem only if the teeth are not properly lubricated or if they are overloaded by a vibration resonance (Ref 13). If resonance of the shaft occurs for a rotor natural frequency that includes significant coupling motion, reciprocating slip may occur at the coupling teeth, leading to fretting wear. The only solution in this circumstance is to redesign the shaft or to use a different weight coupling to shift the natural frequency out of running speed range.

Bearing wear in pumps can take the form of gross plastic deformation, frictional softening or melting, and subsequent abrasive wear if there is a severe shaft overload or inadequate or improper lubrication. Improper lubrication in such instances is usually caused by lubricant emulsification when contaminated with water by a seal failure or by atmospheric condensation. More common than catastrophic bearing failure, however, is the gradual deterioration of the bearing by surface fatigue due to:

- Marginal lubrication, again perhaps because of lubricant contamination
- Steady loading somewhat in excess of the rated surface pressure of a journal bearing (between 1.4 and 14 MPa, or 0.2 and 2 ksi, depending on the bearing material and geometrical details) or above the rated 20,000 h B_{10} life of a rolling-element bearing
- Large oscillating loads caused by excessive vibration, usually because of either a rotor dynamic or a bearing housing natural frequency resonance (Ref 14)

In its final stages, surface fatigue is recognizable by loaded surface "craze cracking" and spalling of surface material in laminar chunks.

Vertical turbine pumps (VTPs), used for deep well, low suction head, and wet pit service, are unique with respect to their lightly loaded bearings (gravity is parallel to the shaft) and the multiple-bearing support of the often long "line-shafting" that connects the deeply submerged impeller or bowl assembly to the above-ground motor driving the pump. Another unique feature of VTPs is the "product lubrication" (that is, lubrication by the pumped fluid) of the lineshaft and bowl bearings. Bronze or bronze-filled Teflon is a good bore material in such bearings, and their wear rate has been found to be minimized by using a relatively large length-to-diameter ratio (an L/D ratio of 2.5 is common). The greater length of these bearings tends to restrict the flexure of the relatively thin lineshafting, keeping whirling amplitudes and thus bearing loads low (Ref 15). In poorly lubricating fluids, such as water, and in abrasive fluids, rubber has been found superior to bronze, particularly when combined with axial or spiral grooves to feed bearing surfaces and wash out entrapped particles. The inside surfaces of such bearings can be made polygonal or corrugated to further enhance lubricant feed and flush in the presence of low bearing loads. This style of bearing, inexpensiveand popular in irrigation pumps, gives good service as long as the pump is not allowed to run dry.

Reciprocating pumps are more prone to rubbing wear than centrifugal pumps, because they have several sliding components, including the following (Fig. 5):

- Lower crosshead versus the crosshead ways
- Tie rods versus their linear bearing surfaces
- Plunger or piston rod versus the packing
- Plunger or piston surface versus the bore walls
- Valve lateral surfaces within the valve retainer or guide

In addition, each suction and discharge valve is subject to impact wear at the seating surface, particularly if cavitation is occurring. Finally, there are several sets of highly loaded bearings: crankshaft bearings (one for each one or two cylinders plus the coupling), connecting rod "small-end" bearings attached to each lower crosshead pin, and connecting rod "large-end" bearings that attach each rod to the crankshaft.

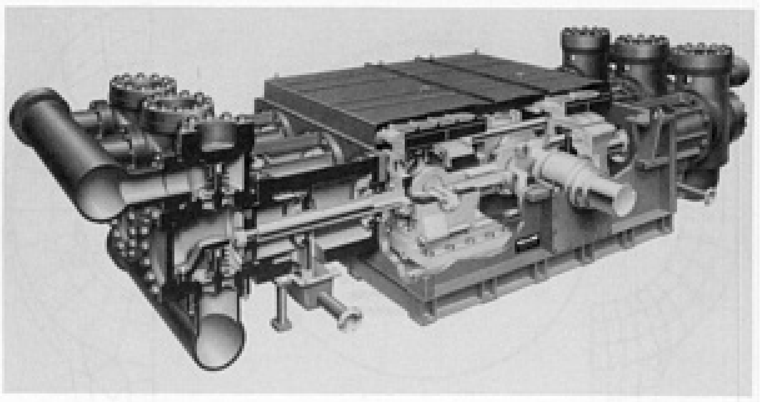

Fig. 5 Cutaway view of a reciprocating pump. Courtesy of Dresser Pump Division, Dresser Industries

To minimize wear in reciprocating sliding components, it is critical to provide clean flushing fluid to unlubricated areas and to filter the oil and rigorously maintain its quality for lubricated areas. Ceramic plungers and bore liners together with clean flushing fluid are effective for avoiding excessive wear induced by third bodies during abrasive service. In the crosshead ways, excellent alignment must be maintained with the crosshead to avoid locally high bearing pressures, and area-averaged surface bearing pressure during the highest load portion of the stroke should be kept well under 690 kPa (100 psi) by properly sizing the crosshead bearing surface during design.

Valve surfaces and their retainers must be maintained at a high hardness (on the order of 40 HRC), with a hardness differential of 50 HB, and must be properly selected from the compatibility chart (Table 1). In addition, valves should be designed and tested such that absolutely no cavitation occurs during the initial valve opening, when static pressure is at its lowest. Otherwise, severe valve impact or "hammer" can occur, damaging the valve and the seat and, through the transmitted elastic wave, jeopardizing the entire drive train (Ref 16).

Finally, special vertically mounted spherical or conical seat valves should be used in slurry or abrasive pumping service or if deposits are expected to build up near the cylinders. Such valves tend to discourage the trapping of debris in the seating interface (Fig. 6) (Ref 17).

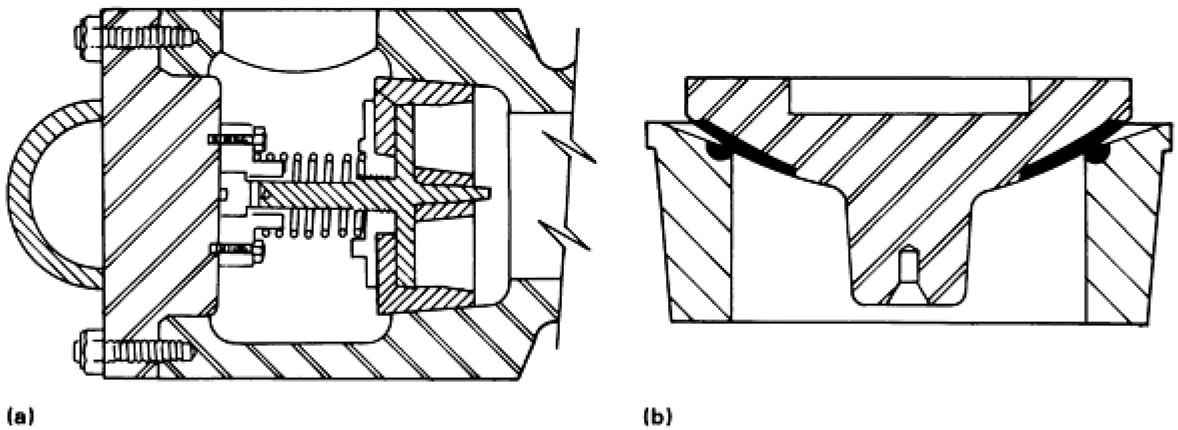

Fig. 6 Cross-sectional view of abrasive-resistant slurry valves used in reciprocating pumps. (a) Rib-supported conical type. (b) Spherical type. Source: Ref 17

Reciprocating pump journal bearings tend to be highly loaded, with surface pressures from 6.9 to 13.8 MPa (1 to 2 ksi). Special bearing babbitt materials are needed, and configurations adapted to reciprocating motion, such as "bedded arc" nonsymmetrical bore designs for connecting rod small-end bearings, are used for higher load capacity (Ref 18).

It is also important that the bearing bore and journal be kept aligned and that the journal bore clearances be maintained. This requires careful assembly, as well as a design procedure that accounts for transient thermal differences in the bore versus the journal and for elastic deformation of the bearing supports. For example, if connecting rod "eye" cross sections at either the small end or large end are not sufficient, the bearing can ovalize to the extent that all of its side clearance is taken up, "pinching" the journal and causing possible seizure of the bearing (Fig. 7).

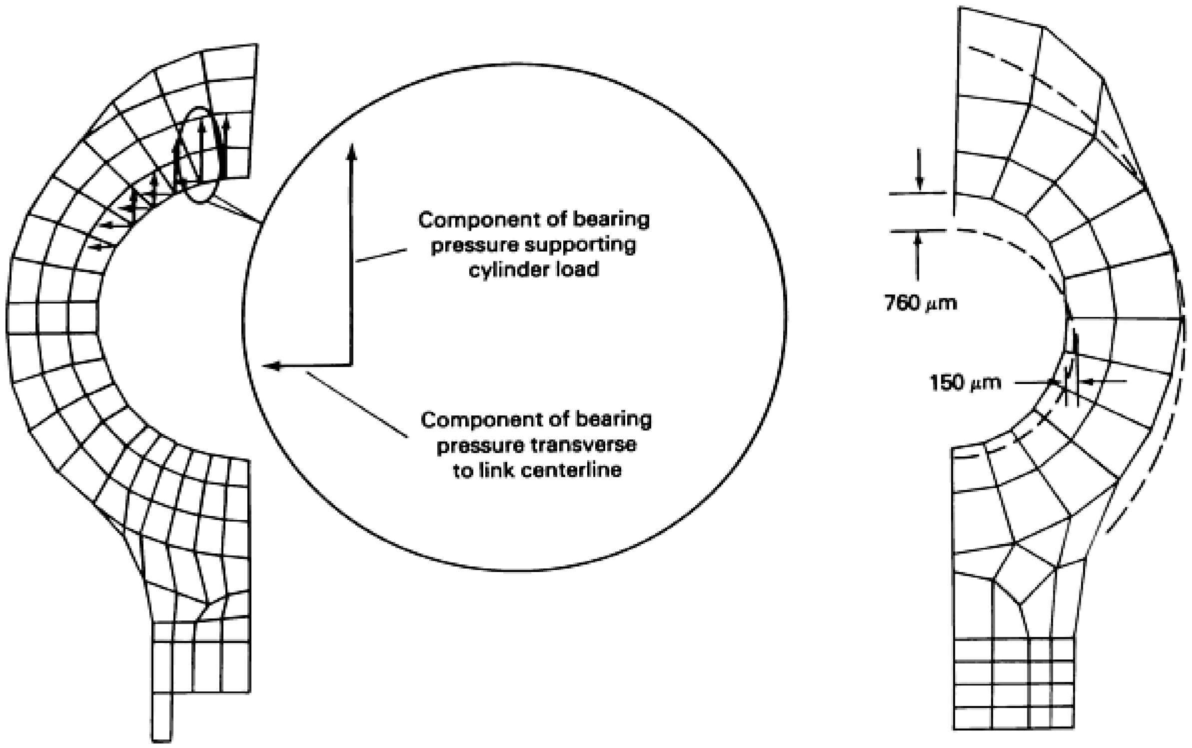

Fig. 7 Bearing "pinch" generated by deformation of a small-end connecting rod

The crankshaft bearing is also prone to elastic support problems. If the crankshaft is relatively stiff, care must be taken that the bearing support stiffness of the pump frame is optimized to carry the load and yet allow the bearings to translate and thus distribute the plunger loads of the rigid crankshaft to several bearings. If the crankshaft is relatively flexible, on the other hand, the bearing support stiffness must be adjusted to avoid locally high bearing pressure at bearing corners when the crankshaft tilts within the bearing shell.

Particulate Erosion

Problems of third-body erosion can occur in all types of pumps if they are subjected to abrasive service, such as slurry service. Commonly pumped slurries include coal, mined phosphate, mined metal ore, and water with fly ash captured during flue-gas desulfurization. The pumping of paper pulp is another common erosive service. Such services must compromise hydraulic performance for wear resistance and require designs that allow ease of inspection and repair (Ref 19).

The abrasivity of a fluid can be quantified using the Miller number index, as outlined in ASTM Standard G 75 (Ref 20). The effective viscosity of an abrasive slurry is often quite high compared with the virgin fluid and should be considered along with abrasivity in selecting an appropriate pump. Otherwise, the pump may have a head and flow capability that are too low for the intended service.

Centrifugal Pumps. The typical centrifugal slurry pump is of an overhung single-stage end-suction design. It should have reasonably low required value of net positive suction head (NPSH), as explained below in the section on cavitation. This is because suction piping velocities must often be kept high so that the slurry stays above its "critical carrying velocity" or "nonsettling velocity" below which the slurry cannot be kept evenly suspended (Ref 21). This requirement is particularly strong if the slurry particles are larger than roughly 65 μm.

The areas of a centrifugal pump most prone to abrasive wear are the impellers and the casing interior, where flow-path velocities are high. One approach to decreasing erosive wear of these areas and to maintaining the pump is the use of hard, wear-resistant, replaceable liners. Elastomeric liners are sometimes used as an alternative to hard metal liners. Natural rubber, neoprene, nitrile, and chlorosulfonated polyethylene have exhibited high abrasion resistance when used as external liners for impellers and as internal liners for casing volute passages. However, care must be taken that the pressure in the flow passage next to the liner does not fall below the pressure between the liner and the wall, which is typically close to atmospheric pressure. When this occurs in service, unless the liner is mechanically bolted to the casing at key locations, it may billow out, catching the impeller blades and destroying the rotor. Another caveat is to stay below the softening temperature of the rubber, typically about 115 °C (240 °F). Also, for elastomeric materials to exhibit good abrasion resistance, the abrasive particles must be less than 5 mm (0.2 in.) if they are dull and less than 2 mm (0.08 in.) if they are sharp. Finally, the head per stage should be kept below about 50 m (165 ft) (Ref 19).

When metal impellers and casing liners are used, they should be as hard as possible, not only because wear resistance generally increases with hardness, but also because abrasive erosion in pump components generally occurs due to the impingement of particles at very oblique angles to the surface. As pointed out by Finnie (Ref 22), such abrasion attacks ductile materials much more readily than it does hard, relatively brittle materials. Finnie's equation for hard materials is:

$$\text{Wear rate} = (\text{Number of impinging particles}) \cdot (\text{Average particle mass}) \cdot (\text{Impingement velocity})^2 \cdot (\text{Angle of impingement}) \qquad \textbf{(Eq 1)}$$

Particulate erosion of a ductile steel impeller by a catalytic fluid that was not expected to be erosive is shown in Fig. 8.

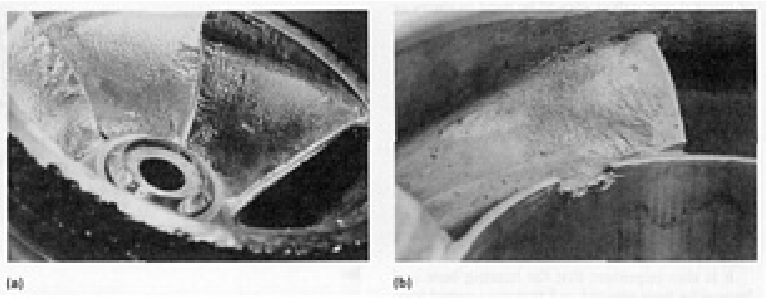

Fig. 8 Particulate erosion of a ductile steel impeller by an abrasive catalyst. (a) 0.25×. (b) 1×

Typical hard, erosion-resistant metals include white cast iron (standard gray or ductile cast irons are poor), high-chromium (that is, 13 to 28%) alloy steel, cobalt-base superalloys such as Stellite, and special nickel-base alloys such as Ni-Hard. These materials are useful not only for the flow-path surfaces but also as sleeves in sealing areas, particularly if packing is used. It is good practice to use hard metal or ceramic expellers near seal entrances to keep particles out of the sealing clearance. If thorough flushing of packing presents a design problem, abrasion-resistant SiC ceramic mechanical seals together with an expeller or minimal flushing can be used. Some of the newest designs of mechanical seals for abrasive service are even axially split, for ease of replacement.

Design steps other than material selection can be taken to maximize the ability of a pump to withstand abrasives. For example, the casing volute tongue can be retracted to avoid the highest-velocity region of discharge flow, and casing volute walls can be contoured to minimize impingement angles in high-density zones of particle trajectories (Ref 23). The impeller can be redesigned with its blades recessed into toroidal cavities, thus avoiding many mainstream particles (however, a stiff efficiency penalty can be expected for this configuration). Impeller vanes can be made thicker so that it takes longer for their edges to erode. Also, larger pumps than required can be selected and then run at less than design speed, through use of a simple adjustable pulley or variable-frequency drive excitation of the motor (Ref 24).

Even if optimum materials and design configurations are chosen, centrifugal pumps still face practical limitations in abrasive service. For example, head per stage should be kept below 100 m (330 ft) or else the implied volute velocities will be too high. When higher heads are required, pumps can be arranged in series. Also, abrasive particles may collect in impeller side clearances, held in suspension by the counter-tendencies of the leakage flow, which is biased to moving toward lower diameter by design, and of centrifugal forces, which always work away from minimum diameter. This can result in long-lived, particle-filled vortices (Ref 25), which quickly erode the impeller hub unless hardened wear plates are applied at the proper locations.

Open or semiopen impellers are often used for abrasive or slurry service, particularly in the paper industry. Such impellers can be designed with clearance in the axial direction, which sacrifices new pump efficiency but makes the pump performance less prone to clearance increases and allows clearance adjustment by shimming of the impeller to change its position on the shaft. The surfaces of the impellers and casing flow paths, particularly the volute, must be made of a hard metal or ceramic or of a tough elastomer, as discussed above.

Reciprocating and Other Positive-Displacement Pumps. Generally, centrifugal pumps are the best choice if relatively low heads and high flows are required; otherwise, reciprocating pumps are the best choice. Other criteria, however, are involved in abrasive service. As discussed above, centrifugal pump heads face certain limitations in such applications. On the other hand, for particle sizes greater than about 2.5 mm (0.1 in.), even the most particle-tolerant reciprocating pump valves will tend to jam and are not satisfactory.

In such cases, a diaphragm pump driven by air or clean fluid may be suitable up to about 100 m (330 ft) of developed head. Above this pressure, a progressive cavity pump might be considered (Ref 26). One type of progressive cavity pump, the single- or double-screw pump shown in Fig. 9, is capable of high pressure and relatively high flow. In abrasive service, screw pumps have been shown to pump abrasives and even mixed-phase fluids reliably with the use of hard metal screws and high-durometer (about Shore 68) rubber liners.

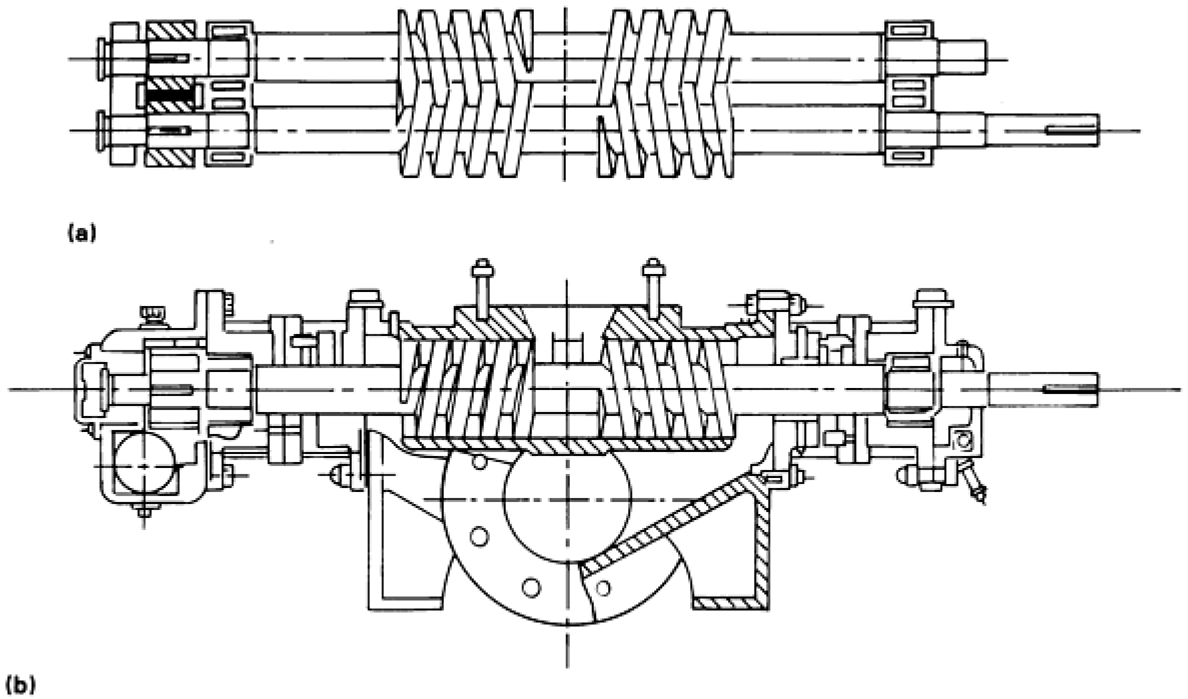

Fig. 9 Cross-sectional view of a double-screw pump. (a) Top view. (b) Side view. Courtesy of Dresser Pump Division, Dresser Industries

If particle size is below 2.5 mm (0.1 in.), reciprocating pumps are applicable, and in services where they compete with centrifugal pumps, they may even be the economical choice because of their high thermodynamic efficiency (on the order of 95%) (Ref 27). Two classes of reciprocating pumps are piston and plunger types. The piston types are generally superior for higher flows, but the plunger types can better tolerate sharp and highly abrasive particles.

Special vertically mounted spherical seat or reinforced conical seat valves should be used in slurry or abrasive pumping service, or if deposits are expected to build up near the cylinders. Such valves tend to discourage the trapping of debris in the seating surface, as illustrated by the valves shown in the earlier discussion of rubbing wear (Fig. 6) (Ref 17).

Cavitation Erosion

Cavitation occurs in portions of the flow path where static pressure drops below the vapor pressure of the pumped fluid. This causes very small vapor bubbles to form, which then rapidly and violently collapse when they enter an area where static pressure once again exceeds vapor pressure. The sudden bubble collapse causes concentrated shock waves that impinge on nearby metal, resulting in stresses large enough to induce fatigue.

Unlike surface fatigue caused by rubbing, which produces subsurface cracks that eventually delaminate the surface in thin flakes, many cavitation fatigue cracks form perpendicular to the surface and tend to remove material in small blocks. The resulting damage leaves a surface finish that initially is matte, later becomes pock marked, and eventually has the appearance of rough, mountainous terrain, with odd eroded surface protrusions. Cavitation is probably the most common cause of rapid component erosion and wear in hydraulic machinery.

The usual measure of likelihood of cavitation is the net positive suction head (NPSH), which is the difference between the static pressure and the vapor pressure of the liquid at the pump inlet flange, expressed in meters:

$$\mathrm{NPSH} = \frac{P_s - P_v}{\rho g} \quad \textbf{(Eq 2)}$$

where P_s is the static pressure at the pump inlet flange (in Pa), P_v is the vapor pressure of the liquid (in Pa), ρ is the liquid density (in kg/m^3), and g is the gravitational constant, 9.8 m/s^2. A required value of this number, the NPSHR, is determined by the pump manufacturer, generally on the basis of when sufficient bubble formation occurs to drop the head produced by the pump by 3%. The system's available NPSH, or NPSHA, must be at least equal to this value. If it is not, either another pump that is less demanding at the suction must be chosen or some means must be found to increase the NPSHA, such as an upstream booster pump or, in a centrifugal pump, use of an axial inducer. The latter looks like a corkscrew protruding from the first-stage inlet and controls the inlet flow angle while adding to the initial suction pressure. Care must be taken to include in NPSHA the losses due to suction pipe friction, valves, and strainers. In reciprocating pumps, the effect of pulsating flow inertia, or "acceleration," can reduce transient suction pressure dramatically and must be accounted for and reduced, if necessary, by using a pulsation dampener.

The situation became complicated in recent years when researchers found that NPSHR based on 3% head drop was insufficient to avoid cavitation damage. Instances occurred in which more than three times as much suction head was required to avoid bubble formation and subsequent damage. Other more stringent criteria have been proposed, such as "1%" and "0%" (that is, on the verge of total head drop) (see Ref 28), but the pump industry still generally uses the familiar 3%, with a factor of safety based on experience for a given class of pumps. Some researchers believe that observation of cavitation beyond a certain bubble length should be the criterion (Ref 29), but so far, general application of this has been impractical.

An early attempt to predict cavitation used the Thoma number, which is a ratio of NPSHA to total head. This number, originally applied to hydraulic turbines, places too much emphasis on discharge conditions to be generally applicable to pumps. A modification is the cavitation number or coefficient, *K*, which is a ratio of NPSHA to suction tip speed squared. *K* is referenced to the suction, but does not account for local increases in velocity and associated decreases in static pressure in the flow passages, especially in the turbulent and sometimes partially stalled inlet of impellers.

Another factor of importance is the ratio of NPSHR--NPSHA to vapor pressure, where NPSHR is the value of NPSH at which cavitation damage begins (not necessarily the same as the 3% NPSHR, as discussed above). Once cavitation damage begins, this ratio is higher for cold fluids than for warm ones, because a warm fluid has a higher vapor pressure than a cold one. This higher ratio suggests that cavitation is more severe in cold fluids, which is exactly the case. A warm fluid, with higher vapor pressure, will cavitate at a lower suction pressure; however, the rate of bubble collapse and hence the severity of the cavitation once it occurs is roughly dependent on the ratio of the static pressure differential to the vapor pressure, so the bubble collapse damage is less severe.

Centrifugal Pumps. A useful approach for assessing the potential for cavitation damage in centrifugal pumps is the concept of suction-specific speed, *S*, developed by Karassik (Ref 30):

$$S = \frac{[\text{rpm} \cdot (\text{flow})^{1/2}]}{(\text{NPSHR})^{3/4}} \qquad \textbf{(Eq 3)}$$

As *S* becomes larger, the chances become greater that cavitation damage will occur despite the 3% head drop NPSHR value being met, and if it does occur it is more severe, on average, as *S* increases. Cavitation in pumps without inducers becomes highly probable as *S* increases beyond the range of 13,300 to 16,000, where NPSH is in feet and flow is in gallons per minute (Ref 31).

An indirect but important cause of cavitation is suction and discharge recirculation (Ref 6, 7), which occurs when the pump is run well below the flow it was designed for, and the inlet or exit flow angles match poorly with the pump vane angles. This leads to local secondary flow eddies on the high-pressure side of the blade. The locally increased velocity in these eddies can decrease local suction pressure sufficiently to cause cavitation and subsequent damage. This damage is usually distinguishable from direct cavitation, because it usually occurs on the pressure side of the blade. Direct cavitation generally occurs where the flow-path static pressure is low in the primary flow--namely, on the suction surface of the blades, usually close to the inlet. An example of direct cavitation damage is shown in Fig. 10.

Fig. 10 Early stages of centrifugal pump cavitation and damage

As discussed earlier in the section on rubbing wear, recirculation and its associated problems can be avoided by ensuring that the continuous (that is, long-term) flow of the system is not below the flow associated with the onset of suction recirculation, which is typically somewhere between 25 and 75% of the rated capacity of the pump. This may be difficult in an existing installation, and a redesigned impeller to lower recirculation onset flow should be considered, although this may reduce efficiency somewhat.

In instances of either direct or recirculation-induced cavitation damage, if it is not possible to directly fix the cause (that is, by increased suction pressure or increased minimum flow, respectively), then a material with greater cavitation erosion resistance can be used to replace the existing impellers. In general, cast iron, low-carbon steel, and austenitic steels have low cavitation resistance, although they are often used where significant cavitation is not expected. Titanium, aluminum bronze, Nitronic 50, and a new alloy called Hydrolloy have good cavitation erosion resistance, the tradeoff being increased expense.

A standardized accelerated test procedure (ASTM G 32) (Ref 32) is available for assessing the cavitation damage resistance of materials if existing data cannot be found. This procedure is based on the use of high-frequency vibrations to excite cavitation close to the metal surface.

Reciprocating Pumps. The components of a reciprocating pump most likely to suffer cavitation damage are the suction valves. Suction valves should be designed and tested for a given pump flow and quoted NPSHR such that absolutely no cavitation occurs during the initial valve opening, when the annular valve area is small and fluid velocity is high, causing locally low pressures through Bernoulli's equation. When even a small amount of cavitation occurs in one valve, it triggers an "impulse response" of the suction manifold acoustic natural frequencies, with resulting pressure pulsations large enough to make all of the suction valves severely cavitate. This can cause "valve hammer," where the valve sharply impacts its seat at an acceleration in excess of 100 G's. The resulting shock tends to peen the valve seating area, causing fatigue, and can send strong stress waves through the entire drive train. This can loosen bolted connections and cause fatigue or bearing problems far from the source of the problem (Ref 16).

If suction valve cavitation occurs, either suction pressure must be increased or the valve design must be changed to lower the NPSHR. When determining reciprocating pump suction pressure, it is important to include the suction line inertia effects when the suction valve opens, known as acceleration head. This reduces the effective NPSHA and can be minimized by shortening the suction piping or by placing a large-volume pulsation dampener in the piping, as close to the pump as possible (Ref 17).

Additional information about cavitation damage can be found in Ref 33 and in the article "Cavitation Erosion" in this Volume.

Friction and Wear of Compressors

Royce N. Brown, Dow Chemical Company

Introduction

A COMPRESSOR is a mechanical device that is used to increase the pressure level of compressible fluid. These pressures can be at any level, from vacuum to high positive levels. The fluids can consist of either vapors or gases, singularly or as mixtures. Because the compressors described in this article use mechanical motion to perform the compression function, they are subject to friction and wear. Each of these compressors is defined below by type and function, followed by a brief discussion of how friction and wear are manifest in each.

Reciprocating Compressors

The reciprocating compressor is one of the more complex types of machines, in terms of moving parts. It performs compression by trapping a volume of gas in a cylinder that contains a piston. The piston displaces and compresses the gas on the head end stroke (Fig. 1). The two most common forms of reciprocating compressor are the trunk and crosshead types.

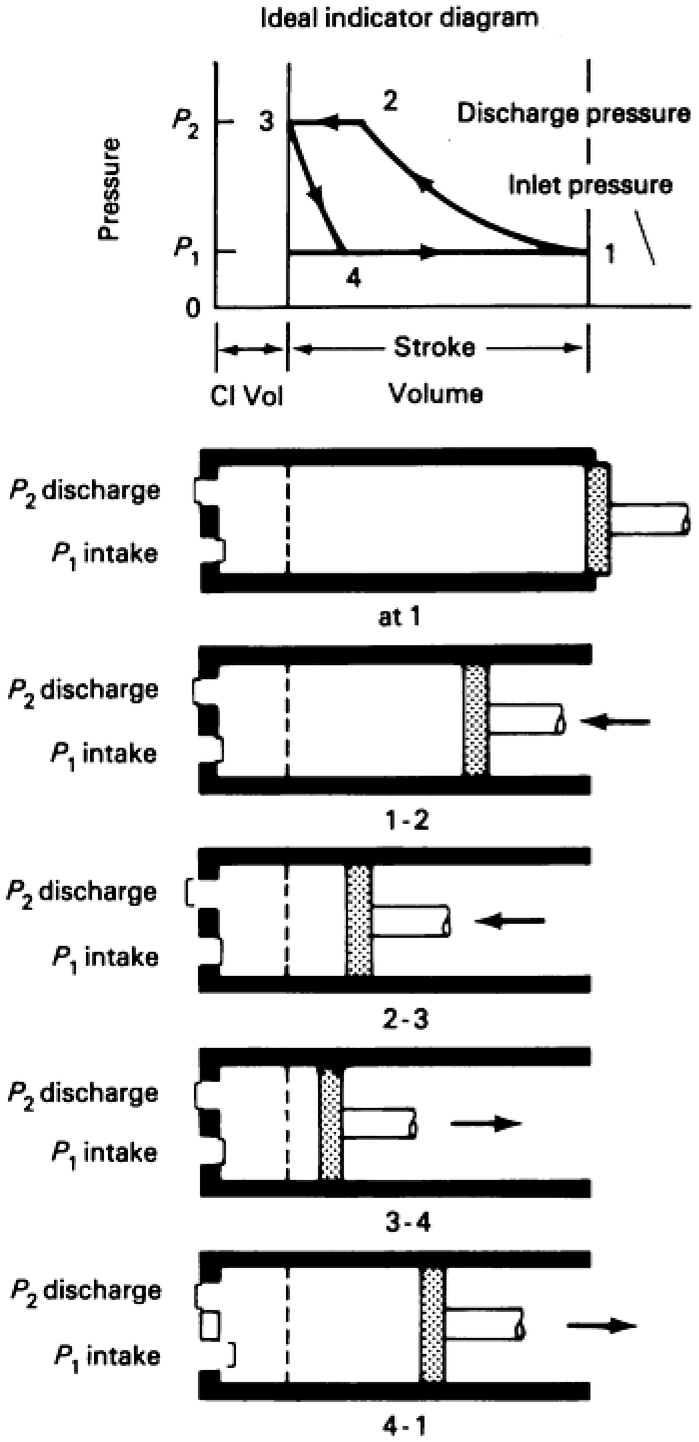

Fig. 1 Reciprocating compressor cycle

The distinguishing feature of the trunk-type compressor (Fig. 2) is that the piston is directly connected to the connecting rod. This type of construction is normally used in smaller machines, such as small shop air compressors and refrigeration service compressors.

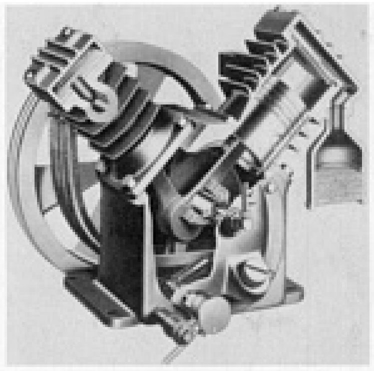

Fig. 2 Trunk-type reciprocating compressor. Courtesy of Ingersol Rand

The crosshead-type compressor (Fig. 3) is normally found in process gas service. The connecting rod is attached to the crosshead, which is connected to the piston rod that moves the piston. The cylinders are normally double acting, a feature that permits compression to occur on either side of the piston, which essentially doubles the capacity for a given-sized cylinder. It can be noted that a gas seal in the form of packing can prevent gas leakage from the compressor cylinder to the crankcase.

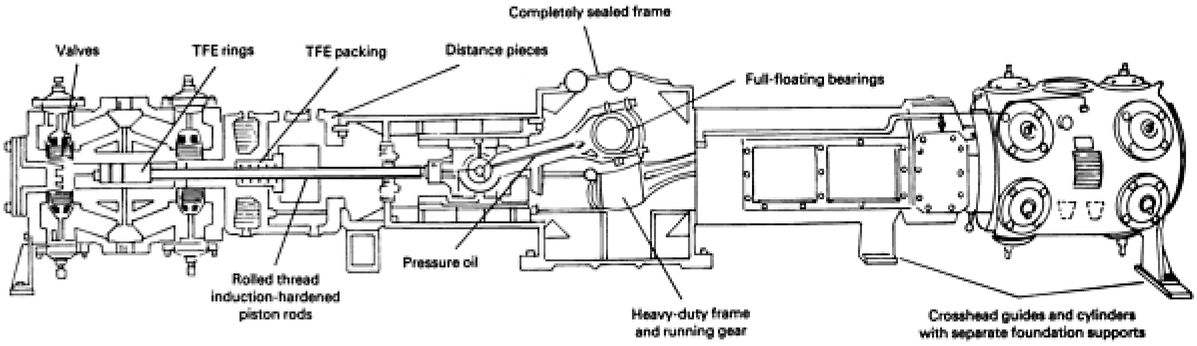

Fig. 3 Cross section of crosshead-type reciprocating compressor. Source: Dresser-Rand

The cylinder, which is the gas-handling part of the reciprocating compressor, contains the piston, which is the gas displacer. Motion is transmitted to the piston by the connecting rod in the trunk-type compressor, and by the piston rod in the crosshead type. The cylinder includes the valves that control the inlet and outlet gas flow. The compressor valves are spring loaded and gas actuated. There are one or more inlet valves and one or more discharge valves. Flow and pressure considerations would dictate the number and when multiple valves are needed.

Cylinder Wear. The piston includes a set of seals, more commonly referred to as piston rings. Because the rings rub the cylinder walls, wear of both the rings and the cylinder wall becomes a consideration in material selection. The majority of cylinders used for process gas service utilize replaceable liners that act as the cylinder wear surface.

Cylinder orientation has an influence on the wear of the cylinder and rings. Vertically oriented cylinders would be preferred if wear were the only consideration. Small compressors are generally constructed with the cylinders vertical, or nearly so in a "V" configuration. As compressor size increases, height also increases, which causes head-room problems and makes maintenance unwieldy.

Generally, the larger compressors are arranged with horizontal cylinders; this arrangement makes spaces management easier and facilitates maintenance. However, these gains are somewhat offset by the effects of gravity. The weight of the piston causes additional rubbing forces to the cylinder wall and increases the potential for wear, particularly to the rings. To counter this, nonmetallic (usually) rider rings are supplied with the pistons. The rider rings are larger and act as the

wear surface for the piston. American Petroleum Institute (API) Standard 618 provides guidelines on the loading limits of rider rings used in reciprocating compressors for refinery service.

As stated earlier, the piston rings act as a seal to minimize the quantity of gas that can bypass the piston. Again, the need for compromise becomes evident. If there are many rings and/or a very tight fit to the cylinder wall, then sealing is excellent, but friction force and wear are increased. Besides the wear considerations, increased friction results in a larger drag on the piston. This absorbs energy and results in an increased parasitic load on the compressor. Ultimately, this loss results in a decrease in efficiency. A piston is shown in Fig. 4.

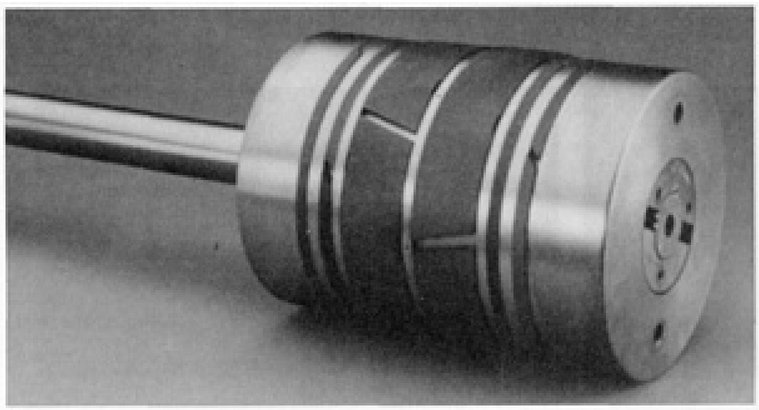

Fig. 4 Crosshead-type reciprocating compressor piston and rod. Courtesy of Dresser-Rand

Piston speed is a key factor in the wear of a cylinder and the rings. Average piston speed is defined as:

$$PS = 2SN \qquad \textbf{(Eq 1)}$$

where PS is piston speed in m/s, S is stroke in m, and N is crankshaft speed in rev/s. Piston speeds normally range from 2 to 6 m/s (400 to 1200 ft/min). It is obvious that the higher the piston speed, the higher the wear. Industrial compressors are normally selected in the range from 3 to 4 m/s (600 to 800 ft/min). If the cylinder is of a nonlubricated design, then the piston speed should be toward the lower end of the given speed range to minimize wear.

Cylinder lubrication depends on the type of compressor being considered. In trunk-type compressors, cylinder lubrication is normally obtained from the crankcase, and reaches the cylinder wall by a splash action. Although not sophisticated, this method does provide adequate lubrication.

In crosshead-type compressors, cylinder lubrication is divided into either nonlubricated or lubricated cylinder compressors. The nonlubricated cylinder compressor does not supply an outside source of lubricant to the cylinder. The term nonlubricated is probably not the most accurate description of the lubrication process. In actuality, the ring materials are chosen for their inherent low friction or self-lubricating characteristics. The lubricated cylinder compressor is furnished, by an outside source, with a lubricant that is either a conventional mineral oil or a synthetic oil, depending on the process gas.

Two methods of supplying the lubricant to the cylinder and rod packing are available. The amount of lubricant furnished to any lubrication point is quite small, on the order of droplets per minute. Use of the metering-type lubricator permits precise tailoring of lubricant quantity to the cylinder points and packing without compromising the frame lubrication system, which is much larger.

One type of mechanical lubricator consists of a multiplunger pump, where an individual plunger is dedicated to each lubrication point. A sight glass is normally included in each plunger feed to allow visual monitoring of the point. Another common type of mechanical lubricator system consists of a single metering pump sized for the total combined flow to all points. A divider block distributes the flow in the required amount to the individual lubrication points. Each system has

pros and cons associated with it. Generally, the compressor supplier can provide recommendations to users who have not developed a preference.

Cylinder Materials. In many smaller compressors, the wearing portion of the cylinder is made of the same material as the balance of the cylinder (usually, gray cast iron). In some instances, a cylinder can be nodular, or ductile, iron. On smaller high-pressure service cylinders, steel is used. Smaller compressors of the more standardized type normally use an unlined cylinder.

On larger compressors, cylinders with replaceable liners are more common. Liner material can be chosen for its wear properties, as well as compatibility with the application. If cylinder wear does occur, then the liner construction represents a renewable part. For an unlined cylinder, the only recourse after significant cylinder wear is to either rebore or replace the cylinder.

The piston ring materials are made of either a fluorocarbon compound or polyether etherketone (PEEK) for nonlubricated service. The fluorocarbon is generally a carbon-filled type. For lubricated service, rings can be either metallic or nonmetallic. Bronze and cast iron are common for metallic service, whereas carbon-filled fluorocarbon is normally used for nonmetallic service. Rider rings generally use carbon-filled fluorocarbon.

Valves are used to control the gas that either enters or leaves a cylinder. Valves can be one of the higher-maintenance items on the reciprocating compressor. Because valve duty is quite severe, it is subject to cyclic stresses that are due to the requirement that it open and close on each stroke. Upon each open and close cycle, the valve is subjected to impact loads. It also experiences all of the temperature changes that occur in the compressed gas. On lubricated cylinders, the presence of lubricant does not extend valve life. Valve motion is difficult to lubricate. Also, in some cases, the lubricant in combination with high temperatures may cause carbon to form on the valves, shortening their lives. As the valves wear, compressor performance deteriorates, which lowers efficiency and raises temperature, furthering the deterioration problem.

A plate valve is shown in Fig. 5 and a channel valve is shown in Fig. 6. In most cases, the material of construction is metallic. Gray iron, nodular iron, and steel are commonly used for valve seats and guards. Valve springs are chrome, silicon, stainless steel, or inconel. Higher alloys may be needed for reactive process gases. Valve plates are usually stainless steel, plastics, or PEEK.

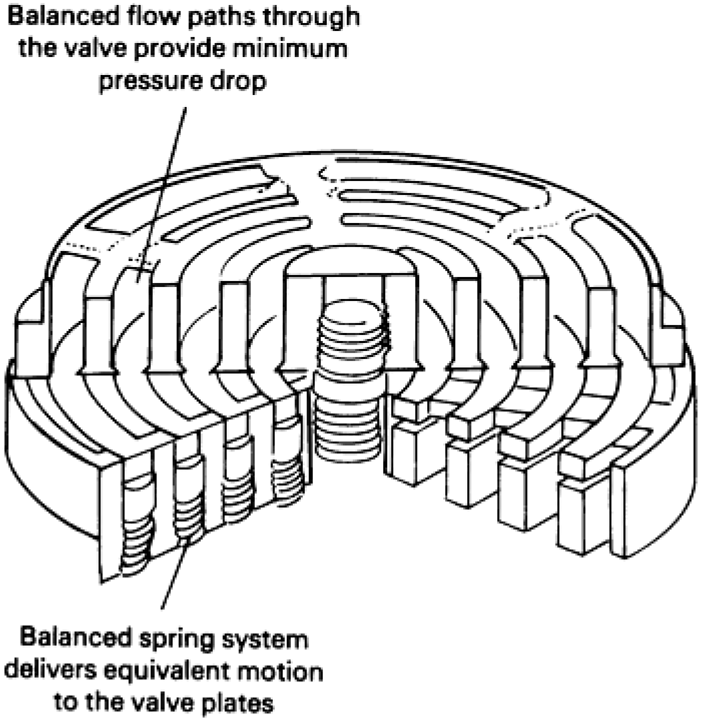

Fig. 5 Plate valve. Source: Dresser-Rand

Fig. 6 Channel valve. Courtesy of Dresser-Rand

Piston rod packing is required on double-acting cylinders where the piston rod passes through the crank-end cylinder closure. This may also be true on the head end if a tail rod is used. The purpose of the packing is to contain the gas in the cylinder. The piston rod must have a high degree of finish in the packing area. Various methods of surface hardening are used. These features are needed to minimize the packing and rod wear in the packing region. On lubricated compressors, the packing is given lubrication from the cylinder lubricator, which helps reduce the friction and wear at this point. The packing rings are generally a segmental type, and are usually made from a carbon-filled fluorocarbon-type material.

In addition to being a source of wear, packing is another source of friction, which can contribute to loss in efficiency. Gas release that is due to excessive leakage is an extreme result of excess wear.

The crosshead is the point where the connecting rod motion is converted to pure linear motion. It provides the feature that makes double-acting cylinders possible. A crosshead and associated parts are shown in Fig. 7. The crosshead is lubricated by the frame lubrication system. The critical requirement for the crosshead is that the piston rod provide a force reversal at the crosshead pin. This reversal causes the pin to change its position in the crosshead bearing clearance. This movement allows oil to enter both sides of the bushing to ensure adequate lubrication.

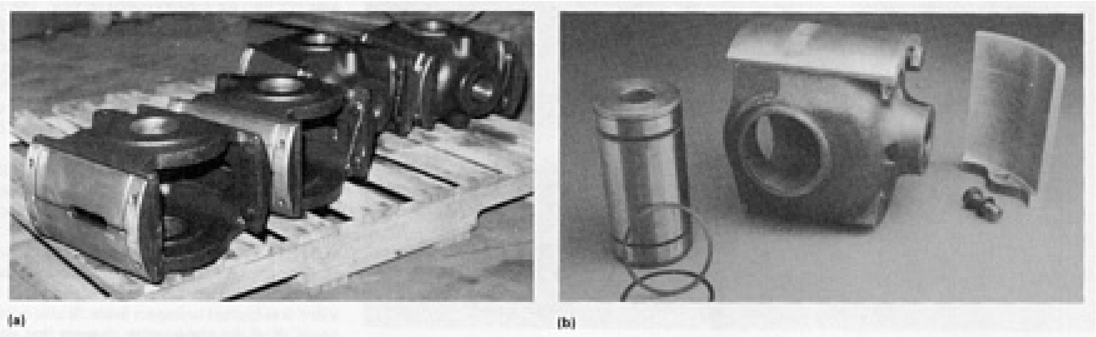

Fig. 7 (a) Crossheads. (b) Crosshead with pin and shoes. Courtesy of Dresser-Rand

On a fully loaded cylinder, rod reversals are not a problem. However, if one end of the double-acting cylinder is unloaded, the gas load could exceed the inertial load and prevent the reversals from taking place. Clearance pocket unloaders or external clearance bottlers can be used for alternate unloading schemes to solve rod reversal problems.

The frame portion of the reciprocating compressor is a major component of the compressor, in terms of physical size and weight. It houses the crankshaft, where rotary motion is translated into the reciprocating motion required to move the pistons. It provides the mounting base for the cylinders and provides for their alignment to the crankshaft, which is cradled in a set of main bearings located in the frame. The crankshaft also has journals for the connecting rod bearings.

These bearings can be either the hydrodynamic oil film type or the rolling-element type. There may also be a combination; the main bearings could be one type and the connecting rod journals, the other type. Normally, the larger process compressors use the hydrodynamic type for all bearings.

On the crosshead-type compressor, the crosshead housing is attached to the basic frame member, and the distance piece and cylinder, in turn, attach to the crosshead housing. In some designs, the crosshead housing is integral to the basic frame member.

It could be said that the frame makes a contribution to valve life. This connection is not really all that mysterious, in that the crankshaft speed dictates the valve cycle rate. If the crankshaft speed is high for a given service, then the valve cycle rate is high. The cycle rate has a direct impact on valve life.

Frame Lubrication. The frame section of the reciprocating compressor is independently lubricated in crosshead-type machines. For the trunk type, it has been noted that all lubrication, both for frame and cylinders, is supplied by the frame system. One method used in smaller machines is a very simple nonpressurized system, which lubricates by splashing the oil. The splashing is accomplished by the dipping of the crank throws into oil contained in a sump in the crankcase. Dippers can be attached to the connecting rods to aid in the oil distribution.

Pressurized systems have at least one oil pump, which is driven by either the compressor's crankshaft or a separate electric motor. There can be additional pumps, such as a start-up pump for shaft-driven main pump configurations. The auxiliary pump may alternately take the form of a full-sized electric motor standby. A filter that provides for oil cleanup can be duplicated to allow servicing while the compressor is operating.

When the heat duty cannot be dissipated in the sump, an external oil cooler is required. This exchanger is either a liquid-cooled or air-cooled device. For critical service, two coolers can be used to permit servicing while the unit is operating. Service valves and instrumentation for monitoring pressure, temperature, and level also may be included depending on the critical nature of the service and on the size and type of unit.

Reciprocating Compressor Overview. The interaction of economics and life is an ever-present challenge to the user of any equipment, but this is particularly true for the reciprocating compressor. If, for example, a volumetric rate of gas is specified, then several choices are available. First, a cylinder size and speed are selected, and then a small-diameter long stroke can be chosen. This has some first-cost advantage over choosing a larger bore, shorter stroke. The disadvantage is that the piston speed may be too high for good life. Crankshaft speed is also a factor. A higher speed will reduce the overall size of the cylinder and again lower the first cost, but this impacts both piston speed and valve cycle rate.

The final selection is normally the best compromise of first-cost and compressor component life. This will vary from application to application, based on the critical nature of the service and the ability to withstand downtime. Even if downtime is not considered serious, another factor is the projected cost of maintenance and its impact on the life cost of the machine.

Rotary Compressors

Many rotary compressor types have a low-pressure design and are generally referred to as blowers. Their pressure differential capacity is normally limited. This discussion focuses on rotary compressors with a somewhat higher pressure range, as well as the capability for a higher pressure rise. To some degree, these compressors are capable to competing with the reciprocating compressor.

Like the reciprocating compressor, the rotary compressors are of the positive-displacement type. In actuality, they supplement the range of applications of the reciprocating compressor, rather than duplicate it.

Lobe Type

Lobe-type compressors all have some features in common. However, the most significant type is the helical lobe, or screw compressor, which is also referred to as the SRM and Lysholm compressor. It can be configured as either a non-flooded (dry) or flooded compressor. The dry configuration is generally larger in capacity, but is limited to a lower pressure ratio. The flooded compressor is used for lower volumetric flow, but can achieve a higher pressure ratio.

The dry helical lobe compressor consists of two rotors, one male and one female, which are arranged in their casing to intermesh when they turn. The compression cycle is shown in Fig. 8. The gas path takes the form of the helix cut in the female rotor. The rotors are timed by a set of timing gears located at one end of the machine. Gas path sealing is accomplished by seal strips located at the tips of the rotors. Two rotor profiles are shown in Fig. 9.

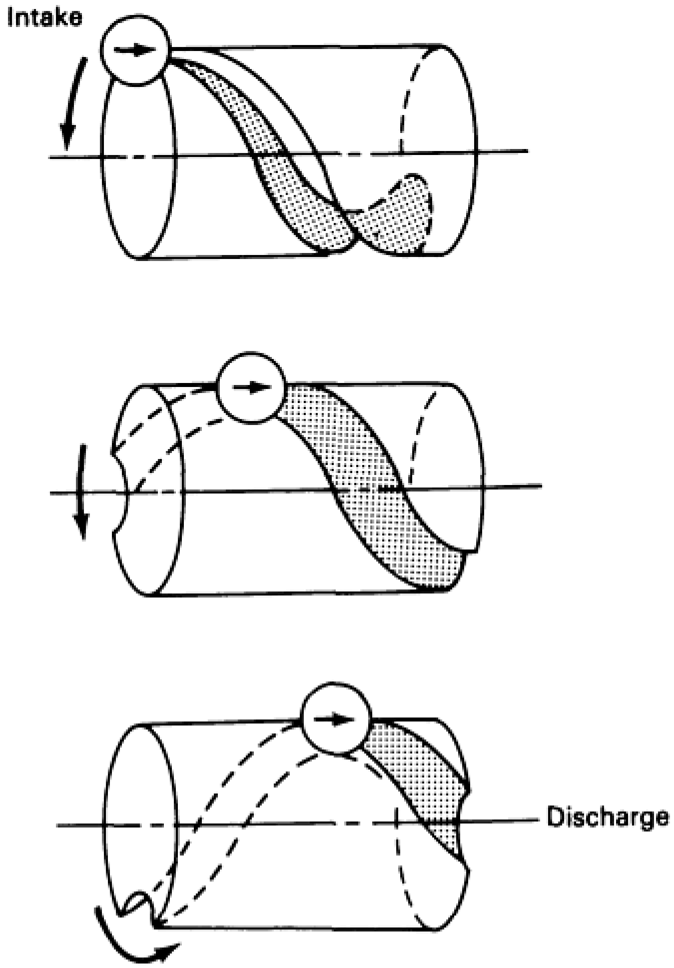

Fig. 8 Compression cycle of helical lobe compressor

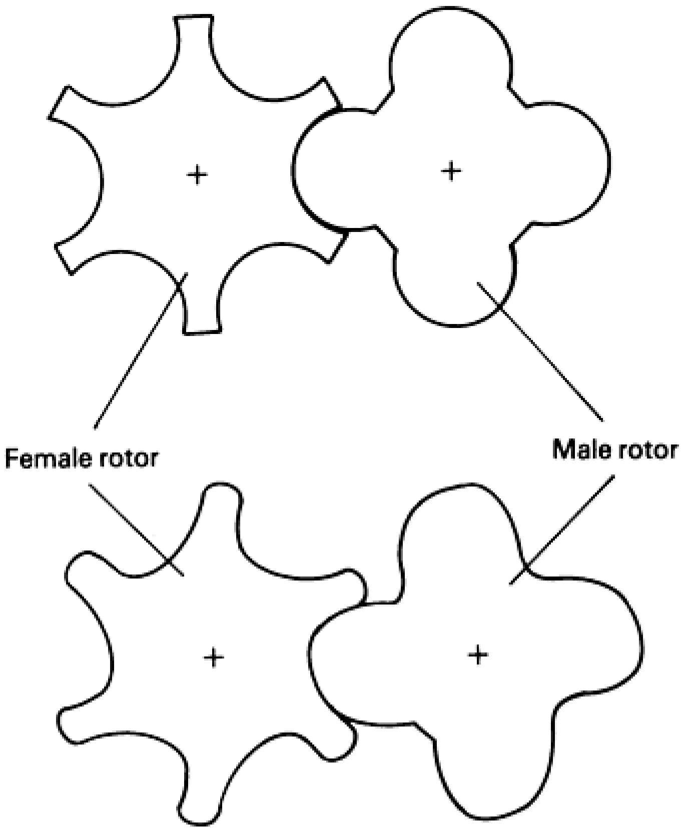

Fig. 9 Rotor profiles

The rotor discharge ports are cut to match the application pressure ratio. The purpose is to release the pocket of trapped gas being compressed at the application level to prevent overcompression and undercompression. This allows the compressor to operate at its optimum efficiency. A set of helical screw compressor rotors is shown in Fig. 10.

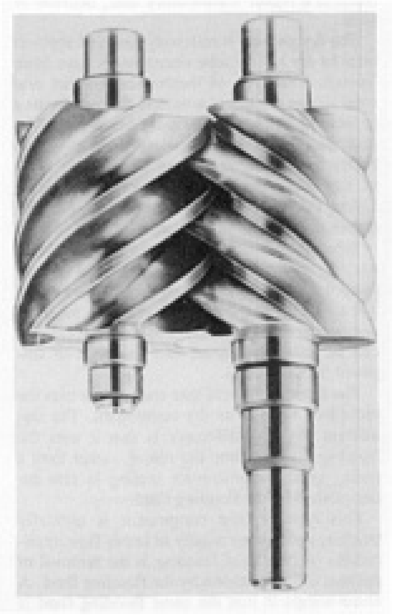

Fig. 10 Helical screw compressor rotors

Rotor Wear. The rotors, in ideal service, would not wear because they would not touch, being synchronized by the timing gears. Realistically, wear does occur. Although this style of compressor works better in dirty gas service than many other compressors, the presence of particulates are what causes wear. Normally, this occurs on the seal strips. This compressor also tolerates liquid mist better than the other compressors. If this type of operation is anticipated, the supplier can overlay the casing with a welded material to add abrasion or corrosion resistance and to minimize rotor bore wear. Although seal strips can be renewed, it is difficult and therefore expensive to repair a badly eroded casing.

Bearings and Seals. Dry helical lobe compressors normally have hydrodynamic radial and thrust bearings, which are pressure fed from an outside oil system. Because of the nature of the oil film that develops from rotation, hydrodynamic bearings do not suffer from much wear. Wear normally is due to the lack of lubricant cleanliness. If the particle size in the lubricant is larger than the minimum lubricant film thickness, then excess wear occurs. This is true for the four journal bearings and the thrust bearing. A well-maintained lubrication system with properly sized oil filters should prevent this.

There are a few applications for which rolling-element bearings may be used by the manufacturer. However, this is not very common on dry helical lobe compressors used in process service.

The dry helical lobe compressor requires four shaft end seals, which can have many configurations. The application dictates the basic requirements of leakage. On an air compressor, a relatively simple labyrinth or carbon ring seal is adequate. This type of seal is generally referred to as a restrictive seal, because it limits, rather than stops, leakage. Of the two, the carbon ring seal is more effective, but unfortunately is more subject to wear than the plain labyrinth.

Two other basic forms of seals are commonly used, depending on application requirements: the liquid film and the mechanical contact seal. The liquid film seal uses a metallic sealing ring, which is liquid buffered to maintain a liquid film in the ring clearance area. The presence of the liquid film excludes the gas, thereby effecting a seal. The liquid normally is a lubricant, which helps prevent wear to the bushing. Water can be used for applications where the lubricant and gas are incompatible. Carbon bushings are sometimes used in water-buffered service.

The mechanical contact seal is more expensive, but also provides the greater degree of gas containment. This seal type can have either a liquid buffered or dry gas form. The preferred fluid for buffering is a lubricant. When lubricating oils is compatible with the process, lubricant from the bearing lubrication system can be used. The control of the lubrication system pressure becomes more complicated, because several pressure levels may be required. However, no additional liquid supply system is needed. In some rare applications, this seal is used with a liquid that has poor lubrication properties. The result is a higher maintenance cost, because of wear.

The dry gas seal is relatively new and applications in dry helical lobe compressors have been limited. This type of mechanical contact seal uses a clean dry gas as a buffer. The gas forms a separating film so that the seal does not rub. The seal uses less-parasitic power than its liquid buffered counterpart. It can be obtained in a variety of configurations. To prevent premature failure that is due to excessive wear, the seal buffer gas must be well filtered.

When the application requires very low leakage, the mechanical contact seal should be considered. However, as of early 1992, no commercial seal with zero leakage is available for these compressors. With careful engineering, leakage can be either contained and retrieved or disposed, in most cases.

The flooded helical lobe compressor uses the same lobe form as its dry counterpart. The significant physical difference is that it uses the flooding fluid to time the rotors, rather than a timing gear. Rotor-to-rotor sealing is also accomplished by the flooding fluid.

This type of lobe compressor is normally smaller, and is used mostly in lower-flow applications. A benefit of flooding is the removal of the heat of compression by the flooding fluid. A disadvantage is that the same flooding fluid is used to lubricate the bearings. If the gas is not compatible with lubricating oil, then special bearings may be required to operate with a gas-compatible flooding fluid.

Because of the size of the flooded compressor, rolling-element bearings are commonly used, although hydrodynamic bearings are also quite common. Seals are of the buffered mechanical contact type, because the sealing fluid must be contained with the gas.

An advantage of the flooded helical lobe compressor is that it is a relatively simple machine. It can accommodate a moderately high pressure ratio in a single casing. Therefore, it is more compact than some of its competitors. Its major

disadvantage is due to the same feature that provides its advantage: the flooding fluid. Incompatibility with the fluid limits the possible applications. The fluid must be removed from the gas stream to prevent interference with the process. This requires complex separation equipment in some applications. Additionally, the auxiliary system to supply the lubrication and flooding fluid is quite large. In many cases, it dwarfs the compressor.

Sliding Vane

The sliding vane compressor is a positive-displacement rotary-type compressor. It consists of a slotted rotor mounted eccentrically in a cylinder that is slightly larger than the rotor. The rotor slots hold a set of vanes, which are free to move radially within the slots. Centrifugal force moves the vanes out of their slots and keeps them in contact with the cylinder wall. A cross section of this compressor is shown in Fig. 11.

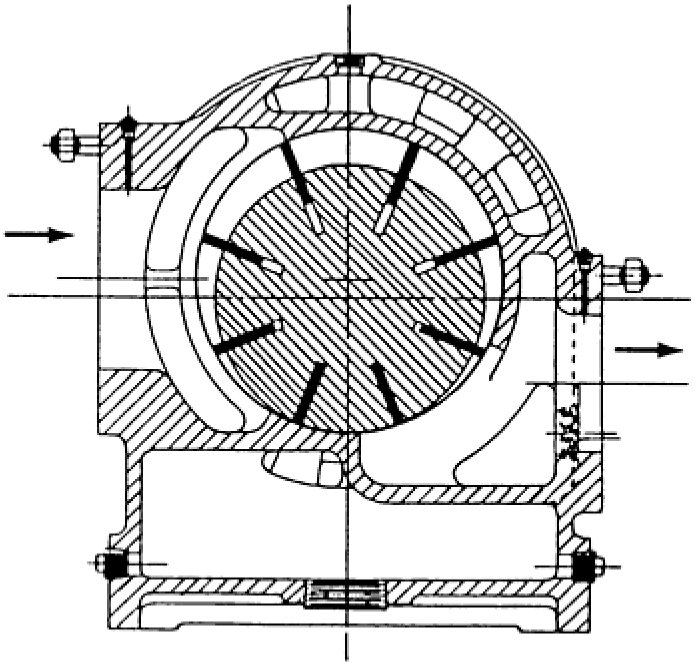

Fig. 11 Cross section of sliding vane compressor. Courtesy of AC Compressor Corporation.

The space between the rotor, set of vanes, and the cylinder forms the gas cell. The inlet is located such that the cell expands when passing the inlet port. The cell then decreases in size as the rotor continues to turn, compressing the gas. The outlet port is strategically located to be passed when the compression matches the outlet conditions. This compression process is similar to the one described for the lobe compressor.

Components. The cylinder is most commonly made of cast iron, with the bore being machined to a fine finish. The vanes are made of a laminated construction impregnated with a phenolic resin. The vanes are in continuous rubbing contact with the cylinder wall, which causes vane wear. This, of course, makes vane replacement a routine maintenance item.

To minimize the effects of vane friction and wear, most of the rotary vane compressors inject a lubricant into the cylinder. A mechanical plunger-type metering pump is commonly used, and is similar to the point lubricator described for the lubricated reciprocating compressor. Although there is much less lubricant than would be used in a flooded helical lobe compressor, it represents a disadvantage if there are gas or process compatibility problems. Its removal further compounds the problem.

Rolling-element bearings are commonly used in all but the largest of these compressors. With the plunger-per-point lubricator, a point is normally devoted to each bearing, which takes care of bearing lubrication.

Centrifugal Compressors

The centrifugal compressor normally is applied in applications where the volumetric flow is larger than that which is typical of positive-displacement compressors. Compared to the latter, the pressure ratio across a typical centrifugal compressor is less.

This compressor is different from the positive displacement type because it causes gas to be compressed by using gas dynamics. The active element of the centrifugal compressor is the impeller. All work done to the gas occurs in the impeller. The balance of the gas path components are used to convert the energy in the gas from velocity head to pressure. Other components are used to guide the gas through the compressor with minimum losses.

The impeller consists of a set of vanes enclosed in a front and back shroud, as in an enclosed design. The front shroud can be stationary, with the vanes attached to the back shroud, as in a semienclosed design. Sometimes, the vanes are simply supported, in spider form, as in an open design.

As the impeller rotates, a quantity of gas is taken up into the passage between the vanes. The shape of the impeller vanes and rotation speed move the gas along the passage, imparting energy to the gas. Some of the energy is converted into the velocity of the gas. Depending on the design, the balance of the energy conversion is to pressure. As with all compressors, a temperature rise is associated with the compression.

Types. Centrifugal compressors are available in many different configurations, the most basic of which is the overhung single-stage compressor, that is, a single impeller in an overhung configuration (Fig. 12). One method of compounding the centrifugal compressor is to use the overhung single-stage compressor with a gear. Gas passes from one stage to another on the gear frame by way of coolers between the stages. This is a common configuration for plant air, and is shown in cross section in Fig. 13. An assembled gear-mounted centrifugal compressor is depicted in Fig. 14. A form of multistaging is shown in Fig. 15. Figure 16 shows a straight-through multistage centrifugal compressor built with a horizontally split casing.

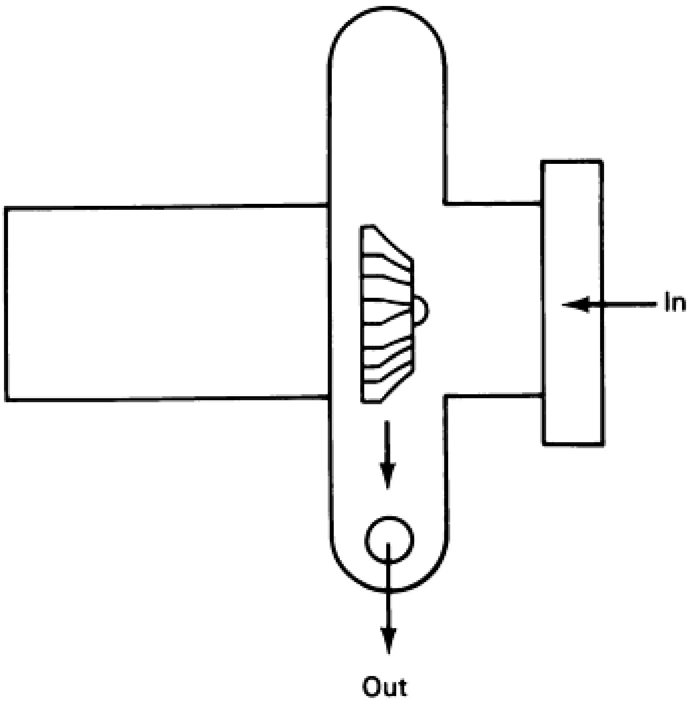

Fig. 12 Single-stage compressor

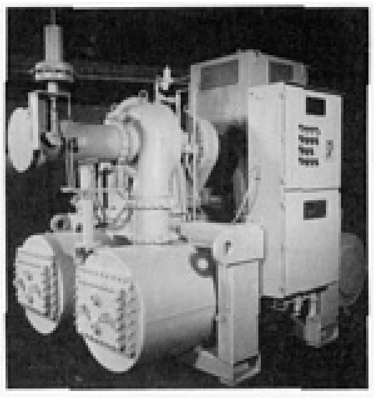

Fig. 14 Integrally geared centrifugal compressor. Courtesy of Elliott Company

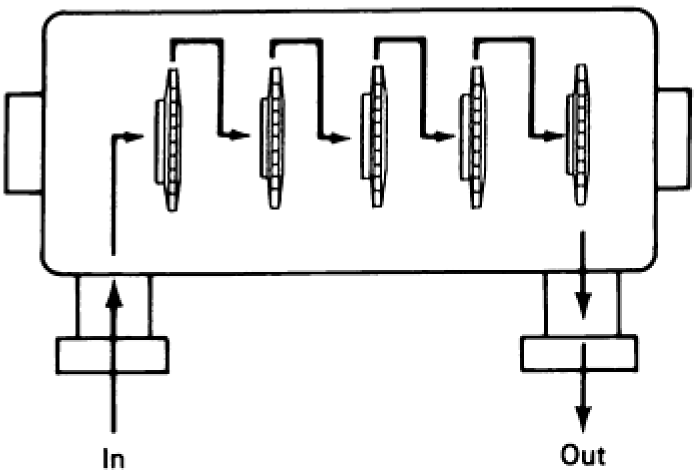

Fig. 15 Multistage centrifugal compressor with straight-through flow

Fig. 16 Horizontally split centrifugal compressor with straight-through gas path. Courtesy of Dresser-Rand

Another form of compounding is to use several impellers in series, take the gas out of the casing, cool it, and then return to the casing for more compression by a series of impellers (Fig. 17). This compounding can be repeated up to two times in one case.

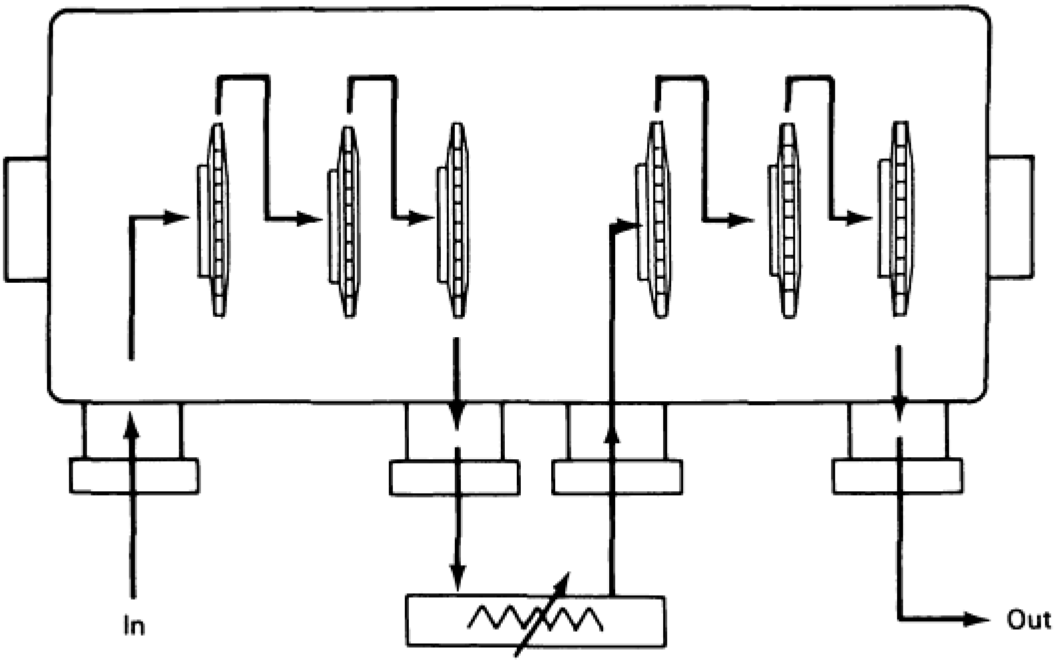

Fig. 17 In-out compound arrangement with intercooler

One common, somewhat complex configuration used in both process gas and refrigeration is the side-stream design (Fig. 18). The gas passes through one or more impellers, and is then joined by gas from an additional inlet at a compatible pressure level. This can be repeated several times. Gas can also be extracted from one of the side-stream nozzles.

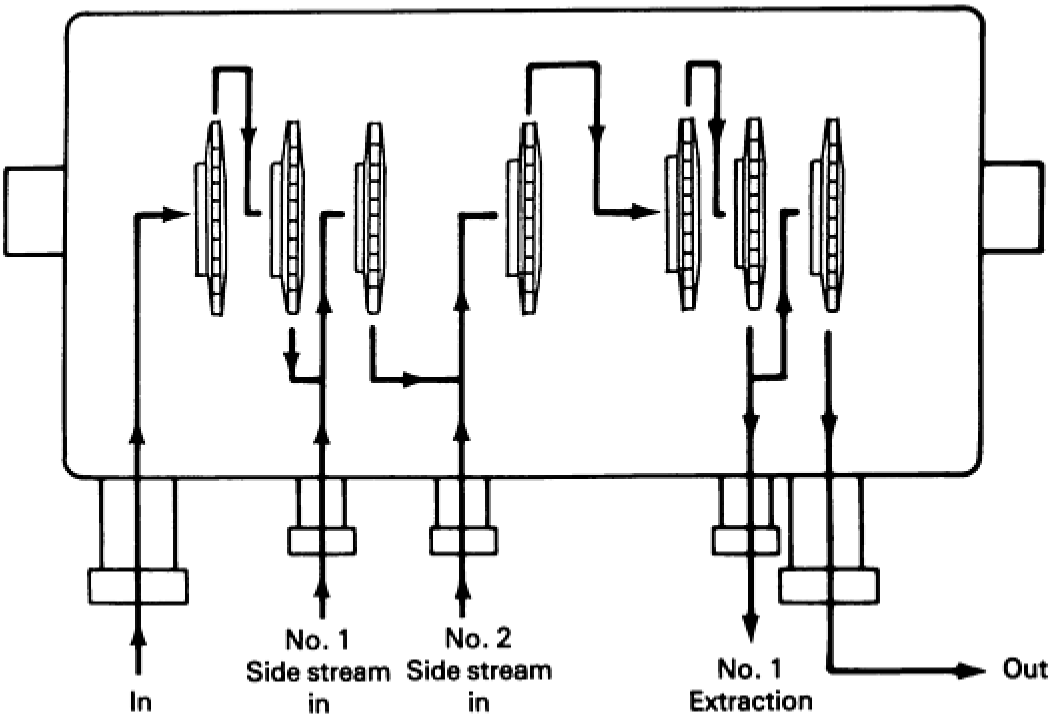

Fig. 18 Flow path through side-stream compressor

Bearings and Seals. The bearings used with a centrifugal compressor are of the oil-lubricated hydrodynamic type. Generally, the bearing designs are somewhat more sophisticated on the centrifugal compressor, because it operates at much higher speeds than the positive-displacement type. Rotor dynamics control is much more of a factor with the centrifugal compressor. Because the bearing is an integral part of the rotor support system, its dynamic characteristics must be known and controlled. The bearings can also contribute to rotor instability.

A bearing that has evolved for usage in the centrifugal compressor is the tilting pad bearing. It consists of a series of segments (pads) that are able to pivot in a manner that allows each pad to independently form an oil firm. Instabilities caused by oil whirl effects are thus eliminated. The thrust bearing is a tilting pad design that is symmetrical and carries an equal thrust load in either direction.

A new bearing design being used in commercial service is the magnetic bearing. Its advantage is that no lubrication is required, thereby eliminating a large external lubrication system. An external control cabinet for the bearing control is needed, but it is more modest in size. Because of the lowered friction that is due to magnetic levitation, the bearing losses are lower. With further development, the bearing will gain applications.

A disadvantage is that it cannot carry a unit load that is as great as a hydrodynamic bearing. This is normally not a problem for the compressor, but it is a problem for a gear or steam turbine. If a lubrication system is needed for the compressor driver, some of the advantage is lost.

Interstage seals are required on multistage (multiimpeller) configurations to minimize the leakage between one impeller and another, which has a direct impact on efficiency. It should be recalled that the labyrinth is a clearance seal that controls leakage by disrupting the flow with a series of teeth on the seal.

For air service, the labyrinth seal is also used as the shaft-end seal. A multiple labyrinth, using either injection or ejection, can be utilized with a limited number of gases.

More commonly, the gas compressors use either the carbon ring, liquid film, or the mechanical contact (buffered or dry) seal. These were described in terms of the helical lobe compressor and generally are of the same design.

Lubrication for the centrifugal compressor is provided by an external system. The lubrication system of a gas compressor in critical service is quite large. Although not as dramatic as the size difference described for the flooded helical lobe compressor, it sometimes is larger. One reason for its largeness is that the ability to maintain the lubrication system without shutting down the compressor must be allowed. Centrifugal compressors normally run for several years without shutting down. Three to five years is not unusual.

Except for the larger dry helical lobe compressors, this is not the case with positive-displacement compressors, whose lubrication systems must receive maintenance in that period. For this reason, almost all major components, pumps, coolers, and filters are normally duplicated. Space must be allocated on the skid to perform the maintenance.

Wear Considerations. Because of the nature of the centrifugal compressor, there are few, if any, true wearing parts. The bearings and seals operate with a clearance and, theoretically, do not rub. With oil-buffered seals, the improper cleanliness of the oil system will cause bearing and seal wear. With dry gas mechanical contact seals, the cleanliness of the buffer gas is a factor. Centrifugal compressors tend to foul in dirty service environments. The fouling can cause impeller vane wear. In some cases, liquid injection is used to combat the fouling. However, the cure can sometimes be worse than the malady, because the liquid can cause erosion and wear to internal parts.

This is also true in some applications where the gas is in vapor form near the saturation point. If too much liquid is allowed to form, erosion can occur. Surprisingly, the centrifugal compressor can absorb a misty liquid or a carefully controlled liquid injection very well. Labyrinth seals do tend to deteriorate with time. Although they are designed to not touch, start-up transients, process upsets, and products of fouling do cause wear.

Compressor Comparison

The reciprocating compressor and rotary compressor constitute positive-displacement types. The reciprocating compressor is the more complex machine, and is therefore more subject to problems from friction and wear. The rotary compressor is a much simpler compressor, with fewer wearing parts, but it does not have the pressure range capability of the reciprocating compressor. Applications are more limited, as well.

The centrifugal compressor is unique because it is a dynamic of compressor. Its application is in the higher-flow regime, and it can be used with a wide variety of pressures. The pressure ratio of a given compressor casing is not as high as that of the reciprocating compressor. The friction and wear characteristics are quite low, making the relative maintenance cost quite favorable.

Friction and Wear of Cutting Tools and Cutting Tool Materials

L. Alden Kendall, Department of Industrial Engineering, University of Minnesota, Duluth

Introduction

CUTTING TOOLS WEAR because normal loads on the wear surfaces are high and the cutting chips and workpiece that apply these loads are moving rapidly over the tool's wear surfaces. The cutting action and related friction at these constant surfaces increase the temperature of the tool material, which further accelerates the physical and chemical processes associated with tool wear. In order to remove the unwanted material as chips, these forces and motions are necessary; therefore, cutting tool wear is an economic penalty that must be accounted for in order to machine the part.

The magnitude of this economic penalty can be minimized if the cutting process is planned and controlled based on sound knowledge of the wear process and its dependency on the selection of cutting conditions. The cutting conditions normally controlled are the engagement of the cutting edge with the workpiece, the relative velocity of the cutting edge with the workpiece, and the feed velocity used to keep the tool engaged into uncut material. These cutting conditions are more frequently called depth of cut, cutting velocity, and feed rate. During the process planning stage, an assessment must be made concerning how difficult the material is to machine, the correct tool for the surface to be created must be selected, the appropriate tool material must be selected, and the type of cutting fluid needed must be determined. To make such choices, the wear environment in metal cutting must be understood.

The Wear Environment

Cutting tool wear occurs along the cutting edge and on adjacent surfaces. Figure 1 shows a view of the cutting process where the rake and clearance surfaces intersect to define the cutting edge. Figure 2 shows a similar view but adds the stress and strain states that are present in the material and chip. Figure 3 shows the force equilibrium and kinematic relationships that are commonly used to explain how these states of stress and strain are produced. The tool engages the material to depth t and the force vector **R** (**R** = **R**' = **R**") creates a component force, F_s, that shears the material along the shear plane area, A_s, to form a chip having thickness, t_c. The direction of the chip motion is controlled by the rake angle, α. The magnitude of the chip velocity, V_c, is a function of the cutting velocity, V, the rake angle, and the shear angle, ϕ. Relating Fig. 1 to Fig. 3, force F and the velocity V_c create the secondary shear zone, force F_s and velocity V_s acting along A_s create the primary shear zone, and force F_c and velocity V create the tertiary shear zone. These are idealized average forces and velocities. Cutting tools wear is localized on specific surfaces where stress, strain, velocity, and temperature are above critical levels. It is important to understand where these critical conditions exist and how they interact to cause tool wear.

Wear Surfaces

Figure 4 shows how the sharp tool of Fig. 1 may wear due to the velocities and forces shown in Fig. 3. Along the rake surface, the chip motion, V_c, and high normal stress due to force *N* have produced a wear scar called crater wear. Along the clearance surface, the tool motion, *V,* and high normal stress due to force F_t have increased the area of contact between the tool and work, producing flank wear. Cutting edge wear has increased the radius and is caused by the combined effect of these component forces localized to the cutting edge region and represented by force vector **R** in Fig. 3. Figure 5 shows these characteristic wear surfaces on a turning tool insert, end mill, form tool, and drill. The cutting edge view shown in Fig. 1 and 4 is identified as section A-A in Fig. 5.

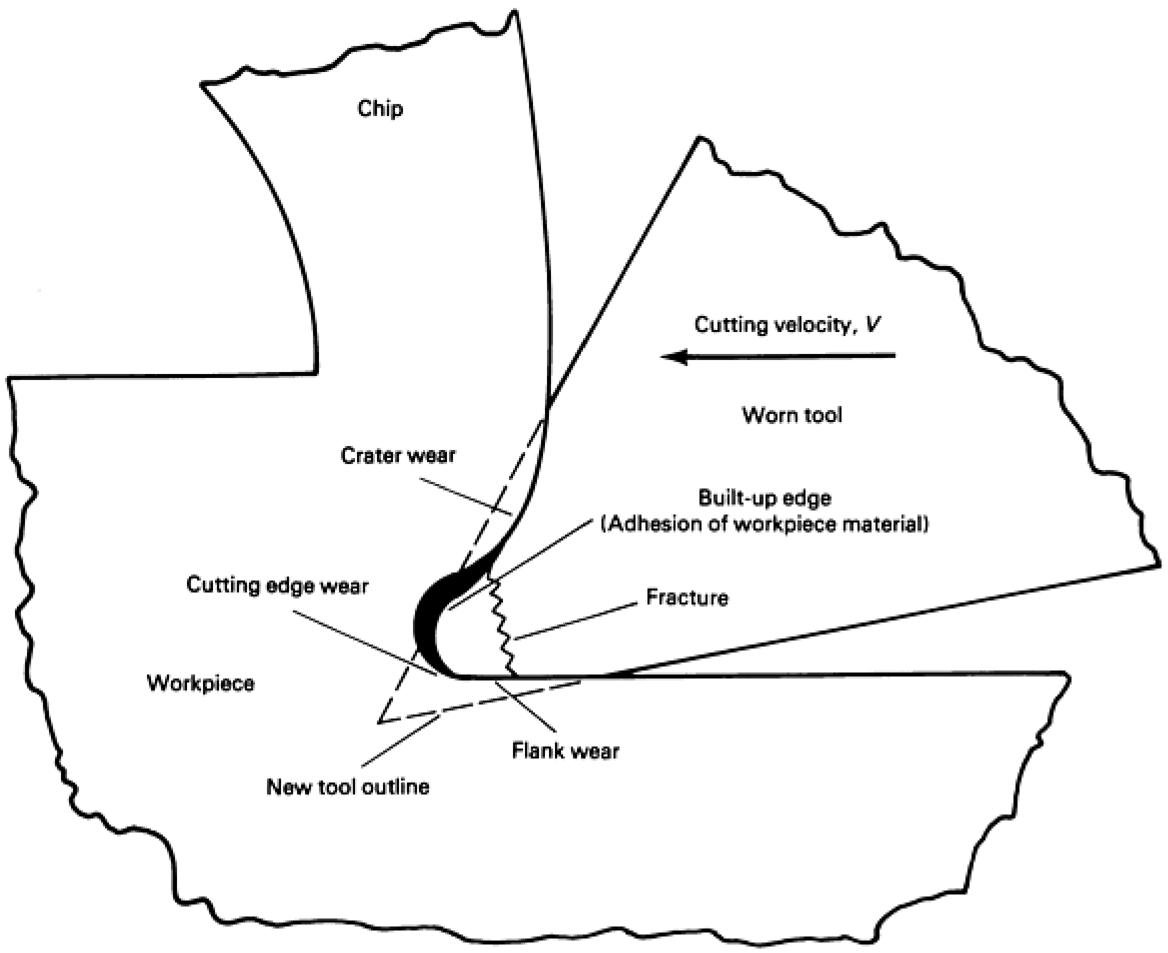

Fig. 4 Typical wear surfaces

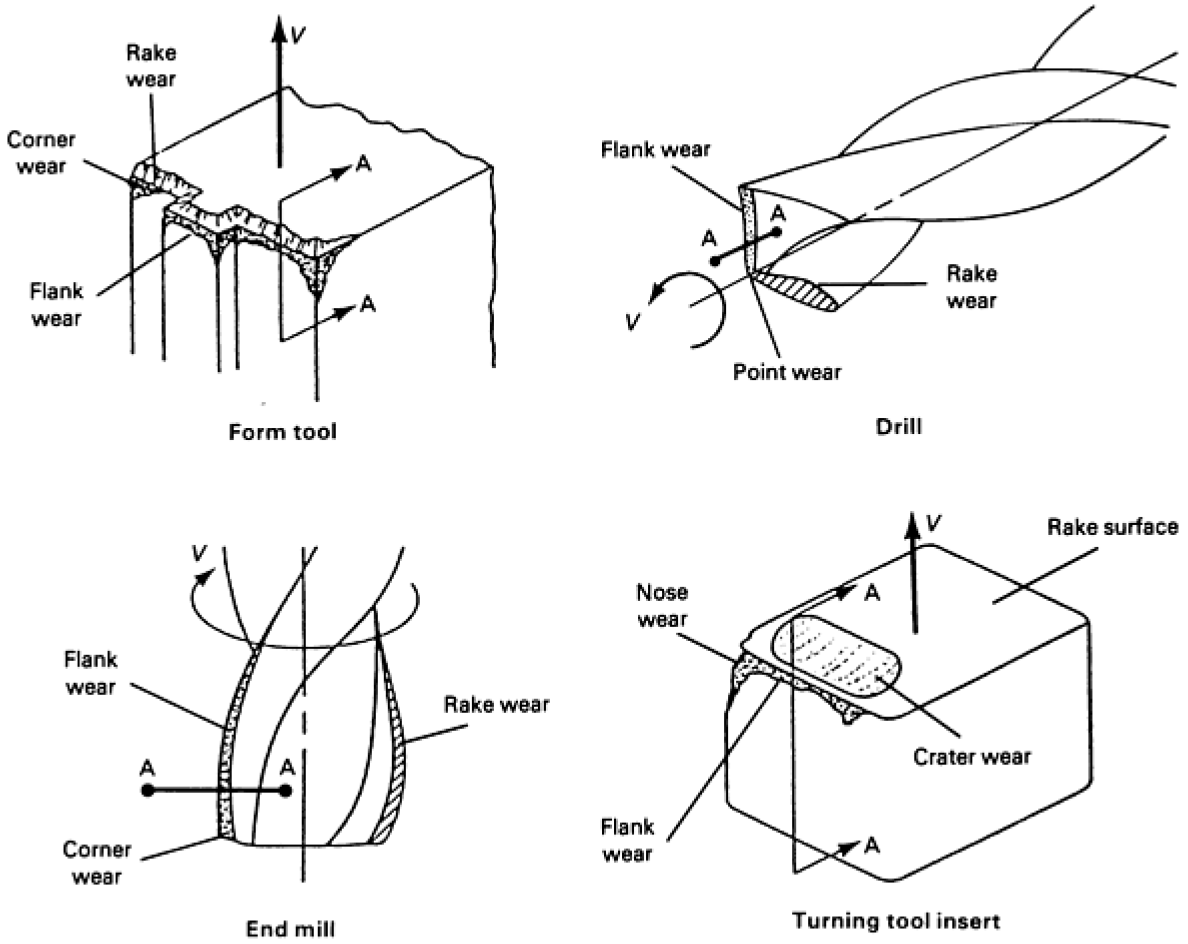

Fig. 5 Wear surfaces on common tools due to the tool motion, *V*

These figures show schematically how the wear process has changed the geometry of these different types of cutting tools. Flank wear decreases the diameter of the end mill and decreases the depth of cut for a lathe tool. Both of these changes in the geometry of the cutting tool could produce out-of-tolerance dimensions on machined parts. The edge wear and crater wear on the rake surface alter the state of stress and strain in the cutting region, thus changing cutting forces and the mechanics associated with the chip-making process. Severe geometric changes due to crater and flank wear can weaken the tool so that the edge may suddenly fracture as illustrated in Fig. 4.

It should be apparent that the location and size of these wear surfaces play an important role in determining the useful life of the cutting tool. Localized stresses on cutting tool surfaces are a major influence on the location and size of wear surfaces.

Stresses on Tool Wear Surfaces. Figure 6 shows the approximate distribution of normal and shear stresses on the tool's wear surfaces. The normal stresses, σ_n, are caused by the normal forces acting along the rake surface, the cutting edge surface, and the clearance surface. In addition to the normal stresses, Fig. 6 shows the shear stresses, τ, that act along the surface of the tool and that are associated with sticking and sliding shear processes. For the sticky zone, the normal force has a magnitude that results in a shear stress component which equals the shear yield strength, τ_y, of the strain-hardened work-piece material. Rather than sliding along the surface, the chip tends to adhere and periodically separate along shear fracture planes within the material, leaving adhered material on the tool or within the tool, which subsequently causes tool wear. The existence and size of this sticky zone are dependent upon the magnitude of the normal force and the frictional conditions along these surfaces. A sizable amount of this material may adhere for extended periods of time. Stable masses of such adhered material are known as built-up edge, and, as shown in Fig. 4, they alter the geometry of the cutting edge.

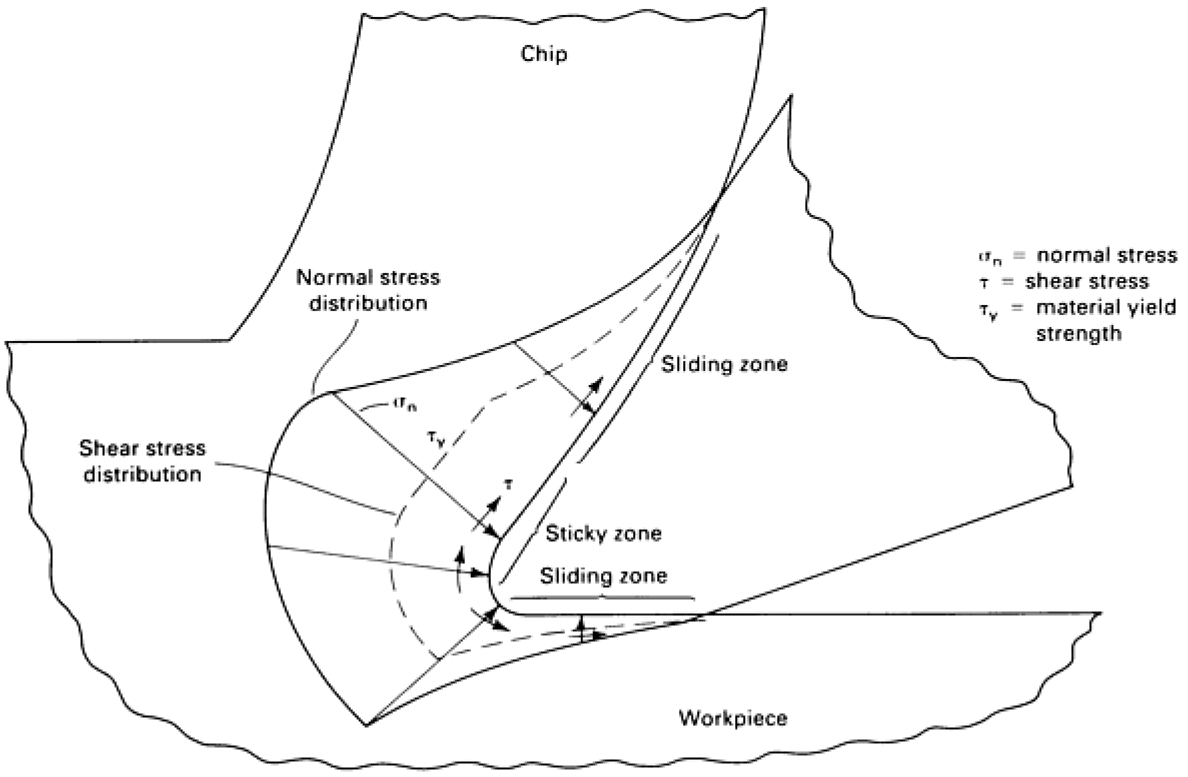

Fig. 6 Wear surface stresses

The sliding zones have friction forces and associated surface shear stresses that vary according to the normal force and coefficient of friction. Tool surface roughness and lubrication conditions affect the magnitude of these surface shear stresses. The state of stress created by the shear loads in the sticky and sliding zones along the rake surface produce the secondary shear zone shown in Fig. 1.

The primary shear zone in Fig. 1 extends from the cutting edge to the work surface; it is the zone where the work material is plastically deformed and sheared to form the chip. The complex state of stress along the cutting edge is caused by the strain associated with the chip separating from the work and moving along the rake surface of the tool and the strained material that remains a part of the work material. This conflict between chip motion strain and stationary workpiece strain produces a plowing action by the cutting edge.

Normal stresses can become very high and exceed the strength of the tool material, causing plastic deformation or fracture of the cutting edge. A sticky zone may not exist for certain cutting conditions; however, the plowing action along the cutting edge will always exist to some degree because it is impossible to create a cutting edge with no radius and a primary shear zone that is a perfect plane. The magnitude of the state of stress in the cutting region also varies with time, and the associated load variations may create a fatigue failure environment for the tool.

Motion along the Wear Surfaces. One way to increase machining productivity is to increase the volumetric chip removal rate, which is a function of the engagement area of the tool with the work material and the velocity at which the tool moves through uncut material. Therefore, one option the process planner has is to increase the cutting velocity. This productivity gain must be balanced against increased tool wear caused by higher cutting velocities.

Figure 3 shows that the chip velocity, V_c, and the shear velocity, V_s, are functionally related to the primary shear angle, ϕ, the rake angle, α, and the cutting velocity, V. The cutting velocity is the relative velocity between the clearance surface and the work, whereas the chip velocity is the relative velocity between the chip and the rake surface of the tool. The magnitude of these two velocities and the related shear stresses at these interfaces determines the amount of thermal energy released per unit of contact area. The velocity within the material adjacent to these two surfaces and the velocity, V_s, in the primary shear zone cause high local strain rates, and the volume of material strained by these stain rates releases additional thermal energy. These thermal energy releases cause the temperature of the workpiece, cutting tool, and chip to

increase. The productivity gain from increasing the cutting velocity proportionately increases wear surface velocities, strain rates, and the release of thermal energy, thus increasing the wear environment temperature.

Temperatures in the Wear Zone

The difference between the thermal-energy release rate and the thermal-energy dissipation rate determines the temperature of the material and tool in these wear zones. Thermal-energy dissipation is a function of the thermal conductivity properties of the tool material and workpiece material. The chip carries some of this thermal energy away from the tool and work material. Additionally, the workpiece size and specific heat determine the workpiece heat capacity, and, to a lesser extent, the surface area plays a role in convective and radiative heat transfer to the surrounding air. In a cutting fluid is used, the rate at which it removes thermal energy from the hot tool and workpiece plays an important role.

Tool materials are developed and selected based on their ability to maintain their hardness, toughness, and chemical stability at high temperatures. Even with the best of tools, such material properties eventually adversely change with increasing temperatures. There have been many studies of temperatures in the cutting tool. Most commonly, average temperature conditions are approximated using the following type of relationship (Ref 2):

$$T = u\left(\frac{Vt}{k\rho c}\right)$$

where *T* is the mean temperature of the tool-chip interface, *u* is the specific cutting energy (which is the energy used per unit volume of material removed), *V* is the cutting speed, *t* is the undeformed chip thickness (see Fig. 1), and *k*, ρ, and *c* are the conductivity, density, and specific heat, respectively, of the workpiece material.

Figure 7 shows a typical temperature distribution. The high-temperature gradient can cause portions of the tool to be at dangerously high-temperature levels, well above the mean predicted temperature. The mean temperature relationship given above does identify the important variables and how they affect temperature. High-strength work materials have high values of specific cutting energy. Some of these high-strength materials, such as titanium, are also poor conductors and are of low density. This combination of conditions results in higher tool temperatures, and the cutting tool material used must maintain its hardness and strength at these temperature levels if it is to have a useful service life. Combining these temperature effects with the state of stress, strain rates, and material motion makes the wear zones of the tool a complex battleground in which these conditions interact to trigger the mechanisms that cause wear.

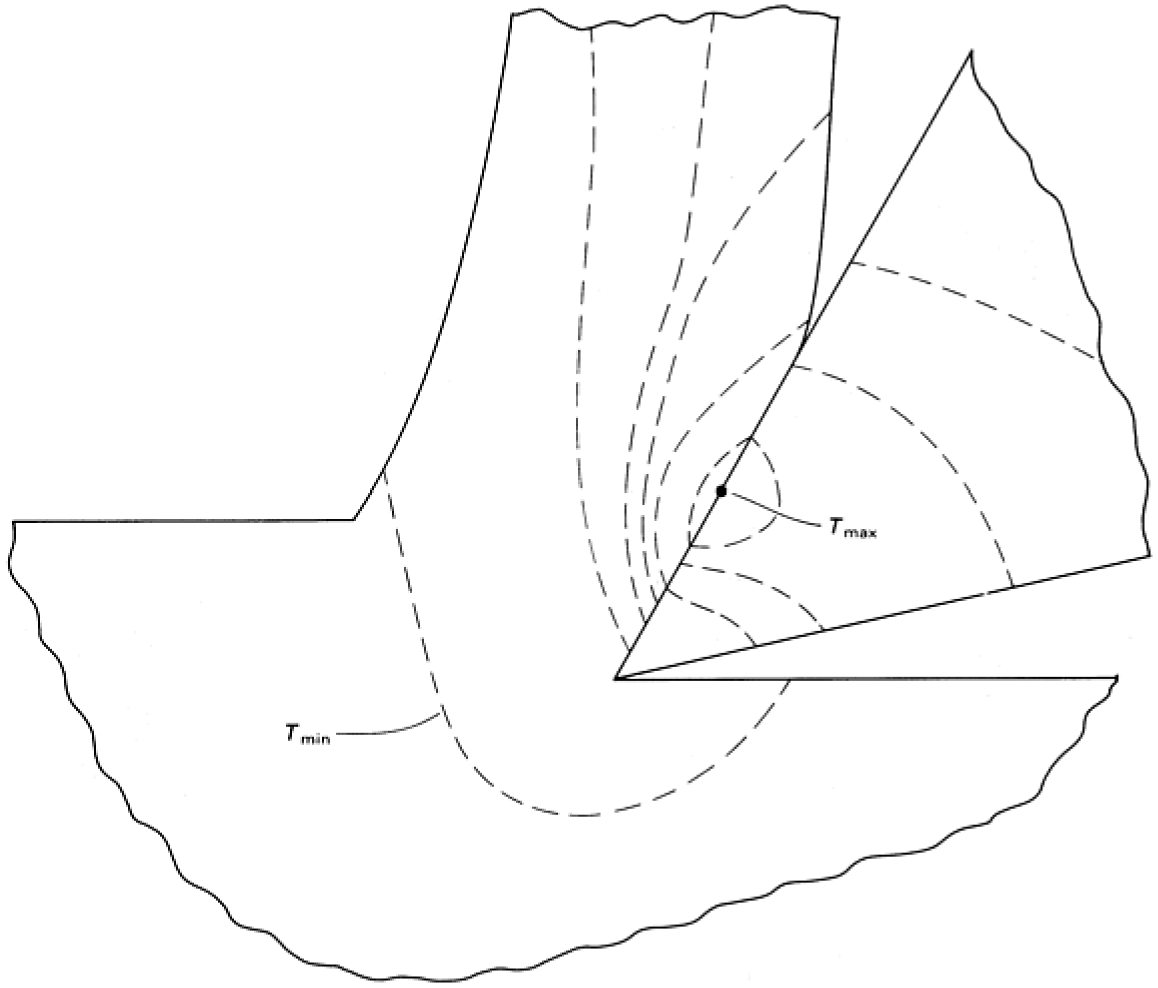

Fig. 7 Generalized temperature distributions in the cutting region

Wear Mechanisms

One important area of concern in wear studies has been the identification of wear mechanisms. What has emerged is that a particular wear mechanism is dependent upon the contact stress, relative velocities at the wear interface, temperature, and physical and chemical properties of the contacting materials. For a particular set of contacting materials, wear mechanism maps have been used to identify the ranges of normal pressure and velocity that result in a particular wear mechanism (Ref 3). Figure 8 shows the general structure of such a map when the area of the contacting wear surface remains constant. Temperature is not a mapped variable, however, it is a variable that depends upon the pressure (normal stress), velocity, and size of the wear surface as discussed in the previous section of this article. The four broad classes of mechanisms shown in Fig. 8 are:

- Seizure
- Melt wear
- Oxidation/diffusion-dominated wear
- Plasticity-dominated wear

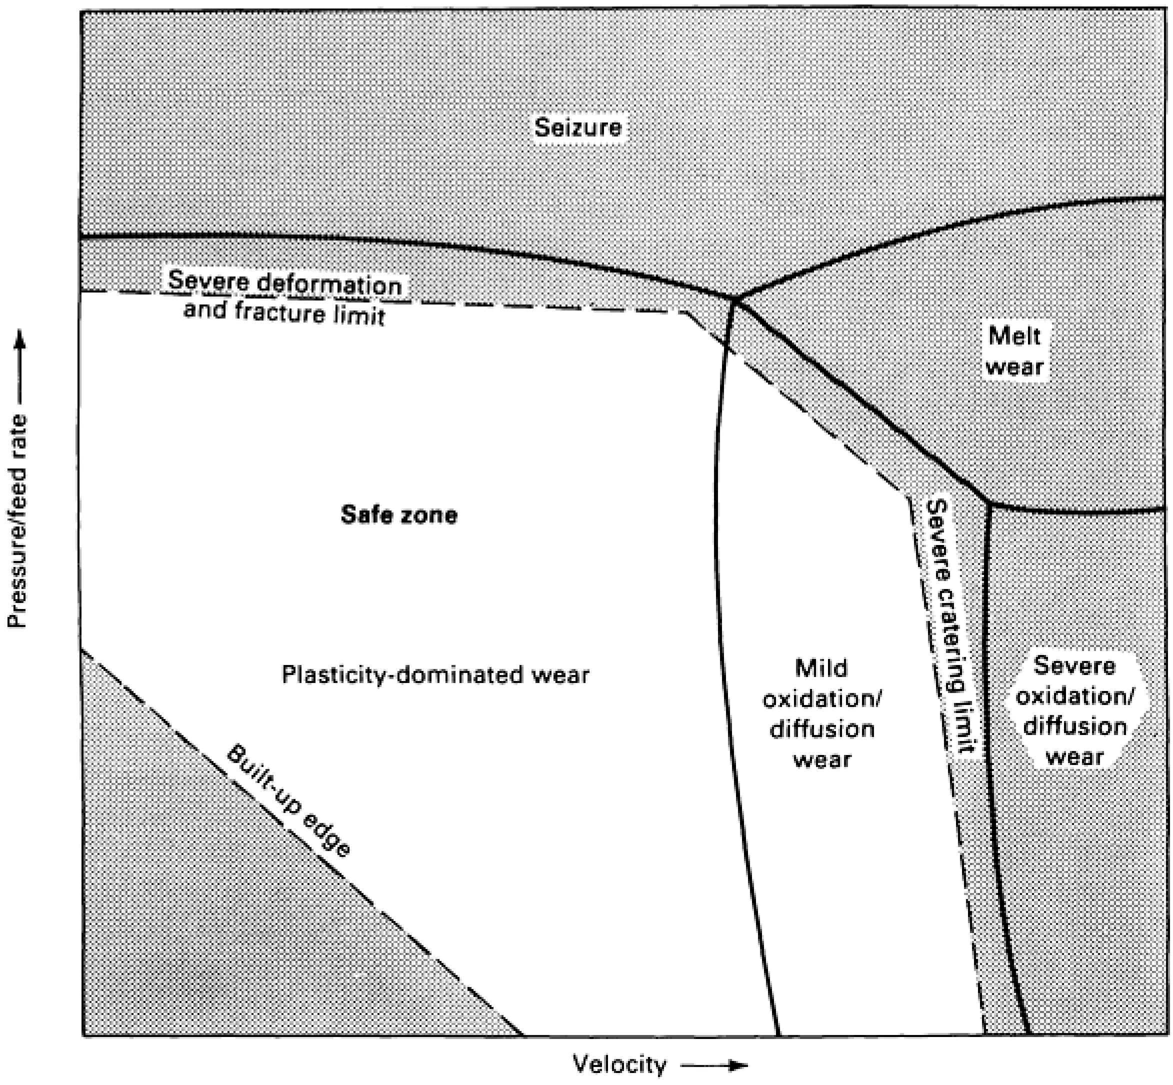

Fig. 8 Wear mechanism maps and safe operating regions for cutting tools. Source: Ref 3

Cutting tool wear research has established similar maps for feed rate, which is related to pressure for a given engagement condition, and velocity (Ref 4). The dashed lines in Fig. 8 show some possible boundaries that could be used to define a safe operating zone. These boundaries provide a framework for discussing the progressive wear and failure conditions for cutting tools.

Initial Wear Mechanisms. The two materials in contact have surface roughness irregularities in the form of protrusions or asperities. At the interface, asperities from the two materials touch, defining tiny contact areas. The total area from these contact points is a fraction of the projected area of the contact surface. The stresses and heat are intensified in the asperities, and partial removal may occur due to seizure accompanied by fracture of the asperity or melting in the asperity. As these asperities are removed, the initial surface roughness is altered and the contact area increases. If the force conditions remain unchanged, pressure decreases and the active wear mechanisms change to plasticity and/or mild oxidation/diffusion-dominated wear. This initial wear period will create small, visible wear surfaces.

Steady-State Wear Mechanisms. A velocity and normal stress condition that would continue to cause seizure and melt should be avoided because it would soon cause complete failure of the cutting tool. Assuming that such conditions do not exist, the wear surfaces will get progressively larger. If plasticity dominated, small particles of material are mechanically deformed and fractured away from the wear surface. This is generally called abrasion and can occur on any of the wear surfaces; it is the most common wear process along the clearance or flank surfaces of most tools. As discussed

earlier, normal stress and temperature vary over the wear surfaces so that a plasticity mechanism that dominates in one wear zone may not dominate in another.

Figure 7 indicates that the maximum tool surface temperature occurs on the rake surface a small distance from the cutting edge when cutting most materials. This is where the crater wear condition occurs; diffusion wear is often the dominant mechanism (Ref 5). The high temperature and pressure cause atoms to move between the contacting materials, and this diffusion process locally aids in the removal of material to form the crater. In very hard cutting tool materials, such as ceramics, where high cutting velocities are commonly used, these oxidation and diffusion mechanisms may be responsible for a majority of the wear.

The dashed line in the lower left-hand corner of Fig. 8 that identifies a built-up edge (BUE) condition affects the process in two ways. Near the cutting edge, the higher pressures could cause particles of work material to adhere to the cutting tool in the sticky zone. If the shear forces due to chip movement are high enough, the bond will be temporary and the adhered material will fracture away from the tool surface. When it fractures, small particles of tool material may be removed with the previously adhered material. This then is a wear process and would be associated with conditions in the safe zone just outside the BUE line. The second effect on the process occurs when the BUE is not fractured away by the chip motion and remains to alter the geometry of the cutting edge. The presence of the BUE changes the shear angle, causing instabilities in the chip-forming process plus damage to the machined surface. The lubricating characteristics of cutting fluids are helpful in eliminating this BUE condition. For rough cuts, the presence of a stable BUE can be beneficial in that it provides an intermediate protective layer between the tool surface and the work material.

Wear can also occur as chipping along the cutting edge. Such chipping more commonly occurs when the cutting edge intermittently removes chips. This results in cyclic impact and thermal loading to the cutting edge. These two cyclic loading states can initiate small cracks and then cause these cracks or other residual cracks to propagate, leading to tool chipping.

These abrasion, oxidation, diffusion, and chipping wear mechanisms that occur at operating conditions within the safe zone shown in Fig. 8 cause the initial wear surfaces to gradually enlarge over time. This surface life period is often referred to as the steady-state wear period.

Tertiary Wear Mechanisms. The steady-state period of wear will eventually enlarge the wear surfaces to a critical size that will trigger accelerated wear. The pressures and velocities on these enlarged surfaces begin increasing the temperature such that the rapid oxidation/diffusion and local seizure or melting conditions cause rapid destruction of the tool. In tools that have a hard, wear-resistant coating such as titanium nitride, wear through this coating or separation of small volumes of the coating from the base material will expose the less-resistant core material to these same rapid wear conditions. A tool change must be made before this point is reached. Figure 9 shows these three zones in terms of the amount of wear over time.

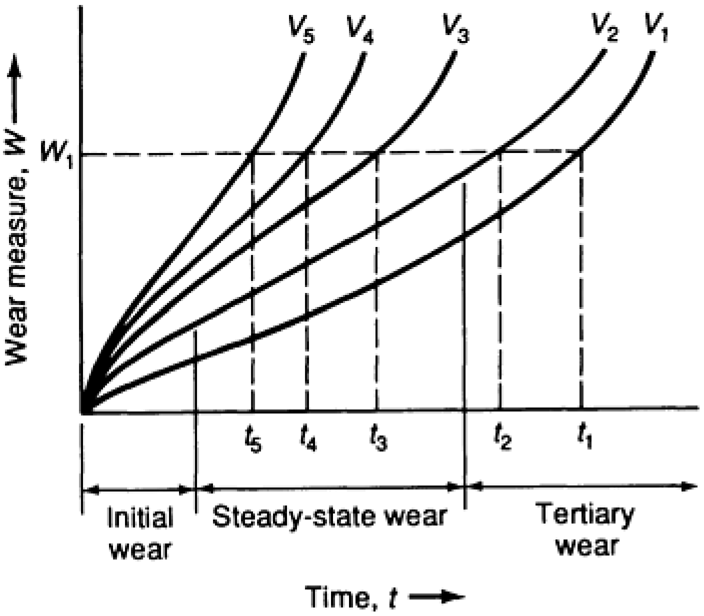

Fig. 9 Tool wear curves for different cutting velocities

To further complicate the understanding of cutting tool wear mechanisms, there is a growing trend toward high-speed machining. This means using cutting velocities 5 to 10 times the normal speed. New tool materials and machine tool designs have made this possible; however, these changes after the wear environment. Proportionally more thermal energy is removed with the chip due to the decrease in contact time between the tool and the chip; however, the higher velocities will increase absolute temperatures on the tool wear surfaces. Under such conditions, abrasive wear may become less important and the diffusion and oxidation processes could dominate in creating and enlarging the wear surfaces.

Machine, Cutting Tool, and Tool Wear Interactions

The cutting tool is only one element of the machining system. This is a complex system consisting of the workpiece, the workpiece holding fixture, the tool holder, the machine tool, and the cutting fluid system. Also, more complex cutting tool geometries are now available that control chip motion or chip breakage such that the process is more productive and the wear rate of tools reduced. When configuring a machining system, the selection process starts by obtaining knowledge about the type and quality of the surfaces to be machined. These surfaces, as well as the material to be machined, are specified as inputs to this configuration process. The geometry of these surfaces will determine the types of cutters that are needed.

The selection of the machine tool depends upon the sequence of surface types that will be used, the quality of each of these surfaces, and machine capacity needed for each of these surfaces. Machine capacity refers to the largest part dimensions, the cutting parameters, maximum power requirements, and the force loads generated by the cutting processes. To determine this machine capacity, tool materials and cutting fluid conditions must be established.

To simplify the discussion, consider a situation where a single type of surface is being machined to a given quality level (that is, tolerance and surface finish). The selection of the machine tool, the type of cutting tool, the type of cutting tool material, the cutting fluid conditions to be used, the feed rate, the cutting velocity, and the depth of cut defines one operating state for the machine system. This state will establish the wear environment at the cutting edges of the tool. How rapidly this wear environment degrades the tool will determine how frequently the tool will have to be changed. A tool change interrupts the machining process, which subsequently decreases the production rate and adds a cost that is associated with the interruption, the tool change expense, and the replacement tool cost. Trying to reduce this cost by lengthening the interval between tool changes will eventually cause the cost to rise again. This rise occurs when the wear process has progressed to induce tertiary wear mechanisms and accelerated wear of the cutting edge. This accelerated wear damages the surface, necessitating repair expense or the costs associated with a scrapped part. Even if the tool-changing interval keeps the wear process within the steady-state wear zone, there is a finite probability that the tool may

fail unexpectedly before a scheduled replacement and cause damage that requires repair or scrapping of the part. How probable such an event is depends upon workpiece material characteristics, the nature of the cutting loads on the tool, and the quality of the cutting tool. Note that without changing the state of the machine system, a fairly complex sequence of decisions has to be made to establish a tool-change strategy. For each new state of the machining system that is examined, a new tool change strategy will result. This search process for the best operating state is not an objective of this article; Ref 6, 7, 8, 9, and 10 describe the methodologies associated with establishing an interactive machining system. The remaining sections of this article focus on the following important factors involved in mitigating cutting tool wear:

- The basic guidelines for selecting tool materials
- Testing of cutting tools to provide information to guide the selection process
- Selecting cutting fluids

Cutting Tool Material Selection Guidelines

Tool materials need to be wear resistant, tough, and have a characteristic referred to as hot hardness. Wear resistance is the ability of the material to have a useful life when subjected to the types of wear mechanisms discussed earlier. Because the type of active wear mechanism varies with the wear environment, tool manufacturers have a broad spectrum of materials available that are wear resistant when used for different cutting conditions (Ref 11, 12, 13). The common tool material categories are high-speed steels (HSS), cast cobalt alloys, micrograin (powder metallurgy) high-speed steels, and various grades of carbides, ceramics, polycrystalline diamond (PCD), or cubic boron nitride (CBN). Some of these materials are further coated with harder material such as TiN, TiC, or Al_2O_3.

Toughness is needed so that the cutting edge will not chip or fracture, particularly when subjected to impact loads. Tough materials can absorb energy and resist plastic deformation without fracturing. As a general rule, increasing hardness decreases toughness. Figure 10 compares these classes of tool materials for toughness and wear resistance.

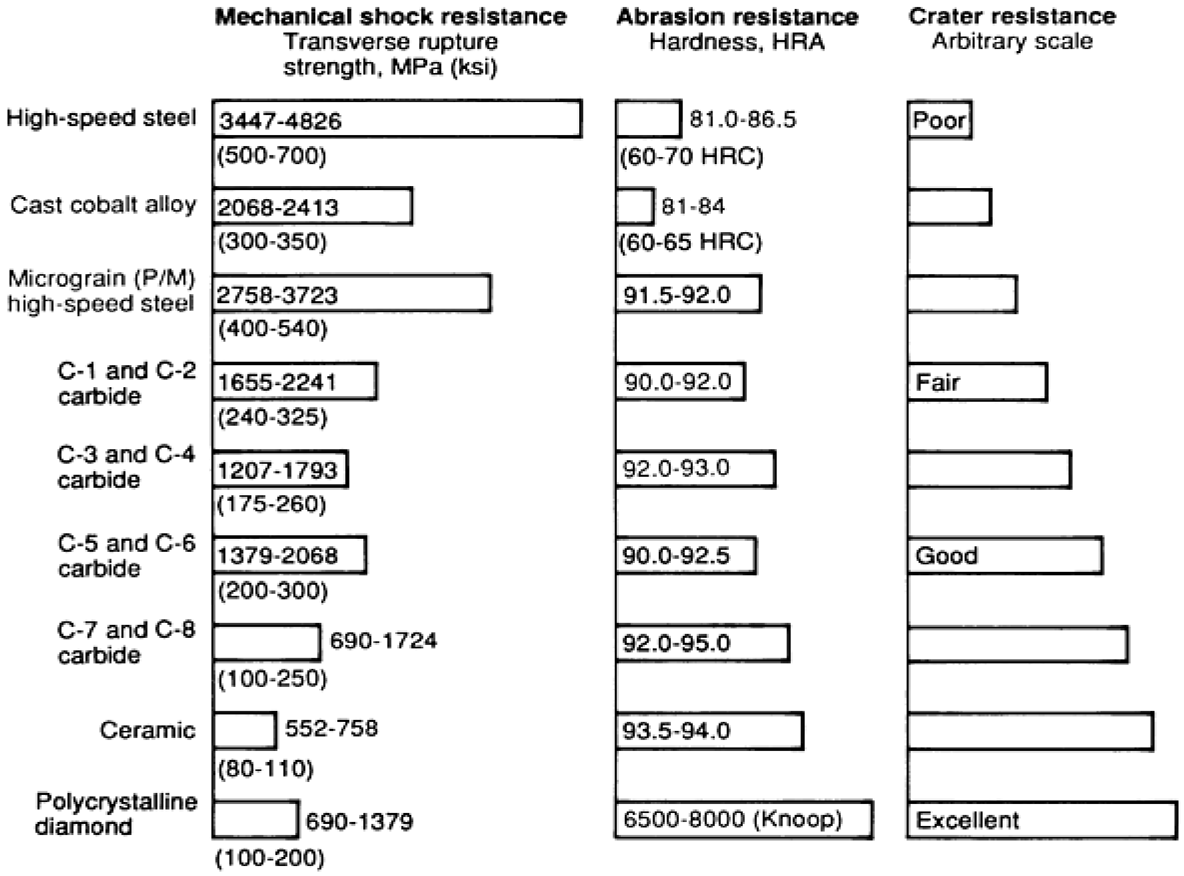

Fig. 10 Toughness and wear resistance of various classes of cutting tool materials. Source: Ref 13

Hot hardness is the ability of the material to maintain hardness at elevated temperatures. Recovery hardness is the ability of the material to regain hardness at room temperature after being subjected to an elevated temperature. Figure 11 compares hot and recovery hardness for various classes of tool materials.

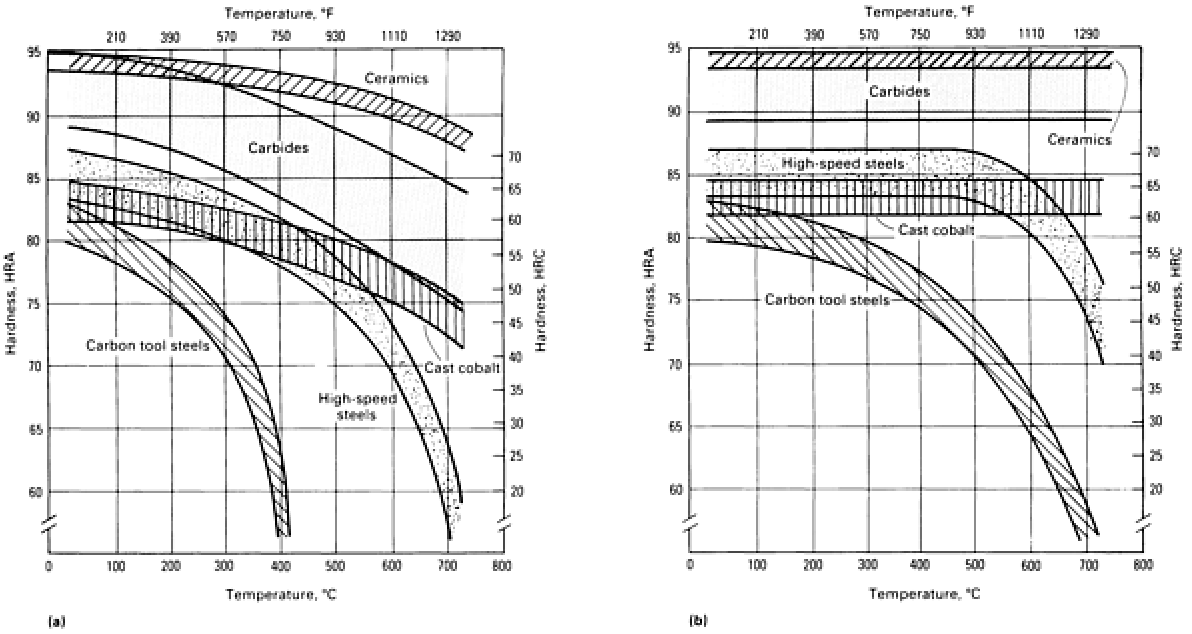

Fig. 11 Hot hardness (a) and recovery hardness (b) for cutting tool materials. Source: Ref 13

To select the correct cutting tool material, the process planner may need to depend upon the expertise of the tool supplier or the work material supplier, on experience, or on the results of cutting tests. The recommendations of tool and material vendors tempered by information gained through experience is the least costly way to make the selection. If the quantity of certain types of cutting tools used is large, the expense of a cutting tool evaluation program can be justified.

As already emphasized, the selection of the tool material is dependent on the type and quality of the surface being machined. A general rule connected with this selection is that a finish cut will have a small depth of cut but a large cutting velocity. The small depth of cut reduces the tool loads, whereas the high velocity may create a harsh wear environment. In this instance, toughness requirements are reduced and wear resistance plus hot hardness requirements increase. If the surface is a rough machined surface, large depths of cut and lower cutting velocities are used. This combination of conditions requires a tool material that is tough but that may not need the high level of wear resistance required for higher-velocity cutting conditions. Cutting tool manufacturers have developed elaborate systems to more specifically classify their cutting tool materials; however, their systems are often based on some logical trade-off between wear resistance and toughness for different levels of tool loading caused by different cutting edge engagements, feed rates, and cutting speeds. Figure 12 relates these trade-offs to tool failure mechanisms. Knowing that this sort of trade-off is being made makes it possible to better evaluate vendor recommendations.

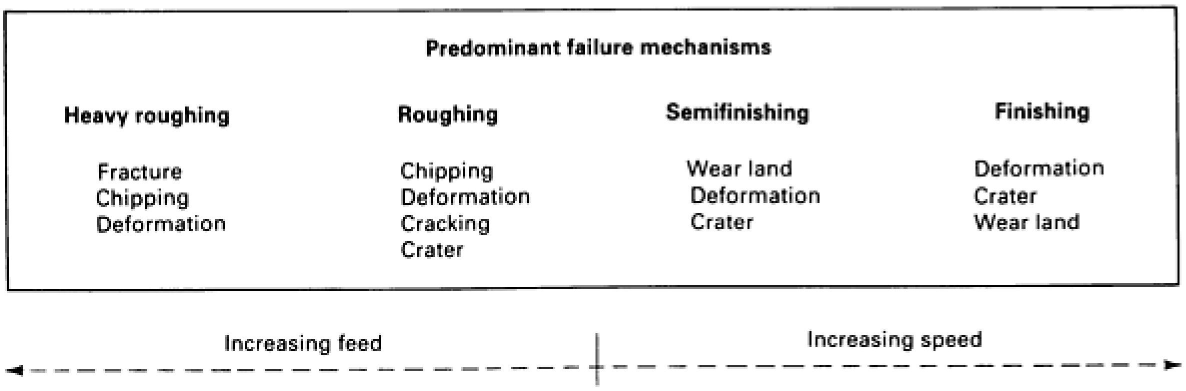

Fig. 12 Failure mechanisms as a function of engagement, feed rate, and cutting speed

When selecting a cutting tool material, a recommended cutting speed range is established. The type of wear mechanism that will likely exist is determined by the cutting speed and the type of material being machined using a particular cutting tool material. This relationship between work material and cutting tool material is discussed later; however, Fig. 13 summarizes some of these relationships. Some general guidelines for selection of cutting tool materials based on the type of machining operation are provided in Table 1. Again, the dependence upon work material is included.

Table 1 Cutting tool material selection based on machining operation and work material

Machining operation	Work material	Applicable tool material						
		High-speed steel	**Carbide**	**Cast alloy**	**Coated carbide**	**Ceramic/ cermet**	**Cubic boron nitride**	**Diamond compacts**

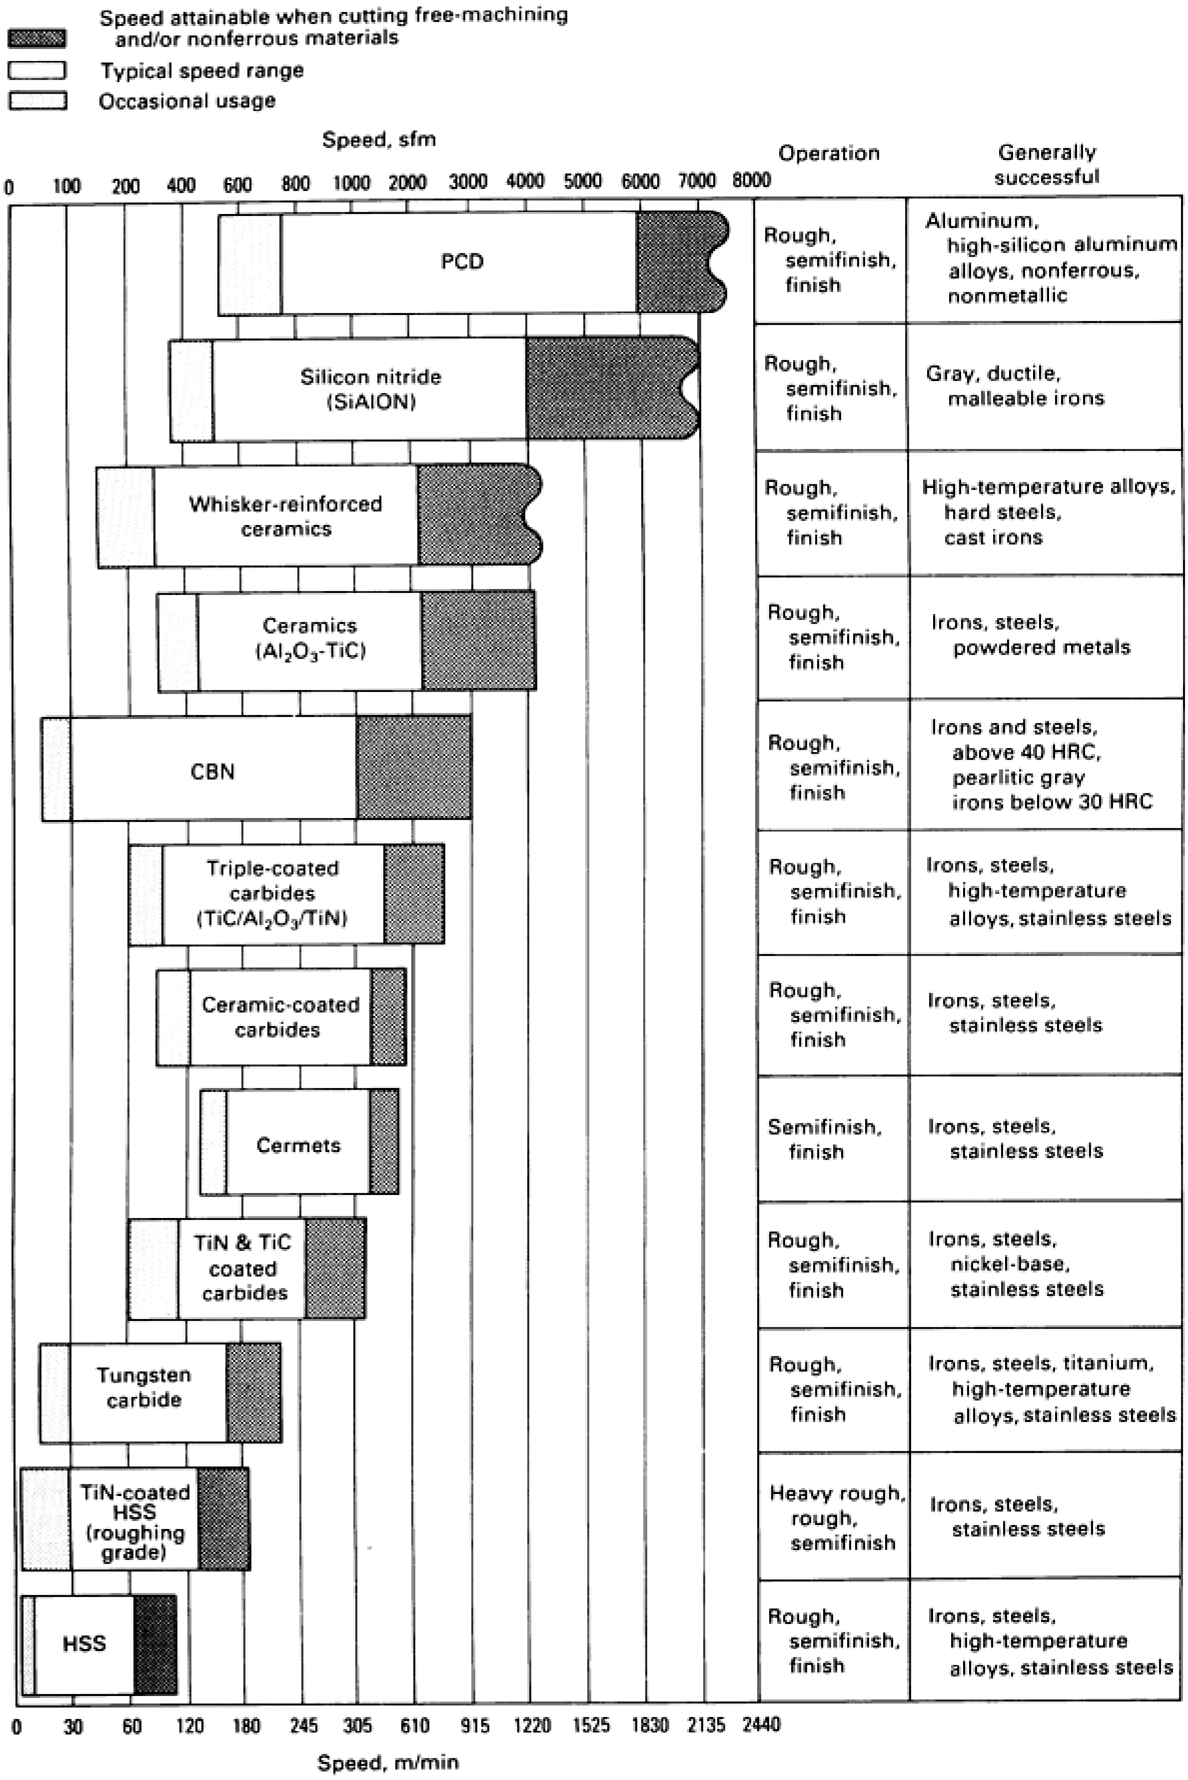

Fig. 13 Relationship between classes of cutting tool materials, cutting speed, and work material. Source: Ref 13

The type of cutting tool and machine tool influence what type of cutting tool material can be used. The versatility needed from the tool and the complexity of the geometry of the tool are such determining factors. An older machine tool with lower speed and power may not have the capability and rigidity to effectively use tools with a higher cutting speed capability. In order to provide some guidance, the following sections describe typical applications for the various types of cutting tool materials. More detailed information on the processing, properties, and applications of these materials can be found in the Selected References supplied at the end of this article.

High-Speed Steel (HSS). In the past, a majority of the machining operations used tools made from this material. The need for higher production rates, however, is resulting in more tool products using more wear-resistant materials. Reamers, taps, thread chasers, gear cutters, saws, and complex form tools use HSS exclusively. Milling cutters and drills are frequently made from this material. High-speed steel is also still used for a wide variety of turning tools because it is inexpensive and performs well when machining at moderate cutting velocities on many of the more machinable materials. It is the easiest material to grind to the desired geometry and has good impact strength compared to the other harder cutting tool material alternatives. This makes HSS very good for tools used for interrupted-cut, low cutting velocity machining operations on difficult-to-machine materials such as heat-treated steel, titanium alloys, and high-temperature materials.

High-speed steel comes in a range of grades that provide various combinations of wear resistance, hot hardness, and toughness. High-speed steel tools can also be coated with hard carbides or nitrides to provide tools with higher wear resistance that still maintain the toughness of the HSS core material.

Cast Cobalt Alloys. Tools cast from cobalt-chromium-tungsten alloys have high hot hardness, are reasonably tough, and have good wear resistance. This material is often a good choice for machining conditions between the conditions generally used for HSS and those used for tungsten carbide. It is also a good material for tooling used in a multiple-tool setup in which the variety of cutting conditions used for the machining operations require that the tool perform well at low and high cutting speeds as well as in a variety of tool-loading states. Typical applications for cast cobalt alloys include solid tools cast to shape, cutting blanks that are brazed to the tool, and cast inserts that are mechanically fastened to a tool holder. Turning tools, drills, mills, and cut-off tools can all use these blanks and inserts for cutting edges.

Micrograin high-speed steels are made using powder metallurgy (P/M) processing techniques. The atomized powder is extremely fine and of uniform composition; no binders are used. Either hot isostatic pressing (HIPing) or vacuum sintering can be used to produce a dense and uniform product. The material can be further heat treated in the same manner as wrought HSS. The microstructural uniformity (carbide distribution) of P/M tool steels and the absence of metallurgical defects make the material tough, and the HIPed or sintered shapes retain their dimensions when heat treated to the desired hardness level. Increasing alloy content to improve wear resistance is possible without severely affecting toughness. Almost all types of tools are made from this material; thus, P/M tool steels should be seriously considered if the machining benefits justify the increased cost over a competing material.

Cemented Carbides. A variety of carbide materials are available in fine powder form and can be produced using P/M processing into a coherent, hard material using binders such as cobalt. The variations and grades that are now commercially available are too numerous to discuss in detail (Ref 13, 14). The development of coated carbides has led to an increased range of applications. The type of powder, binder, and powder particle size determine the final properties. Cemented carbide cutting tool suppliers provide a broad range of grades, from those suitable for finished surfaces using high cutting speeds and small depths of cut to tougher grades more suitable for the lower cutting speeds and heavy tool loads found in rough cuts.

Carbide inserts come in a variety of sizes and are mechanically clamped to the tool at a position and orientation that is needed for the tool to effectively remove the material and create the required surface geometry. Manufacturers have found ways to clamp these inserts on many types of turning tools, mills, and drills. Such inserts usually have three to four cutting edges; when one edge is worn, the insert can be unclamped, indexed to a sharp cutting edge, and reclamped. After all edges are worn, the insert is not resharpened but instead thrown away. This indexability feature has made cemented carbide inserts very popular in production environments because they reduce the cost of tool replacement while achieving high material removal rates.

The hardness of these insert materials makes them resistant to abrasive wear, but vulnerable to chipping and other forms of fracture wear. Cyclic thermal loading can induce fatigue cracks. The clamped carbide insert conducts heat poorly, and generous use of coolants is needed to prevent thermal load damage. They have high hot hardness and can cut effectively at high temperatures. For certain work materials, temperature conditions, and cutting surface pressures, diffusion and

oxidation wear processes very rapidly degrade the cutting edge. In such applications, ceramic inserts may be more effective.

Ceramic inserts can be made from aluminabase or silicon nitride-base materials, or they may have 15 to 39% titanium carbide or other alloying elements added, in which case they are commonly called cermets. Ceramics and cermets have a higher hot hardness and are more chemically inert at high temperatures than cemented carbides, making them more wear resistant and permitting higher cutting velocities. The low coefficient of thermal conductivity for these materials causes the heat flow to be primarily directed into the chips, thus reducing the proportion of heat flow into the cutting tool. These materials are more brittle and cannot be used in applications that generate shock loads or cyclic loads induced by the cutting action or thermal cycles. For some metals such as titanium and certain aluminum alloys, a built-up edge and related wear mechanisms readily occur, making these applications unacceptable for ceramic and cermet tooling. These inserts are mounted in tool holders like carbide inserts but are sometimes made thicker in order to ensure adequate strength. This size difference could make it impossible for them to be fit into the same toolholder that is used for cemented carbides.

Ultrahard Tool Materials. Industrial grade single-crystal diamonds, polycrystalline diamond (PCD), and polycrystalline cubic boron nitride (CBN) are finding greater use in tools used for precise, smoother finishes. These very hard materials are very resistant to abrasive wear and have smooth cutting surfaces that reduce the surface shear stress and related friction forces. These smooth surfaces also help prevent built-up edge. Tooling made from these materials can be used on rigid machine tools at very high cutting velocities to produce precision machined surfaces. Both diamond and boron nitride have a cubic structure, but diamond will react with ferrous, materials at moderate temperatures; therefore, diamond tooling can be used only to cut nonferrous and nonmetallic materials. Steels and cast irons can be machined with CBN.

The polycrystalline forms are made by sintering fine single crystals of diamond or CBN together. Lapping is used to produce the geometry for single-crystal tools. Polycrystalline materials can be sintered into blanks or indexable inserts. Despite the costs, the use of ultrahard tool materials can be justified where precise, high-quality surfaces are needed or when higher productivity and fewer tool changes cycles result in competitive operating costs.

Cutting Tool Testing

Testing is done by tool users to evaluate tool vender products, to obtain information for tool replacement, and to establish the machinability of a material. In each of these instances, the amount of wear can be established by direct measurement of the size of the wear surfaces and the amount of damage to these surfaces due to chipping and fracturing. Figure 14 shows the types of wear surfaces that can occur. Such direct measurements require that the cutting process be stopped and optical inspection be used to clearly show the sizes of the wear scars and presence of chipping/fracturing. The deterioration of the tool due to wear can be indirectly established by monitoring surface finish, dimensions, power levels, tool loads, or acoustic events (Ref 16, 17, 18, 19, 20, 21). Correlation studies must be made to relate wear conditions to the indirect measured value.

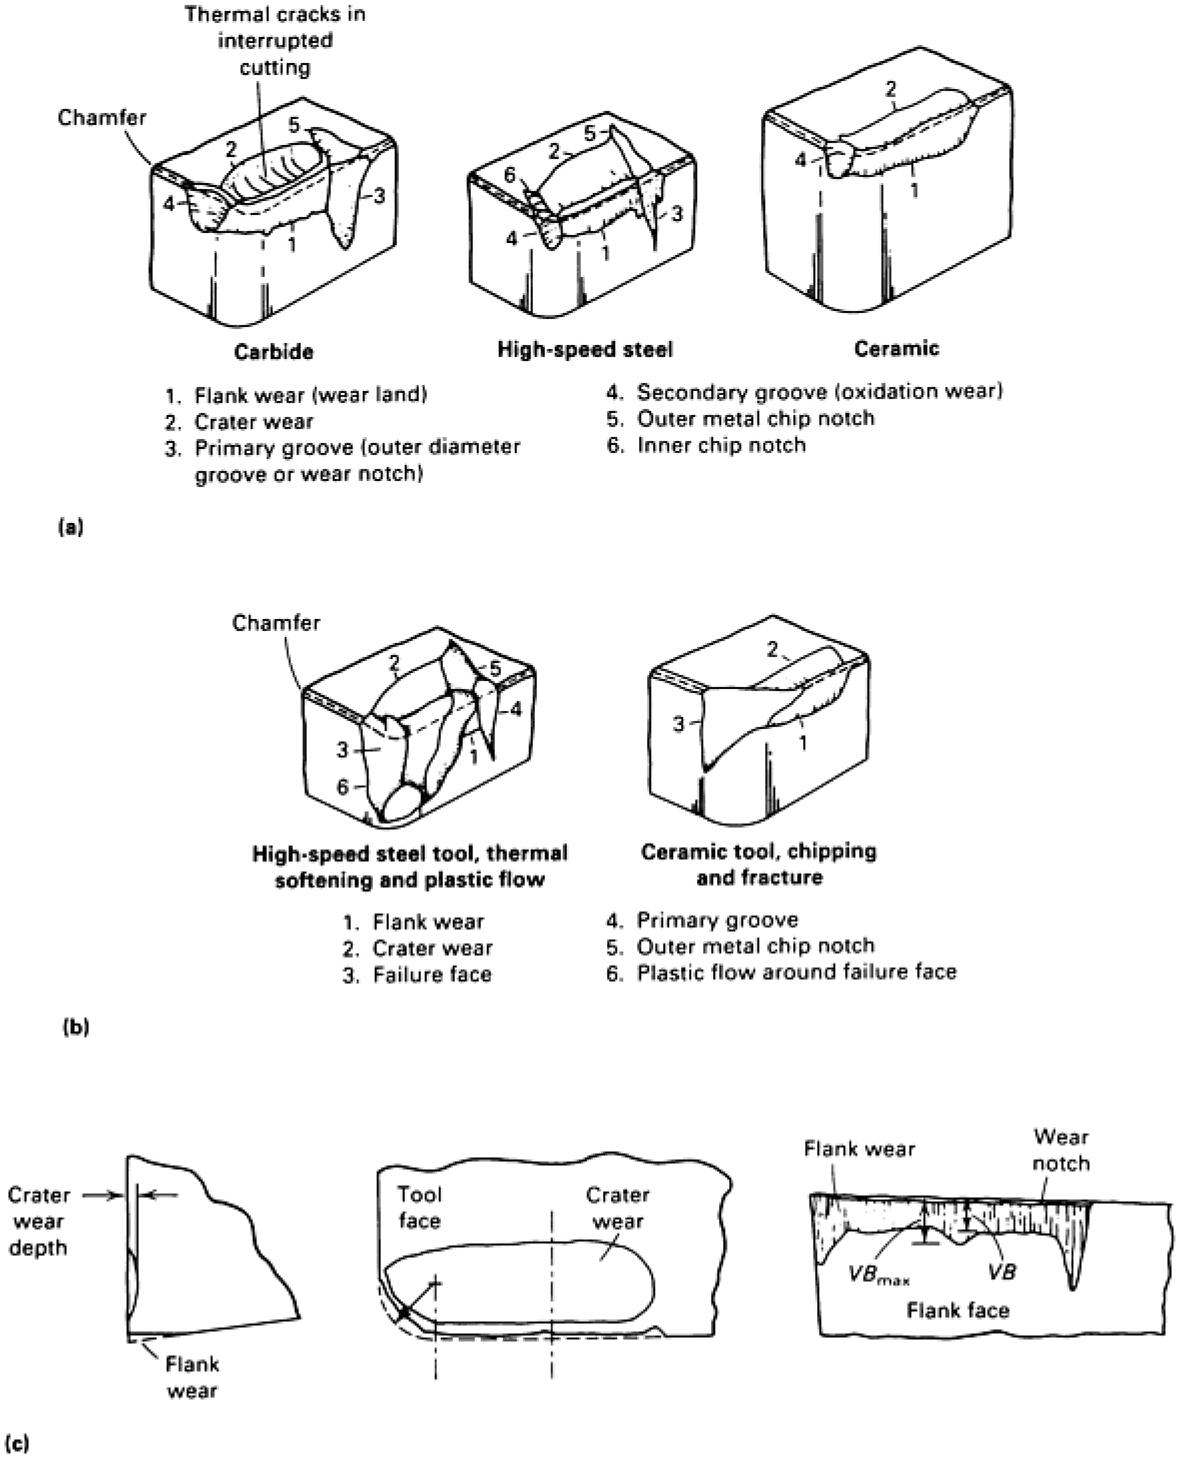

Fig. 14 Cutting tool failure modes. (a) Characteristic wear and fracture surfaces on cutting tools. (b) Catastrophic failure. (c) Typical wear measurements for a turning tool. *VB,* flank wear. Source: Ref 15

Tool life is an important result from testing programs. To establish tool life, a tool failure criterion is needed. This criterion will depend on the cutting application. For example, if the critical wear level is tied to surface finish, then a critical surface roughness level becomes the tool life criterion. To more completely define tool life, the elapsed interval before the critical wear condition is reached should be established for different cutting conditions. Figure 9 shows how a wear measure may vary when one cutting condition such as cutting velocity is varied. The elapsed interval before the wear value reaches the critical value, W_1, varies. This elapsed interval would be the tool life for each of these cutting conditions. The elapsed interval can be time, as in Fig. 9, or the number of parts. Relating this elapsed interval to cutting

conditions produces tool life equations that have been extensively studied and used to establish operating conditions and tool change intervals (Ref 6, 8, 9, 10).

Machinability testing evaluates the cutting characteristics of a material. These characteristics may vary depending upon tool type and tool material. Tool life and the parameters in a tool life equation may be used as one set of measures of machinability; however, they are generally not exclusively used. A general definition of machinability is "the relative ease or difficulty of removing metal in transforming a raw material into a finished product" (Ref 14). Such a comprehensive measure requires information from tool life or wear tests, surface finish tests, cutting force tests, power consumption tests, and cutting temperature tests. Even with reliable results from such a range of tests, the user of these data must combine the information in a way that will provide meaningful comparisons between different materials being machined using different types of tools and tool materials. Methods for doing this are available, but the reader will find that there is not uniform agreement concerning a best measure. The machinability of a material and the performance of particular tool materials in machining a surface can vary considerably depending upon whether or not a cutting fluid is used and, if used, how the cutting fluid is applied.

Cutting Fluid Systems

A cutting fluid can be in the form of a solution or an emulsion. A solution has a base fluid and additives that are soluble in the base fluid. An emulsion uses water as a continuous phase with a discontinuous phase of small suspended particles. Cutting fluids are generally used to improve tool life and increase productivity by allowing higher metal removal rates and decreasing the number of interruptions due to tool failure or replacement. This is generally achieved by lubricating mechanisms that reduce the quantity of heat generated by the cutting process and by cooling mechanisms that control the temperatures in the cutting region.

Solutions of oil or synthetic liquids have the highest lubricating capabilities and the lowest cooling efficiencies. Water-based solutions are better coolants than lubricants. Emulsions often can be formulated to provide both lubrication and cooling.

Cutting fluids often simultaneously control built-up edge on the tool, flush away chips, and protect the workpiece, tooling, and machine from corrosion. With such important purposes, the success or failure of machining operations may depend upon the selection of the cutting fluid system.

The cutting fluid system consist of the cutting fluid, the application mechanism, and the cutting fluid handling system. All three elements of this system must be carefully considered if cooling, lubricating, chip removal, and corrosion control are going to be achieved and maintained. These system issues are best addressed by having a clear goal concerning what the cutting fluid is to accomplish. A related system problem is that this goal must be achieved without endangering the worker and the physical environment. To continuously achieve this goal without environmental damage, the system must control the quality of the cutting fluid. Because of the system issues and varied goals, cutting fluid specialist need to be consulted.

Cutting Fluids. Many different types of cutting fluids are available, and the reader will find extensive literature and vendor help regarding the appropriate type of cutting fluid to use (Ref 22, 23). During such investigations and consultations, the information will be easier to evaluate if there is some basic understanding of the cooling, lubricating, corrosion, and chip removal mechanisms.

Cooling Mechanisms. To cool, the fluid must gain access to the cutting region and must have the thermal capacity to remove the heat generated by the cutting action. The high cutting pressures result in the contact areas between the work and the wear surface that are nearly equal to the projected geometric areas. The lack of void space reduces the amount of cutting fluid that can access the interface region via simple flow mechanisms. Access to these areas is thought to occur via capillary action (Ref 22). To access contacting surfaces, some have suggested that the fluids can penetrate through the metal lattice via diffusion (Ref 24); others have suggested that the cutting fluid may volatilize and the gas phase of the fluid penetrates into the interface (Ref 22). Some form of access must exist if the cutting fluid is expected to reduce friction. The importance of accessibility will vary in that large cuts result in larger contacting wear surfaces. In such instances, friction reduction and related heat generation may have to be controlled by altering other machining conditions, such as reducing cutting velocity.

The cutting fluid thermal properties that are important in removing heat are thermal conductivity, specific heat, heat of vaporization, and wettability with metal surfaces. Emulsions and solutions with greater water contents will have the best

thermal properties. The trend toward higher cutting velocities and larger material removal, rates that inhibit accessibility puts more importance on heat removal. The additives that are present in these solutions and emulsions are selected for their ability to provide some lubrication under such difficulty circumstances. Such lubrication is particularly needed when machining high-quality surfaces.

Lubricating Mechanism. Since a liquid film is unlikely to exist continuously, if at all, in the wear surface contact areas, additives that provide lubrication need an additional mechanism in order to be effective. Additives that promote boundary lubrication are thought to be effective if they react chemically with the workpiece material and tool material to form compounds on the surfaces. These compounds are then believed to interact with the work material to reduce heat generation caused by the strain processes in the work material adjacent to the contacting surfaces (Ref 24). This may or may not be the mechanism, but there is sufficient experimental work to show that these additives do reduce cutting forces, tool wear, and improve surface finish. The fact that some of these benefits lessen at higher cutting velocities suggests that insufficient reaction time is available for compound formation and accessibility is inhibited.

The additives that are effective vary with the severity of the cutting operation. For light cuts, fatty acids can be effective because they are able to form quasi-solid film compounds that are stable up to about 95 to 150 °C (200 to 300 °F). For more severe cutting conditions, extreme-pressure additives are available that form true solid compounds which are stable up to 980 °C (1800 °F).

Corrosion Protection Mechanism. Since fluids that chemically react to corrode metals are needed in cutting fluids to make them effective as lubricants and coolants, other additives are needed to counteract these reactions. Some additives are used to control the pH and obtain an alkaline cutting fluid. Other additives provide a physical barrier by coating the surface of the exposed metal. Establishing and maintaining the correct chemistry is essential. Cutting fluid systems should use treated water of known composition. Careful addition of additives plus the reprocessing of used cutting fluid will maintain the chemistry and prevent biological contamination. Commercial systems are available that provide these control features.

Chip Removal Mechanisms. The need for this mechanism varies with the type of cutting tool and operation. Drilling (deep-hole drilling in particular) depends upon the flow of the cutting fluid to prevent the chips from clogging the flutes of the drill. Other tools that are less confined by the machined surfaces use the flow of the cutting fluid to prevent the chips from remaining in the cutting region where they could interfere with the cutting action and damage the machined surface. If the cutting fluid has a tendency to foam when severely agitated, the flow rates and flow patterns needed for chip removal may need to be carefully controlled because the foam can clog filters in the circulation system.

Application Methods. Cutting fluids that are primarily used to lubricate must be applied so that they form films on sliding surfaces, whereas cooling applications require good contact with the cutting region tool surfaces. The need to remove chips imposes another application requirement. Obviously, the application technique will be closely tied to the goal selected for the cutting fluid system.

Hand application of cutting fluids is used only in low-production situations because it is difficult to continuously apply sufficient quantities of cutting fluid by hand to cool the tool. When used for drilling and tapping, it is best to hand apply the cutting fluid periodically when the drill or tap is backed out of the hole to clear chips.

Flooding is the most common application method because it is effective at cooling, can provide good lubrication, and is an effective way to remove chips. The volume required depends upon the cutting operation, the size of the surface feature being machined, and the cutting conditions (tool engagement, feed, and cutting speed). The number of nozzles and their orientation is as important as the quantity of cutting fluid used in flooding. The cutting region should initially receive the cutting fluid; in some instances, a particular portion of the cutting region will receive more fluid than another region. In turning and boring, the primary application of fluid should be directed at the chip and cutting edge region. A secondary application area is the clearance surfaces where lubricating films reduce flank wear, particularly at slower cutting speeds. For drilling, the task is to get the cutting fluid down the hole and the cutting chips up out of the hole. Proper alignment of the nozzles and proper volumes and pressures can be effective, but more drilling tools now have cutting fluid holes positioned through the shank so that the fluid is delivered directly to the cutting edge region. For milling, it is desirable to have at least two nozzles--one directed to the cutting region and the other used to clear the chips.

Mist application is possible where smaller engagements and high cutting speeds are used. Mist particles easily vaporize upon contact, efficiently removing heat during the vaporization process and reducing the quantity of cutting fluid needed

for the application. Mist application improves visibility of the cutting region. A danger in misting is that, if not properly controlled, suspended particles in the air will contaminate the working environment.

Very-High-Pressure Application. Recently, several techniques have been developed to provide very-high-pressure coolant streams for cooling lubrication and chip control. Most of these techniques are in the development stage, but a few are beginning to emerge as products. These very-high-pressure streams appear to reduce the chip pressures against the rake surface and help the coolant gain access to the wear surfaces (Ref 25).

Cutting fluid systems can range from simple hand application to plant-wide distribution systems served from a common recirculation and cleaning system. It is very important that the system protect the workers from exposure to cutting fluids that pose health risks. The system should maintain a level of cleanliness that is consistent with accepted health standards for the industry. The cleaning of the recirculated cutting fluid is very important. Tramp oil from machinery lubricating systems and metal chips must be removed as well as much finer contaminants. Contaminants can come from the cutting process or from the plumbing of the circulation system, they can even exist as microbes that biologically grow in such environments. All must be removed and the chemistry adjusted back to the specified level. Lastly, and most importantly, the system must safely dispose of its waste materials.

Friction and Wear of Dies and Die Materials*

Rajiv Shivpuri, Department of Industrial Engineering, Ohio State University; S. Lee Semiatin, Materials Directorate, Wright Laboratory

Introduction

WEAR OF DIES AND MOLDS is a complex time-dependent phenomenon that primarily depends on the four components of the system: die (mold), interface, workpiece, and processing conditions. The effect of these four components can be categorized into six process-related considerations: die (mold) design, die (mold) material, heat treatment, lubrication, surface treatments and coatings, and processing conditions.

Dies or molds impose a geometry on the deforming material. The design of the die cavities governs the sliding velocities, temperature, and interface pressures. Especially important considerations from a wear and failure standpoint are the radii of corners and fillets in die cavities. For example, in die casting the design issues are: size of die cavity with respect to the die blank; distance of cavity from the gates, cooling lines, and outer surface; cavity contours (radius of stress intensifiers); and sudden changes in cavity cross sections.

Another important consideration for wear is the micro- and macrostructural properties of the die material, its composition, microstructure (uniformity, internal defects, and secondary carbides), and mechanical and physical properties. Mechanical and chemical interaction of the die material with the rubbing body (workpiece) and the contaminants (lubrication, debris, and scale) is dependent on composition and microstructure.

Heat treatment of dies has a major influence on the resultant microstructure, hardness, and toughness of the dies. The casting cycle or quenching cycle determines the amount of pearlite, bainite, and martensite microstructures, which control the hardness, toughness, and temper resistance. Decarburization often results and has to be accounted for. Also of considerable importance is the austenizing temperature of the treatment.

Lubrication is important in that it determines the frictional conditions at the interface. In addition, it alters the contact conductance (thermal coefficients) and the oxidation behavior of the interface. In die casting and injection molding, lubricants also react with the melt. Experimental studies in hot forming suggest that sometimes good lubrication enhances abrasive wear. This is because lower interface friction permits larger sliding velocities at the interface and, consequently, higher wear rates. In addition, lubrication inhibits the formation of brittle (untempered martensite) layers on the die surface.

Surface treatments and coatings have found increase usage for wear resistance. Some of the important considerations are coating thickness, thermal and chemical stability, adhesive strength, spalling behavior, and cost. Exotic coatings such as ceramic coatings have found use in high-temperature applications, such as hot extrusion, and in drawing dies.

Processing conditions such as mechanical and thermal loading histories and sliding distances and velocities have a profound effect on die wear behavior. Factors such as maximum temperature, die preheating temperature, and dwell time (contact time under load) are critical to the success of hot-forming operations. Acceptable die lives can be obtained by proper control of processing factors. Forming equipment influences the wear process by imposing predetermined mechanical time histories on the process.

Die Wear and Failure Mechanisms

Wear of materials occurs by many different mechanisms. The terminology used to describe these mechanisms depends on the field of application. Some of the wear mechanisms identified in die and mold wear and failure are:

- Adhesive wear
- Abrasive wear
- Erosive wear
- Corrosive wear
- Thermal fatigue (heat checking)

- Mechanical fatigue
- Thermal shock
- Plastic deformation
- Gross cracking

The first three of the aforementioned wear mechanisms are common to most forming processes.

Adhesive wear is the predominant wear mechanism in the cold adhesion and galling behavior in sheet metal forming and cold extrusion. Surface finish and hardness play an important role in adhesive wear, with similar materials (rubbing pair) showing greater wear than dissimilar materials. Surface treatments such as nitriding are preferred in adhesive wear applications.

Abrasive wear is the predominant wear mechanism in hot forging. The surface films such as oxide scale break down during the deformation process and act as abrading particles. This three-body wear situation is also present in other hot-forming processes. In the manufacturing of composites, however, the second phase (reinforcement) acts as the abrasive. Sliding distance and velocity, and interface pressures are important considerations. The hardness ratio (hardness of the abrasive/hardness of the surface) has a major influence on the amount of wear. Surface platings and coatings that increase surface hardness significantly reduce abrasive wear. Care must be taken in the use of coatings because they can crack in service and lead to enhanced wear rates due to spalling.

Erosive wear is predominant in solidification processes such as die casting. The liquid metal spray impinges on the die surface resulting in localized loss of material due to erosion. Temperature differential between the molten metal and the die surface, the velocity of the molten spray, and the angle of impact are some of the important factors in die erosion.

Corrosive wear occurs in combination with the other wear mechanisms described above. It results from the chemical affinity between the flowing material and the dies. Grain size and the composition of the die material influence corrosive wear.

Thermal Fatigue. The most common reason for discarding die casting dies is the development of heat checks (craze cracks) due to thermal fatigue. This also arises during hot forging due to the temperature difference between the dies and the hot metal. As the die surfaces are heated, compressive stresses develop due to constraints provided by the cooler interior material. This situation is reversed when the part is unloaded and the die surfaces cool. Cyclic compressive and tensile stresses during production result in thermal fatigue. The most important factor in thermal fatigue is the strain amplitude imposed during the forming cycle. In turn, this depends on the magnitude of temperature change during each cycle and the thermal properties of the die material. Other factors include composition and purity of the die material. Composition influences the metallurgical phase transformations, which lead to additional large increments of straining above that which leads to failure. The presence of second-phase particles and other inclusions decreases the hot ductility of the material considerably.

Mechanical fatigue of forming dies is influenced by the magnitude of applied loads, the average temperature of the dies, and the surface condition of the dies. Fatigue cracks initiate at locations of stress concentrations (cavities, corners, and fillets) or features such as hotels, keyways, and deep stamp markings on die sets. Design changes to minimize stress concentrations are often recommended. Surface treatments, including nitriding, micro-shotpeening, and ion implantation, effectively reduce surface fatigue. However, plating and coating treatments may lead to a brittle layer that cracks under cyclic loading and causes spalling.

Thermal shock in die casting often causes heat checking and occasionally, gross cracking. The temperature difference between the die surfaces and the liquid metal is the driving factor. Important material properties for thermal shock are the heat capacity, conductivity, and expansion coefficient. Elastic modulus of the material is also of significance.

Plastic deformation in dies results from excessive pressure and low hot-yield strength of the die material; the former can be alleviated by cavity redesign, and the latter by proper selection of the die material. Die cooling also reduces these effects, but care must be taken to avoid temperature cycles, which may cause phase transformations.

Gross cracking, or catastrophic die failure, is a limiting condition from a die life standpoint. Failure occurs quickly (in a few cycles) because of high applied stress or low toughness of the die material. As in the case of mechanical fatigue,

high stresses may result from poor die design, improper press fitting or shrink fitting of dies and die inserts, or lack of control of forging load and energy.

Materials for Dies and Molds

A wide range of materials are available to the designer of tools and dies. This section summarizes the important attributes required of dies and the properties of the various materials that make them suitable for particular applications. Among the important attributes are hardenability; machinability; and resistance to wear, plastic deformation, shock loading, and heat checking. The needed levels of resistance to wear, plastic deformation, and so forth, are determined by factors such as type of equipment used, workpiece temperature, expected die temperature, and number of parts to be fabricated. Low-alloy steels and hot-work die steels are often suitable for conventional metalworking, casting, and molding operations. On the other hand, high-temperature die materials are required for special applications such as isothermal forging of titanium and nickel-base alloys. These die materials include various superalloys and TZM molybdenum. Recommendations on the selection of these materials are made in this section. The approach used in making these recommendations and the tool materials themselves are discussed in detail for hot forging tooling. Short summaries of material recommendations are also provided for other fabrication techniques.

Die Materials for Hot Forging

The selection of materials for hot-forging dies is done by considering the types of loads and temperatures that are to be imposed on the dies. Once this is known, an evaluation of die material properties can be made with respect to the known loads and thermal conditions that the dies will experience. The important factors in the selection procedure and their interrelation are schematically shown in Fig. 1. The important forging process variables include the following:

- Type of forging equipment employed (which determines the maximum load that can be applied and loading rate)
- Workpiece material and its preheat temperature (which affect die pressure and temperature)
- Size and shape of the part (which influence overall die loading)
- Type of lubrication and die heating/cooling system (which affect the thermal history and surface wear of the dies)
- The number of parts to be forged (which determines the number of load and thermal cycles)
- The production rate

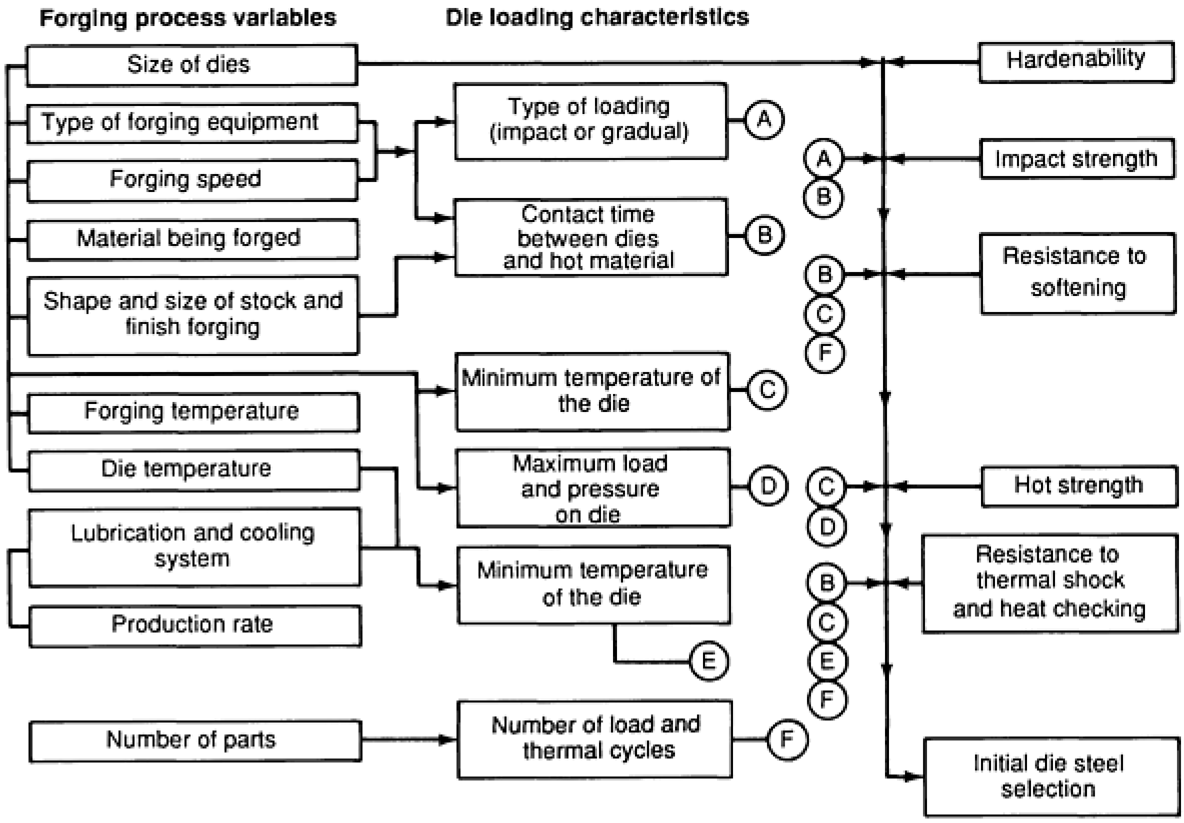

Fig. 1 Schematic representation of die steel selection procedure. Source: Ref 1

In turn, the die material attributes of importance are hardenability; machinability; wear resistance; hot strength; toughness; resistance to heat checking, thermal fatigue, and mechanical fatigue; possible need of a special protective atmosphere in the forging operation; and the material cost (Ref 1, 2).

Alloy Steels for Hot-Forging Dies. A variety of die steels are available for warm and hot forging (Ref 1, 3). These steels have varying degrees of hot strength, toughness, and fatigue resistance. Before comparing specific steels, however, it is instructive to review the compositions and attributes of the various grades.

Low-Alloy Tool Steels (6G, 6F, 6H). The principal alloying elements in these steels are nickel, molybdenum, and chromium, with vanadium and silicon in smaller additions. The total alloying content is generally small enough so that adequate machinability is retained in prehardened die blocks of these grades. Characterized by high toughness and, in some instances, by good heat resistance (6F4), these steels have very good hardenability. As a tradeoff to their good toughness, they are generally heat treated to relatively low hardnesses. Because of these low hardness, their wear resistance is only moderate. However, they are known to possess good resistance to shock loading (such as encountered in hammer forging), heat checking, and catastrophic failure.

Because of the generally low tempering temperatures, these die steels are employed primarily in hammer operations where the contact times, during which heat transfer to the dies can occur, are short. Alternatively, they can be used in presses as die blocks with heat-resistant inserts made from the hot-work die steels (H grades). An exception to this general trend among the low-alloy tool steels is alloy 6F4. Its large nickel and molybdenum contents impart high hardness and hardenability. Furthermore, it is generally underaged. Because of this, when it is used in presses or upsetters, heat transfer gives rise to age hardening and thus increased resistance to abrasive wear.

Air-Hardening Medium-Alloy Tool Steels (A2, A7, A8, A9). Manganese, chromium, molybdenum, and vanadium are the principal alloying elements in this group of tool steels. These steels have moderate resistance to thermal softening, and, because of their high carbon content, have high strength and good wear resistance. Hence, they are useful for both hot and cold forging.

Chromium Hot-Work Steels (H10 to H19). These steels contain chromium as the major alloying element with additions of molybdenum, tungsten, vanadium, and cobalt. They possess good resistance to thermal softening and heat checking, and moderate toughness at working hardnesses of 40 to 55 HRC. In addition, the tungsten and molybdenum promote good hot hardness. The alloy and carbon contents of these steels are low enough so that they can be water cooled usually without cracking and consequently have improved service life. Also, because of their high hardenability, they can be air hardened (air-cooled after austenitizing or tempering), which minimizes distortion after heat treatment.

As for specific steels in this group, H10 has high resistance to thermal softening. Grade H11 also has high resistance to elevated-temperature softening, but it offers improved toughness over H10. Furthermore, the high tempering temperature of H11 permits relief of residual stresses, thus leading to an optimal blend of strength and toughness. In grade H12, tungsten is added to improve the toughness, hot hardness, and heat checking characteristics over those of H11. However, the presence of tungsten decreases resistance to thermal shock; therefore, water cooling of H12 is not recommended. In H13, a high vanadium content increases resistance to heat checking (below 650 °C, or 1200 °F) and abrasive wear. Also, H13 appears to have good thermal shock resistance and can be water cooled if desired. Grade H19 with its large tungsten and cobalt additions and moderate vanadium addition has excellent hot hardness and resistance to abrasive wear. The presence of tungsten, however, decreases the alloy's resistance to thermal shock; therefore, like H12, H19 should not be water cooled. Because of its high cost and only moderate toughness, H19 is typically used only for inserts in forging dies.

Tungsten Hot-Work Steels (H20 to H26). The principal alloying element in these die steels is tungsten. Various grades contain additions of chromium and vanadium. The higher alloy content of these steels over the standard chromium hot-work steels leads to improved resistance to thermal softening and abrasive wear, but at the same time it gives them only moderate to low toughness at their normal working hardnesses of 45 to 55 HRC. In addition, the high alloy content makes this group of steels susceptible to thermal shock; therefore, they should not be water cooled. If these steels are preheated to operating temperature before use, they can be used for forging dies of rugged design.

Molybdenum Hot-Work Steels (H41 to H43). Molybdenum is the principal alloying element in this group, whose grades also contain varying amounts of chromium, vanadium, and tungsten. The characteristics of these steels are very similar to those of the tungsten hot-work steels, the major difference being the lower cost of the molybdenum hot-work steels. Another advantage of these steels over the tungsten hot-work steels is their greater resistance to heat checking, but, as with all high-molybdenum steels, they must be heat treated carefully to avoid decarburization.

Comparison of Die Steels for Hot Forging. Selection of a die steel for forging depends on careful consideration of the die material's metallurgy as well as its mechanical and thermal properties. Metallurgical factors include hardenability and machinability. Mechanical properties include the following:

- *Resistance to Wear.* The ability to resist the abrasive action of the workpiece metal sliding over the dies during forging. This property is affected by the hot hardness of the die material and its resistance to thermal softening
- *Resistance to Thermal Softening.* The ability of the die material to resist softening, or overaging, during long-term elevated-temperature exposure
- *Resistance to Plastic Deformation.* The ability of the die material to resist deformation under forging loads and expected service temperatures during forging (Fig. 2 and 3)
- *Resistance to Brittle Fracture.* The ability to resist catastrophic failure and is determined by the alloy toughness
- *Resistance to shock loading* as may be experienced in hammers
- *Resistance to Heat Checking.* The ability to withstand surface cracking due to nonuniform die heating (dies with a hot surface and cooler interior)

Rating of Die Steels for Hot Forging. Based on the previous discussion and additional literature supplied by steel manufacturers, die steels can be qualitatively ranked for relative response to wear, impact, high temperature, and so forth. Such a rating, of course, is helpful in selecting among the many materials currently available. Table 1 presents a relative ranking for three of the most important die material properties. The rating on heating-checking quality is not provided because conclusive data are not available. It must be emphasized that the comparative rating is arbitrary. This is because other factors, such as hardness of the die block and the maximum temperature to which the dies are subjected, influence the comparison. For example, H21 hardened to a higher level than H19 may show better wear resistance than H19; in the same context, 6F2 may show a wear resistance comparable to that of H11 if the maximum die temperature does not exceed 370 °C (700 °F). Thus, for a specific application, a closer comparison of the mechanical properties of the die steels is needed to make a selection.

Table 1 Die steel ratings

	Resistance to		
	Wear	Thermal softening	Catastrophic fracture (impact, strength, toughness)
	H26	H26	6F2, 6F3 6F5, 6F7
	H23	H24	
↑	H24, A2	H23	H12
	H19, H14	H19	H11
	H21	H21	H10, H13, 6F4
Increasing resistance	H10, H12, H13	H14	A9, 6H2, 6G
	A9, 6H2, A8	H10	H14
	H11, 6F4	6F4	6H1, A8
	6H1, 6F5 6F7, 6F3	H11, H12, H13, A8	H19, A2
	6F2, 6G	A9	H21, H23, A6
		6F3, 6F5, 6F7, 6H1, 6F2, 6G	H24
			H26

High-alloy steels such as H26, H19, H21, and H14, possess excellent wear and heat-resistance qualities, but have poor toughness. Thus, these steels are best used in forging dies as inserts that can be rigidly supported in the die blocks. In hammers where toughness is the primary requirement, these steels are not normally used for die blocks. Low-alloy steels such as 6G, 6F2, and 6F3 show the opposite qualities. These steels have low wear- and heat-resistance qualities, but high toughness. High resistance to impact combined with the low material costs make these steels very attractive for hammer dies. Medium-alloy steels such as H11, H12, and H13 provide a compromise between the two extremes. These steels are especially suitable for press dies where the die steel must have good resistance to thermal softening as well as reasonable toughness. Medium-alloy steels also find application in hammers where the quantities of parts to be forged are large, and wear resistance becomes an important economic requirement in such applications.

In addition to standard steels, special steels, such as modifications of the H10 and H13 grades, are available for applications where high wear resistance is desired and a reduction in toughness can be tolerated. For large die blocks where hardenability and strength throughout the block are added requirements, 6F5 and 6F7 are especially suitable. Thus, depending upon the needs of a particular forging operation, a baseline selection of suitable steels can be made from the data on mechanical properties of the die steels.

Effect of Process Variables and Workpiece Properties. As mentioned previously, forging process variables and workpiece properties must be considered carefully when selecting die steels in order to ensure that the dies can withstand the loads and temperatures to which they are to be subjected. These considerations are briefly discussed below. Also, specific die steel recommendations for particular combinations of workpiece material and equipment will be given.

Characteristics of Forging Equipment. The main types of equipment used in forging are hydraulic presses, mechanical presses, upsetters, screw presses, and forging hammers. In a hydraulic press, the ram moves slowly, giving rise to large amounts of die heating (because of long contact times) and large loads. Thus, the dies must have high hot strength and be resistant to thermal softening and wear. Toughness and resistance to impact are minor considerations. For these reasons, the chromium hot-work steels (H10 through H16) are often employed. Alternatively, the low-alloy steel 6F4, which hardens during service, can be effectively used.

Mechanical presses and upsetters are similar to hydraulic presses in that forging with these types of equipment leads to relatively high loads and long contact times. Again, the die steels must have high hot hardness and resistance to thermal softening and wear, and usually the chromium hot-work steels or an age-hardening alloy such as 6F4 are used. For screw presses, speeds are comparable to mechanical presses, but because the ram is accelerating when it hits the workpiece, die materials that are somewhat more impact resistant (tougher) than those for mechanical presses are required. In Europe, where screw presses are popular, the most commonly used die steel is H10 (Ref 9).

Die steels for forging hammers require different characteristics than those for presses or upsetters. The very rapid loading rate and short contact time in hammers require die steels that are tough, but that have only moderate resistance to thermal softening. Low-alloy steels such as 6F2 are commonly used for die blocks, whereas 6F2, 6F3, or the chromium hot-work steels are employed for die inserts.

Number of Parts to Be Forged. As a minimum requirement for the production of acceptable forgings, whether the lot quantity is 100 or 100,000, the dies must have adequate hot strength at the service temperature to withstand the forging pressure. However, when the number of parts to be forged is very small, or when the design of the forging is likely to be modified, die life is not the determining factor in die material selection. The least expensive prehardened steel that meets the minimum requirement becomes the logical choice for small-lot applications. Higher-alloyed steels are usually more cost-effective for larger lot quantities because they lower the cost of machining and changing die sets.

Size of the Dies. For small dies, the cost of die material represents a minor portion of the total forging cost; the portion of total cost represented by the tool steel costs increases as the size of the die increases. Thus, for small dies, the tendency is toward using higher-strength steels, which may be more expensive in material cost.

For large die blocks, added requirements are hardenability for uniform properties and toughness. Die steels with high nickel content (6F5, 6F7) are, therefore, used for very large die blocks.

Other Process Variables. Forging speed, die temperature, die lubrication and cooling systems, production rate, shape and size of the stock, and finish shape and size of the forging are the other variables that influence the die-loading conditions, as shown in Fig. 1. These parameters influence the maximum die load and maximum die temperature. The lubrication and cooling systems, together with the die temperature, determine the minimum temperature to which the dies are cooled. Maximum and minimum temperatures during a forging cycle define the conditions of thermal shock to which the die is subjected.

Production rate influences the maximum temperature of the dies. With high production, the die life decreases because of the increase in maximum die temperature.

Workpiece Properties. The workpiece properties play a critical role in determining the forging pressure applied to the dies. In addition, the required loads as well as workability of the material are strong functions of temperature. Thus, the workpiece material strongly affects the die temperatures that can be expected in forging production, particularly for presses and upsetters.

Forging of carbon steels is easy and requires relatively inexpensive die block materials. Typically, low-alloy tool steels are sufficient (Table 2). When forging is done in presses, the dies are usually heat treated to a higher hardness than they would be if forging were done in hammers because wear resistance is more important and toughness less important. In some instances, though, die inserts of the more highly alloyed low-alloy steel, or even of the chromium hot-work die steels, are recommended in regions of the dies exposed to higher-than-average-temperatures or loads.

Table 2 Die steels for forging various alloys

Material	Hammer forging, die steel/hardness, HRC	Press forging die steel/hardness, HRC
Carbon steel	6G, 6F2/37-46 (Die blocks)	6F3, H12/40-46 (Die blocks)
	6F3, H12/40-48 (Inserts)	H12/42-46 (Inserts)
Alloy and stainless steel	6G, 6F2/37-46 H11, H12, H13/40-47 (Die blocks)	H11, H12, H13/47-55 (Die blocks, inserts)
	H11, H12, H13, H26/40-47 (Inserts)	
Aluminum alloys	6G, 6F2/32-40 (Die Blocks)	6G, 6F2, 6F3/37-44, H12/47-50 (Die blocks)
	H11, H12/44-48 (Inserts)	H12/46-48 (Inserts)
Titanium alloys	6G, 6F2/37-40 (Die blocks)	6G, 6F2/37-40 (Die blocks)
	H11, H12/44-52 (Inserts)	H11, H12/47-55 (Inserts)
Heat-resistant alloys, nickel-base alloys	H11, H12, H13/47-50 (Die blocks, inserts)	H11, H13, H26/50-56 Inconel 713C, René 41 (Die blocks, inserts)

Source: Ref 3

For forging low- to medium-alloy steels and stainless steels, more stringent demands are made on the forging dies and die materials. In hammer forging, die blocks can often be made of low-alloy steels (Table 2). However, small dies or die inserts should be made of hot-work die steels. For press forging these alloys, chromium hot-work steels are often used for both dies and die inserts, with die inserts usually tempered to slightly higher hardness than the die blocks.

Typical forging die materials for aluminum alloys are very similar to those for carbon steels (Table 2). Prehardened low-alloy steel die blocks are often used. For aluminum alloys, though, they are tempered to slightly lower hardnesses than dies for forging carbon steel. As for carbon steels, it is often advantageous to use die inserts of more highly hardened chromium hot-work steels in critically stressed regions of both hammer and press dies.

Titanium alloys are similar to stainless steels in that forging dies for these materials are usually made from chromium hot-work steels (Table 2). For large dies, the die impression is made of one of these steels and inserted into a large die block of a low-alloy steel such as 6G or 6F2. As for hardness, hammer dies are only moderately hardened so that they retain a certain amount of toughness. On the other hand, press dies are usually harder than hammer dies (by about 3 HRC points) because of the reduced need for toughness. However, the low end of the recommended hardness range of press die inserts should be used for dies with severe impressions.

The greatest demand upon die material is made when forging heat-resistant alloys and nickel-base superalloys. This is not surprising inasmuch as they have been designed to resist deformation at high temperatures. The primary choices for dies and die inserts for these alloys are the chromium hot-work steels. As for the forging of other alloys, these steels are typically more highly hardened for press application than for hammer applications. In general, the hardness levels used tend to be quite high, primarily to resist wear caused by very high die pressures. For these kinds of demanding service conditions, the tungsten hot-work die steels, such as H26, or nickel-base alloy die materials, such as Inconel 713LC or IN-100, may offer and advantages when considering die life versus material and machining cost.

Other Die Materials for Hot Forging. Several other kinds of steel exist that may be suitable for forging dies. These steels typically have been designed for specialized applications. Nonferrous materials, such as superalloys, TZM molybdenum, and cemented carbides, are also sometimes used for severe applications. Table 3 compares service temperatures of die materials used in forging operations.

Table 3 Typical service temperature of die materials in forging

Tool material	Recommended service temperature range	
	°C	**°F**
Low-alloy steels, air-hardening steels, shock-resisting steels	205-480	400-900
Chromium, tungsten, and molybdenum hot-work steels, maraging steels, tungsten carbide	370-620	700-1150
Superalloys	620-925	1150-1700
TZM molybdenum	925-1205	1700-2200

In shock-resisting tool steels (AISI S series), the principal alloying elements are silicon, manganese, chromium, tungsten, and sometimes molybdenum or nickel. These elements impart high strength and toughness and moderate wear resistance. Their primary application is hammers in which tool temperatures do not exceed 540 °C (1000 °F).

Maraging steels are heat treated somewhat differently than the conventional die steels, which are quenched and tempered. Containing nominally 18% Ni 8 to 12% Co, and smaller amounts of molybdenum and titanium, these steels from a comparatively soft martensite during air cooling following austenitizing. Subsequent hardening is then performed by aging treatments at approximately 480 to 510 °C (900 to 950 °F). Because these steels distort negligibly during aging, they offer a considerable advantage as far as machining is concerned. Among the properties that make them attractive as compared to conventional hot-work die steels are their significantly higher yield strengths (room-temperature strengths between 1380 and 2410 MPa, or 200 and 350 ksi, depending on the specific alloy) and toughnesses (Ref 10). At the same hardness, their toughness can be at least 2 to 2.5 times that of chromium hot-work tool steels, thus making them very useful in hammer forging. In addition, they exhibit a resistance to heat checking and thermal softening equivalent to, or better than, chromium hot-work die steels tempered to the same hardness. These attributes as well as their ease of machining have led to their increasing use in forging of aluminum alloys, stainless steels, alloys steels, and nickel-base alloys. It appears that their only drawback is their somewhat low wear resistance, which can be more than compensated for by surface treatments such as nitriding (Ref 10, 11).

Cast Steels. The discussion up to now has dealt with properties and selection of wrought die steels. It appears that use of cast forging dies and die inserts is receiving renewed attention. This is surprising in view of early bad experiences with these types of die materials. Much of this revolution has been brought about by the use of ceramic or refractory casting mold materials, which can be preheated prior to pouring of the casting (Ref 12). With these types of mold materials, castings cool very slowly, and there is no surface chilling or development of columnar grain structures, the usual source of weakness in cast structures. Furthermore, gas bubbles do not become entrapped and there is much better chemical homogeneity than in the conventionally cast metals.

Cast tool steels have been shown to possess superior hot hardness and wear resistance when compared to their wrought tool steel counterparts, and they have been used extensively in presses as well as in hammers (Ref 13). Among the grades that have been used in cast form are H12, H13, H19, H21, H26, and H42 (Ref 14). It has also been shown that cast dies show improved resistance to heat checking and are tougher inasmuch as they are not as likely to crack in sharp corners (Ref 15). At present, because of the large initial cost of the pattern, it appears that cast dies are not economical unless at least three castings are needed from one mold. However, plant experiences showing increases in tool life in excess of 50% over wrought dies may justify their consideration in some instances.

Superalloys. Conventional forging of titanium and nickel-base alloys and isothermal, hot forging of these and other alloys place stringent requirements on dies and die materials. For this reason, die materials other than the conventional hot-work steels must be employed. Die materials such as the superalloys based on nickel, iron, and cobalt, which possess substantially greater high-temperature strength and resistance to thermal softening, have been found to be useful for these applications in which higher die temperatures are common.

Nickel-base superalloys used for forging dies come in cast and wrought forms. The cast superalloys generally have lower ductility and toughness compared to the wrought alloys but have been found to be useful in operations such as isothermal forging of titanium alloys where these attributes are not important. Among the cast superalloys most often employed are IN-100, Udimet 500, Nimocast 80, and 90, and Inconel 713LC. These alloys have hot yield strengths comparable to that of H11 at temperatures up to 540 to 650 °C (1000 to 1200 °F) (Fig. 4). In contrast to the hot-work die steels, they maintain large amounts of strength up to temperatures of 760 to 925 °C (1400 to 1700 °F).

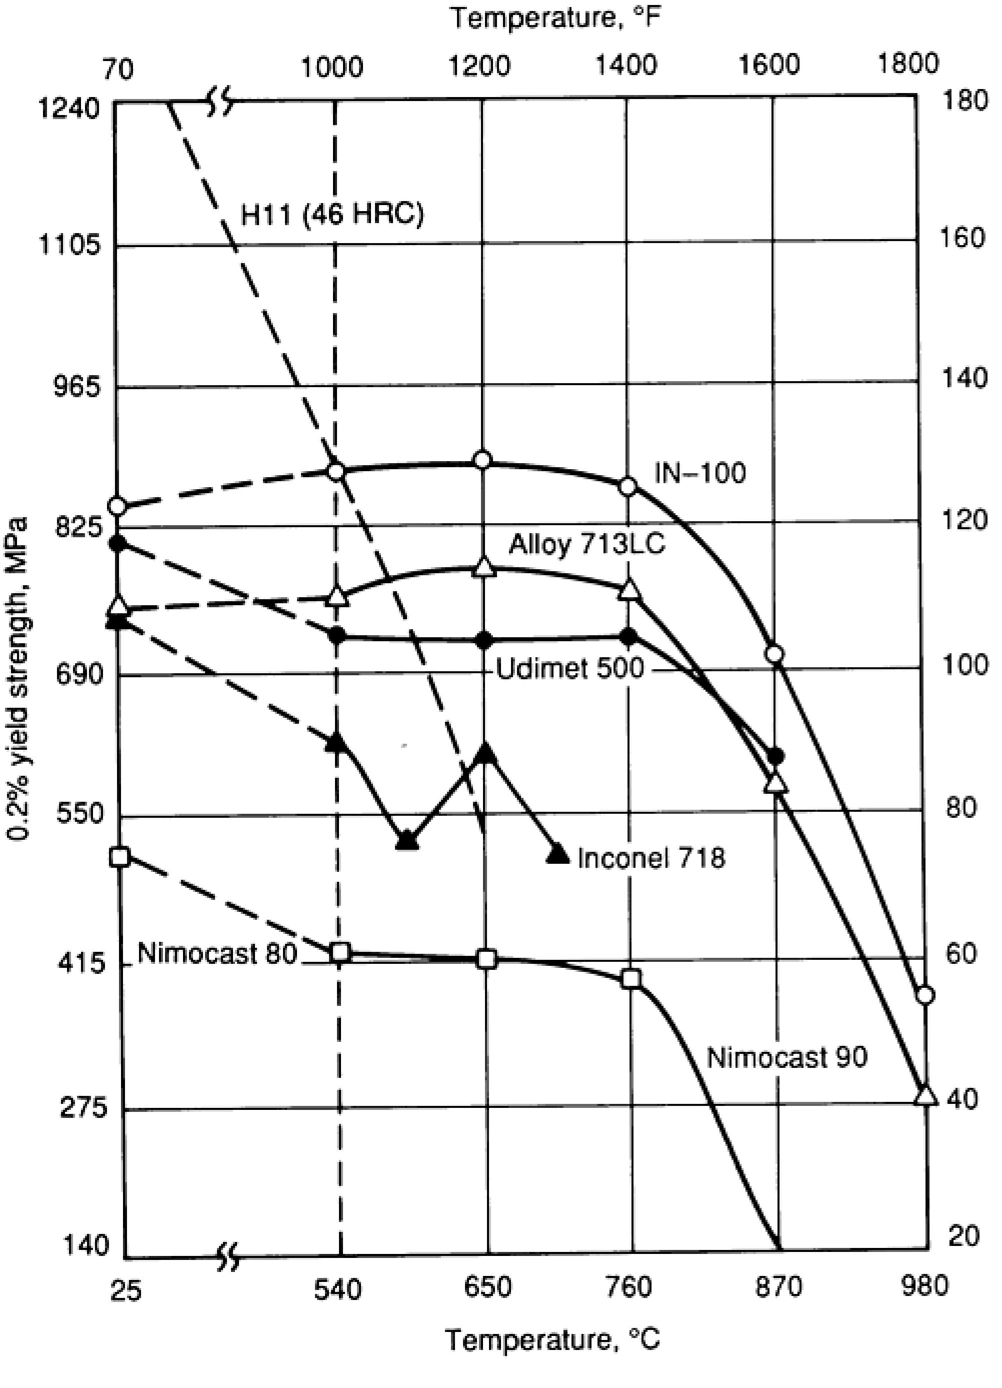

Fig. 4 Resistance of selected cast nickel-base superalloys to plastic deformation at elevated temperatures. H11 is included for comparison. Source: Ref 16

Wrought nickel-base superalloys usually have better overall mechanical properties, which make them favorable over their cast counterparts as far as selection of a forging die material is concerned. Typical wrought nickel-base forging die materials are Inconel 718, Waspaloy, and Udimet 700. Common iron-nickel alloys are Inconel 706 and Incoloy 901. As shown in Fig. 5, these alloys retain high hot strength up to temperatures of 650 to 870 °C (1200 to 1600 °F). As for the cast nickel-base superalloys, the drop in strength above these temperatures is related to γ' precipitate reversion. In the iron-nickel-base alloys, this drop in strength is due to reversion of other intermetallics, such as those based on niobium. The wrought superalloys have far better ductility and impact strength than the cast ones. This difference is particularly noticeable at temperatures between 540 and 870 °C (1000 and 1600 °F), where the superalloys have their greatest use as forging die materials. The values of ductility and impact energy of these wrought alloys are comparable to those of the hot-work die steels at the temperatures at which they are usually employed, namely 370 to 595 °C (700 to 1100 °F).

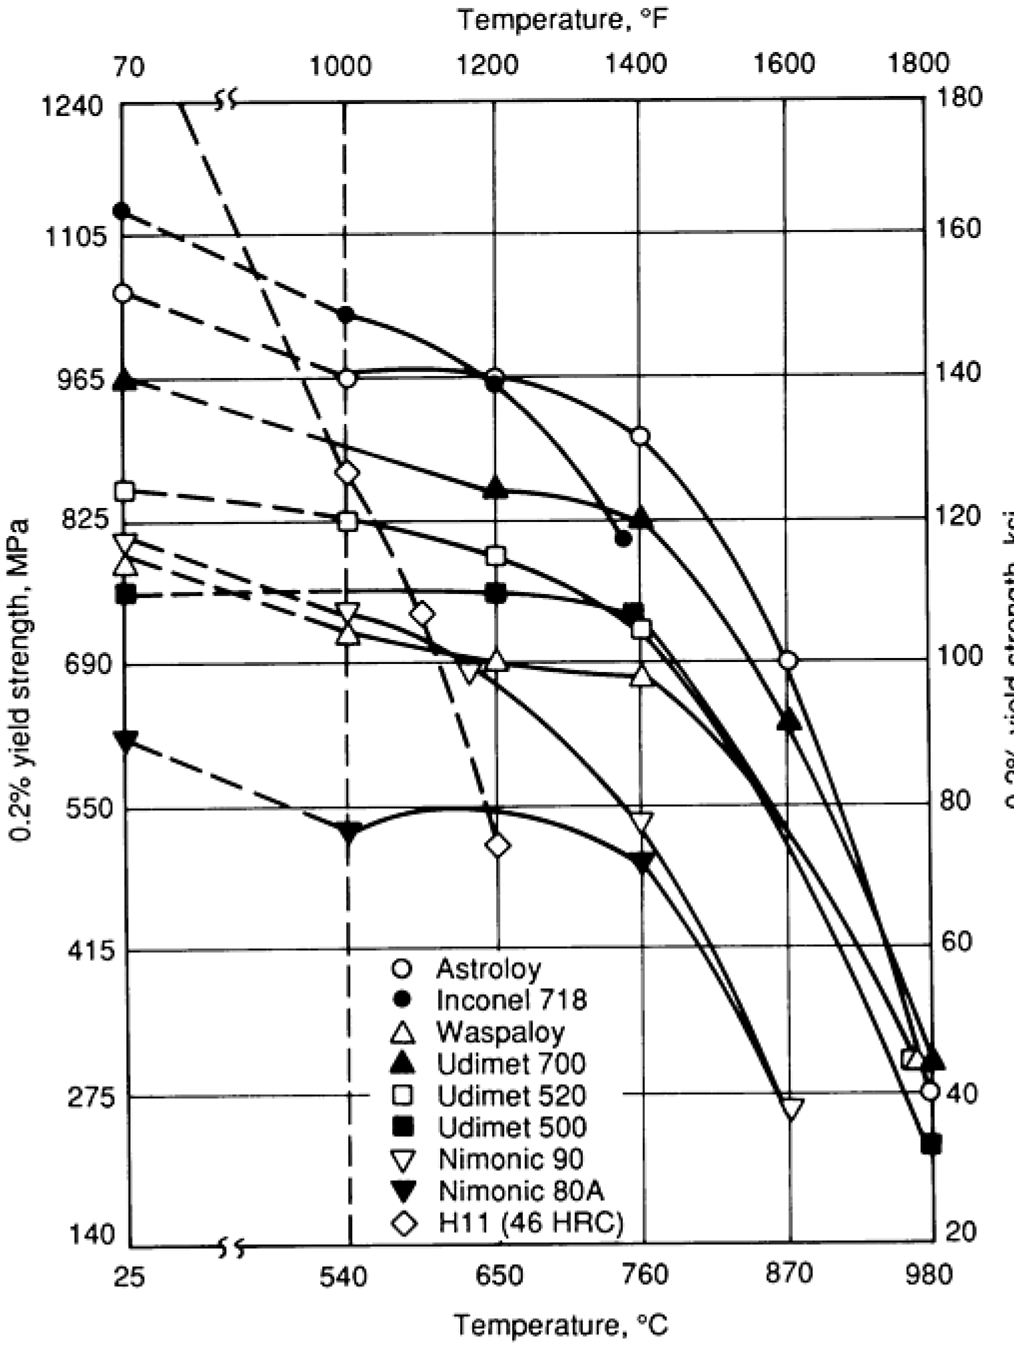

Fig. 5 Resistance of selected wrought nickel-base superalloys to plastic deformation at elevated temperatures. H11 is included for comparison. Source: Ref 16, 17

Cobalt-base superalloys, that find their main application in forging of titanium and nickel-base alloys, are less widely used for die materials compared with nickel- and iron-base superalloys. This is because of their higher cost. However, die wear studies on alloys such as Haynes Alloy 25 have shown that they outwear alloy steel dies by a factor of five to one in forging superalloys (Ref 18).

TZM Molybdenum. The forging of nickel-base superalloys places the greatest demands on forging die materials. Often these alloys must be forged isothermally at temperatures approaching and exceeding 1095 °C (2000 °F). In these cases, refractory metal alloys or ceramics must be employed as die material. Probably the most common alloys for these applications is *TZM* molybdenum (Ref 15). Because this alloy oxidizes very readily at temperatures around 1095 °C (2000 °F), tooling made of it must be enclosed in an evacuated chamber. Moreover, because of the high cost of the alloy and required peripheral equipment, it is used to forge only the most difficult-to-work alloys, which otherwise cannot be forged.

Cemented Carbides. Use of powder metallurgy materials such as tungsten carbide and titanium carbide as die materials, although fairly common in cold forging, appears to be rather limited in warm and hot forging. Carbides for warm and hot forging typically contain large amounts (10 to 20%) of cobalt binder to improve the toughness of the brittle carbide. Grade K3520, for example, is a tungsten carbide alloy that has 20% binder and that was designed specifically for hot working of steels (Ref 19). In addition to its excellent wear and shock loading resistance, it has thermal properties that minimize heat checking. However, because of the tendency of tungsten carbide to oxidize above 540 °C (1000 °F), its usefulness is limited. For die temperatures above 540 °C (1000 °F), titanium carbide materials appear to be more suitable. Although there is limited data on the use of titanium carbides, it appears that their major application is as die inserts in which large amounts of transverse compressive loading are applied to avoid the possible generation of tensile loads, which carbides generally cannot withstand without fracture.

Die Materials for Hot Extrusion

All extrusion tooling components that come in contact with hot billets have limited life and must be replaced periodically. Although the die is exposed to the most severe service, other die components such as backers, bolsters, mandrels, and dummy blocks may also deteriorate rapidly and are thus referred to as perishable tools. Containers, liners, liner inserts, and rams are exposed to less severe service and are known as durable tools. This arbitrary separation is used in Table 4, which summarizes recommendations for tool material and hardness. It will be noted that the 5% Cr grades of hot-work tool steel (H11, H12, and H13) predominate as tool material recommendations, especially for extruding aluminum and magnesium alloys. These tool steels are characterized by a high degree of toughness or resistance to breakage, and moderately high hot hardness to resist softening at elevated temperature. Steel H12 is the most widely used of these three, although H11 and H13 are successfully used. There are no data that conclusively prove the superiority of one of these steels over another, except when special techniques such as water cooling are employed. Although water-cooled tools are not used extensively, some plants have found it advantageous to water cool dies and mandrels, either internally or externally, especially when extruding aluminum and magnesium alloys. This practice is also used in copper, brass, and steel extrusion. For water-cooled tools, either H11 or H13 is recommended in preference to H12, because H12 is more likely to crack.

Table 4 Steels and hardnesses recommended for hot extrusion tools

Tool	Alloys to be extruded		
	Steel, titanium alloys, nickel alloys	**Copper and copper alloys**	**Aluminum and magnesium alloys**
Perishable tools			
Die	H11, H13, H21 at 43-47 HRC[(a)]	H21, H23, H26 at 36-45 HRC[(a)]	H12, H13, at 46-50 HRC[(a)]
Backer	H12 at 42-46 HRC	H12, H13[(b)] at 45-48 HRC	H12, H13[(b)] at 48-52 HRC
Bolster	H12 at 42-46 HRC	H12, H13[(b)] at 42-46 HRC	H12, H13[(b)] at 48-52 HRC

Source: Ref 3

(a) For dies of complicated shape, hardness is usually 4 or 5 points Rockwell C less than the values shown.

(b) Alloy steels such as 6150, 4150, and 4350 are occasionally used.

(c) Higher molybdenum content (usually 0.40 to 0.50%) than standard.

As indicated in Table 4, alloy steels such as 6150, 4150, 4350, and modified 4350 (with higher-than-normal molybdenum content) are sometimes used for tools such as backers and bolsters. Steel 4350 (unmodified or modified) is widely used for containers. These alloy steels are much cheaper than the hot-work tool steels (the base price of 4350 is only about one-fourth that of H12), but the difference in steel cost is hardly enough to show a significant savings in the total cost of

smaller backers or bolsters. For larger tools that have heavier sections, the alloy constructional steels are precluded for backers and bolsters because of inadequate hardenability. Except for containers, the use of low-alloy constructional steels is limited for hot extrusion tools.

The 5% Cr hot-work tool steels are also used in some instances for extruding metals that require higher temperatures than aluminum and magnesium. However, when the temperature of the metal being extruded is above 595 °C (1100 °F), the higher-alloy hot-work steels such as H21 are more widely used and recommended, especially for dies, mandrels, and dummy blocks.

Die Materials for Cold Heading

A large percentage of cold-heading dies can be made from a shallow-hardening steel such as the water-hardening carbon tool steels with or without chromium and vanadium. Steels W1, W2, and W5, with carbon contents from 0.85 to 1.10%, are usually used. Heading dies are also made from tungsten carbides with a cobalt binder. A WC-25Co material is widely used for heading work and has the distinct advantage of being machinable: it can be bored, drilled, and turned with carbide tools. Dies that require greater wear resistance and that are subjected to less shock are made with 13 to 16% Co binder. These grades must be ground or lapped with diamond. Carbide dies are usually of the insert type, with a hardened steel case supporting the carbide insert. Although solid carbide dies have been used, unsupported dies of this type are extremely rare.

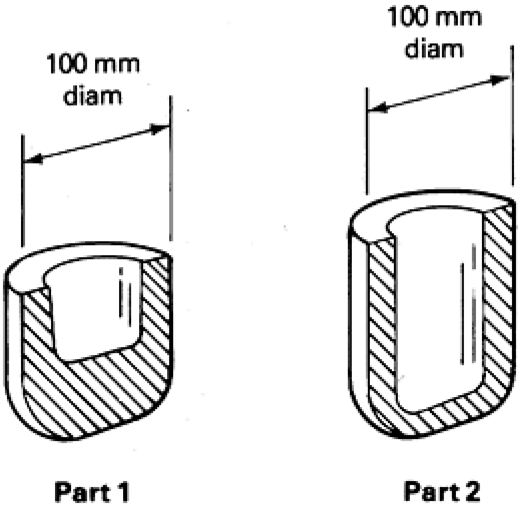
Die Materials for Cold Extrusion

Compressive strength of the punch and tensile strength of the die are among the most important factors influencing the selection of material for cold extrusion tools. Because the die is invariably prestressed in compression by the pressure of inner and outer shrink rings, the principal requirement for a satisfactory die is a combination of tensile yield strength and prestressing that will prevent failure. Punches require sufficient compressive strength to resist upsetting without being hazardously brittle. Thus, almost without exception, and particularly for extruding steel, the primary tools in contact with the work must be made from steels that will through harden in the section sizes involved. This is notably different from cold-heading tools, in which a hard case and soft core are usually desired.

Table 5 shows some typical recommendations for the punch, die, and knockout for two simple backward-extrusion operations. Both operations are similar in severity when part 1 is made from a cylindrical slug and part 2 is made from part 1 (in aluminum, part 2 can be made in a single step directly from a cylindrical blank).

Table 5 Recommended tool steels for backward extrusion of two parts

Metal to be extruded	Total quantity of parts to be extruded(a) 5,000	50,000
Punch material		
Aluminum alloys	A2	A2, D2
Carbon steel, up to 0.40% C	A2	D2, M2(b)
Carburizing grades of alloy steel	A2	M2(b)
Die material		
Aluminum alloys	W1(c)	W1(c)
Carbon steel, up to 0.40% C	O1, A2	A2(d)
Carburizing grades of alloy steel	O1, A2	A2(d)
Knockout material		
Aluminum alloys	A2	D2
Carbon steel, up to 0.40% C, and carburizing grades of alloy steel	A2	A2, D2



Note: Where two tool materials are recommended for the same conditions they are given in order of cost—the less expensive being shown first. (a) For part 1, starting with a solid slug; for part 2 starting with part 1. In aluminum, part 2 can be made directly from a cylindrical blank. (b) Liquid nitrided. (c) The 1.00% C grade is recommended. (d) Gas nitrided on the inside diameter only. Source: Ref 3

Source: Ref 3

The recommendations for dies to extrude these parts from steel are conservative, because a D2 punch might achieve a total life of 300,000 pieces, with 60,000 between redressings; for the dies, O1 might achieve 40,000 pieces between redressings and 160,000 total, as compared with 70,000 and 200,000 pieces, respectively, for A2 steel.

Because of economic considerations, sintered carbide should be considered for punches for long runs (over 500,000 parts) wherever press and die equipment is rigid enough not to cause breakage of carbide tools. When the wear limit of tools (or the part tolerance) is narrow, or when runs are long and production shutdowns must be avoided, carbide is used as insert material in the dies to extrude either steel or aluminum.

Die Materials for Sheet Metal Forming

The useful performance of a forming die is measured in terms of its wear. Total wear is affected primarily by the length of the production run and the severity of the forming operation. Hence, production quantity and severity are the most important factors in selecting die materials for forming. The metal being formed, its thickness, and the finish and dimensional tolerances required in the part are also influential factors.

Recommended die materials range from plastics for low reduction of simple to moderate parts, up to the most wear-resistant tool steels, surface hardened by nitriding, for making severely formed parts (Ref 3). Parts of even greater severity, or those run in quantities larger than one million, may require dies or inserts of cemented carbide.

Reference 3 gives a number of typical tool steels and performance data. Cast iron is a useful die material for forming parts larger than about 300 mm (12 in.). Its performance makes it suitable for use in medium production runs or in short runs of large parts. When cast iron is used with inserts, it will produce greater quantities. Cast iron should have predominantly fine pearlite with no massive carbides and a minimum of ferrite. Graphite should be of AFS-ASTM type A distribution with a preferred flake size of 4 to 5.

The zinc alloy recommended for some sheet forming dies has high pattern fidelity when cast, but requires very accurate shrink patterns to minimize hand labor in finishing. It is economical only for die components at least 300 mm (12 in.) long, and is most economical in dies about 900 mm (36 in.) long. One of its principal values is for complicated dies that would require intricate machining and hand tooling if made of cast iron, but which can be cast more closely with zinc. In tensile strength, compressive strength, and hardness, zinc alloy tools are inferior to other metals used in die construction. Nevertheless, a zinc alloy containing 4% Al, 3.25% Cu, 0.1% Mg, 0.7% Ni, and 0.2% Ti has provided die life up to three times that of the standard zinc alloys.

Where a limited variety of tool materials are available, hot-rolled mild steel plate with carbon content from 0.10 to 0.20% is in major use as a sheet-forming die material, and is also widely used elsewhere for shot-run forming of small parts. This type of steel is not recommended without surface hardening except for quantities of less than 10,000 parts. In addition, hot-rolled mild steel can be used for dies only where straightening facilities are available for correcting distortion induced by heat treatment.

Several medium-carbon alloy steels such as 4140 are available in plate form and are useful for some types of forming dies. For example, steels 8640 and 5140 are suitable alternates for 4140 and cost about the same.

Cast steel is used for forming parts larger than 300 mm (12 in.) long where the shape of the part makes a casting more feasible than wrought stock. Plain carbon steel (0.65 to 0.85% C) and alloy cast steel (0.40 to 0.50% C, 0.90 to 1.25% Mn, 0.90 to 1.25% Cr, and 0.35 to 0.50% Mo) are two commonly used compositions. Cast steel is more costly and more difficult to machine than cast iron and is more likely to gall. However, it is tougher than cast iron. One important advantage of cast steel, particularly the plain carbon grade, is its weldability. It can be rewelded with steel or hardfaced with tool steel, aluminum bronze, or other hardfacing material. Because of its poorer resistance to galling, it is less desirable for dies for forming carbon and stainless steels than for those for forming aluminum and copper alloys. Cast steel is also useful for restrike, flanging, and other types of dies that are less likely to gall or pick up material from the sheet.

Aluminum bronzes, which are alloys principally of copper and aluminum, are available in hardnesses ranging from 120 to 340 HB. These alloys have excellent resistance to galling and are desirable for dies where best finish is required on carbon and stainless steel parts.

For long runs, inserts of sintered carbide are now widely used, especially for deep-drawing dies. In dies of about 200 mm (8 in.) or less for continuous production of over 1,000,000 pieces, carbide has in many instances proved to be the most economical die material. Such dies have maintained size in drawing 60% reductions of more than 500,000 pieces and have made as many as 1,000,000 parts with reductions greater than 40% when the steel to be drawn was surface treated with zinc phosphate and soap. However, carbide is not superior to tool steel such as D2 in complex deep-drawing operations, such as those with reductions greater than 40% that combine drawing with coining or stretching.

Even more than with other tooling materials, the quality and economy of plastic tooling improves with shop experience and volume. Polyester, epoxy, phenolic resin, and nylon have been used. Plastic dies that achieve and longest life are constructed so that the wearing surface is faced with glass cloth that has had most of the plastic material forced out under

pressure before and during curing. Plastics are most economical when a model is available as a pattern for the lay-up of the plastic-impregnated glass cloth facing, which is backed up with chopped glass fibers impregnated with 50% resin. The strength (70 to 275 MPa, or 10 to 40 ksi) and, in particular, the hardness of plastics are inferior to those of metallic die materials. In some instances, the problem of obtaining the required strength in a plastic die must be solved by extra work in design or development. In many dies, however, the regions of high pressure are confined to local areas, which, if anticipated, are strengthened with metallic inserts.

Materials for Die-Casting Dies

The important properties required of materials for die-casting dies are resistance to thermal shock and to softening at elevated temperatures. Resistance to softening is required to withstand the erosive action of molten metal under high injection velocity. Other properties that influence selection of materials for die-casting dies are hardening characteristics, machinability, resistance to heat checking, and weldability. Availability and cost are also important, especially for dies larger than about 200 mm (8 in.).

The performance of die-casting dies is directly related to the casting temperature of the work metal, thermal gradients within the dies, and the frequency of exposure to high temperature. Tool steels of increasingly higher alloy content are required as the casting temperature increases. As indicated in Table 6, hot-work tool steels are not recommended for casting zinc except for long production runs.

Table 6 Recommended materials for die-casting and die inserts

Allow to be cast	Number of shots		
	50,000 or less	**250,000**	**1,000,000**
Zinc (25 mm die cavity)	P20[a][b]	P20[a][b]	P20[b], H13[b]
Zinc (100 mm die cavity)	P20[a][b]	P20[a][c], 4150 mod[d]	4150 mod[d], H13[b]
Aluminum or magnesium	H11, H13	H13, H11	H13, H11
Copper	H21, H20, H22, H23	. . .	. . .

Source: Ref 3

(a) Prehardened to 280 to 320 HB; SAE 4140, prehardened, can be used when best surface finish is not required.

(b) Recommended for die inserts.

(c) Hardenability barely adequate for these conditions.

(d) Tool steel quality modified to desired hardenability in prehardened condition.

Die hardness for zinc casting is less exacting than for alloys of higher lasting temperature, which usually permits the use of steels prehardened by the manufacturer to a maximum hardness consistent with suitable machinability. A typical hardness range is 29 to 34 HRC. Also under development and in preliminary commercial use are precipitation-hardening steels for die-casting dies. In addition to being hardenable, they have superior machinability at higher hardness than quench-hardening tool steels.

Hot-work tool steels are almost always used for casting the higher melting point alloys, such as aluminum and copper. For aluminum and magnesium alloys, the H11 and H13 steels are hardened to about 44 to 48 HRC; the H20, H21, and H22 steels for casting copper alloys are generally used in the hardness range from 38 to 45 HRC.

Forging steels of tool steel quality and increased hardenability occasionally are used for applications requiring die blocks so large as to be unavailable in hot-work tool steel. However, the use of these high-hardenability steels is limited by the availability of the forgings and greater difficulty in welding them. Sometimes unhardened low-alloy steels are used for dies of simple design and for short runs of noncritical parts.

Wear and Failure in Die-Casting Dies

The die-casting process uses internally cooled metal dies to mold aluminum, zinc, brass, and other materials into intricate cast shapes. It provides a rapid, close-tolerance, and high-production method for producing large volumes of parts at a relatively low cost--for example, automotive parts such as carburetor bodies, transmission cases, and valve bodies.

Die life is a major consideration in a die-casting process, because, depending on the complexity of the part being produced, a die may cost more than the die-casting machine itself. Die lives may vary from 20,000 to over 250,000 parts depending on die design, die material, workpiece material, and the thermomechanical processing involved.

A typical design for a die-casting die is shown in Fig. 6. It includes two sections: the fixed die half and the ejector die half. The fixed die half is mounted toward the liquid metal injection system. The ejector die half is mounted on a movable platen of the machine. The casting, on cooling, sticks to the movable die half and is ejected via ejector pins mounted on an ejector plate. Guide pins ensure proper alignment of the two halves. Die inserts contain the outside geometry of the part in a cavity into which the molten metal is injected under pressure. Fixed or removable cores are positioned at positions where holes in the casting are desired. Heat is removed from the die by circulating cold water through cooling vents in the dies.

Fig. 6 A typical die-casting die. Source: Ref 20

During its service life, the die cavity (inserts) and cores experience a large number of thermomechanical cycles. A network of fine cracks develops on the die surface due to thermal fatigue. This failure mode is called heat checking and can cause rejection of the casting. The die may be repaired by grinding or welding, or discarded if gross cracking occurs due to thermal shock. In addition to heat checking and gross failure, other failure mechanisms include abrasive wear, adhesive wear, stress-corrosion, and erosion due to liquid metal attack. With the exception of molten zinc, investigators have found very little evidence of reaction between molten materials and die steels. Table 7 shows some of the factors that limit die lives for different casting metals.

Table 7 Life-limiting factors for die-casting dies

Casting alloy	Factors that limit die life	Normal life, number of shots × 10^3	
		Die	**Core**
Zinc	Erosion, mechanical abrasion	500-1000	500-1000
Aluminum	Heat checking, cracking, erosion, low compressive strength	100-250	50-150
Copper (brass)	Heat checking, low compressive strength, erosion, cracking	10-100	3-20

Wear and Failure Modes in Die Casting

Wear and failure of die-casting dies involve a complex interaction between various failure modes. Some of the important wear and failure modes are (Ref 21, 22, 23, 24, 25, 26, 27, 28, 29):

- Erosive and abrasive wear
- Chemical attack, or corrosion
- Thermal fatigue, or heat checking
- Soldering
- Gross cracking, including thermal shock

Thermal fatigue is the most important failure mode, followed closely by soldering. These two modes often cause frequent shutdowns and redressing of the dies. Erosive wear, which depends on the impinging velocity and the angle of impact, can be minimized substantially by proper gating design (Ref 23). Chemical attack (corrosion) is important in that it influences the initiation and growth of heat-checking cracks. Gross cracking, however, is primarily due to mechanical or thermal overload (thermal shock) and can be mitigated by cavity redesign. These failure modes will be further described below.

The moving parts of the die-casting die (cores, slides, and pins) are required to have all the properties of the stationary parts, and they must also be resistant to wear. The wear of die-casting dies can be reduced by (Ref 22):

- Nitriding one or both of the surfaces of contacting steels
- Using lubricants
- Shallow notching or dimpling of the slide or gib
- Maintaining a proper fit between wearing couples
- Providing polished surfaces on mating members

Erosive Wear. Wear in die-casting dies is primarily due to erosion of the die surface, which involves the washing away of die material by the impinging jet of an incoming molten metal stream. Erosion is a function of gating and casting techniques and properties of the die material. The impingement velocity and angle of molten metal jet against a core or die face at the gate inlet can be reduced by proper die design (Ref 30).

For casting copper alloys, the moving parts and the cavity that come in contact with molten metal are made from the same hot-working die-steel. Parts not in contact with the melt can be made of alloy steel such as 6145, which has good hot hardness.

Test for Erosion and Corrosion Evaluation. In die casting, it is often difficult to differentiate between erosion and corrosion phenomena, and the die damage mechanism may actually be a combination of erosion and corrosion. A laboratory test method has been developed at the Uddeholm Steel Research Department in Sweden to evaluate erosion-corrosion resistance of die steels (Ref 21). A schematic of the equipment setup is shown in Fig. 7.

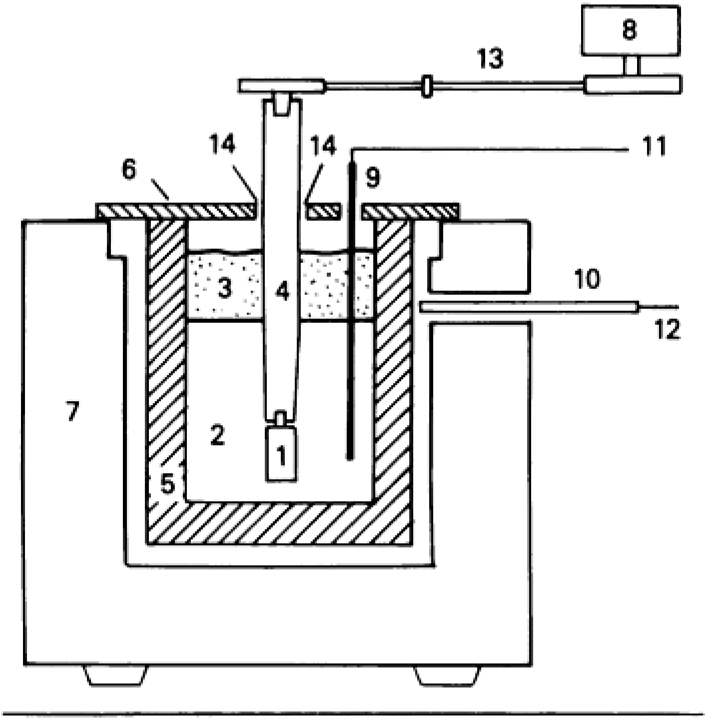

Fig. 7 Equipment for erosion-corrosion test in various molten metals. (1) Testpiece, (2) molten zinc, (3) graphite, (4) graphite bar, (5) graphite crucible, (6) refractory cover, (7) furnace, (8) motor, (9) and (10) thermocouples, (11) to potentiometer, (12) temperature regulator, (13) chain drive, (14) inlet orifice for nitrogen gas. Source: Ref 21

The erosive attack of the melt on the die surface is influenced by both the material properties and process parameters, including steel grade, heat treatment, surface treatment, melt composition, and temperature. Weight loss due to erosion-corrosion in a large number of die steel samples was measured for zinc, aluminum, and brass melts. In a commercial zinc melt at 500 °C (930 °F), the losses were relatively small, but at 600 °C (1110 °F), most steel grades reported significant weight loss differences as shown in Fig. 8. In an aluminum melt, wear losses for soft annealed dies were significantly higher than those for hardened dies (Fig. 9). Brass melts were found to react more strongly in steels with higher nickel content (Fig. 10).

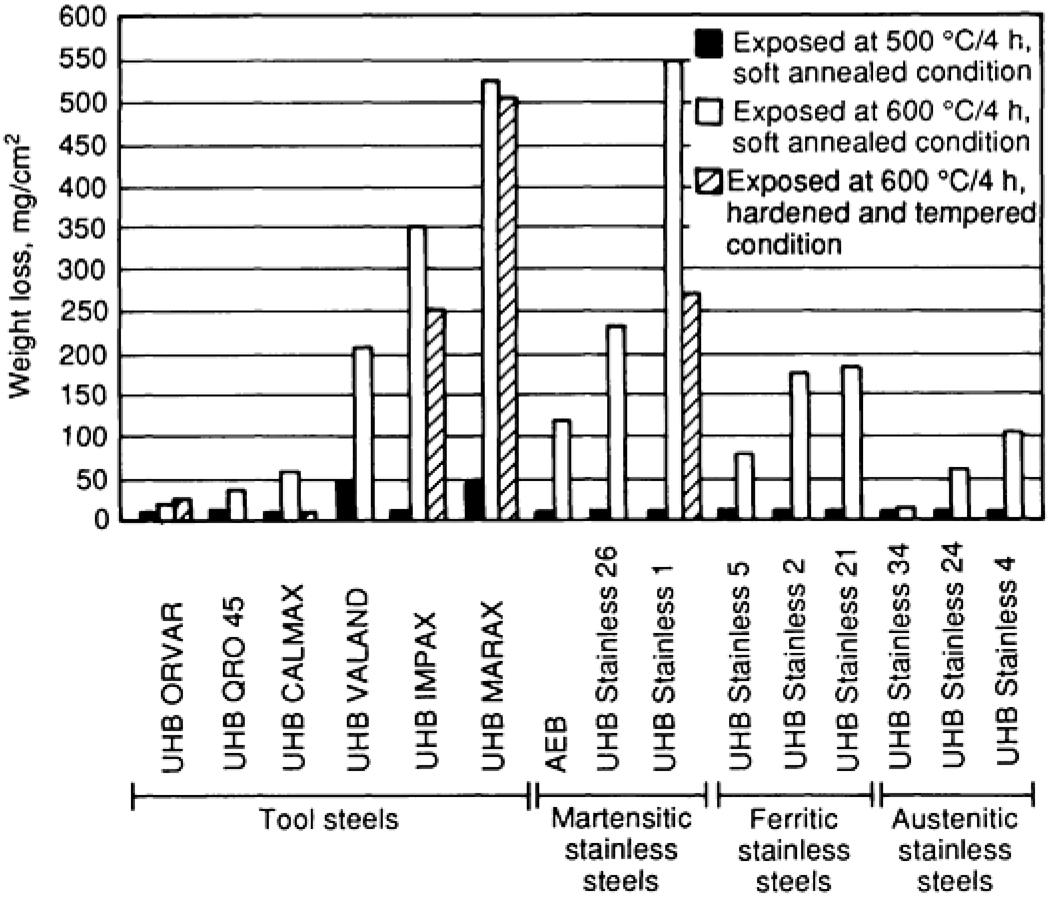

Fig. 8 Weight-loss measurements for different Uddeholm Steel die steel grades tested in a zinc (Zn-4Al) melt. Source: Ref 21

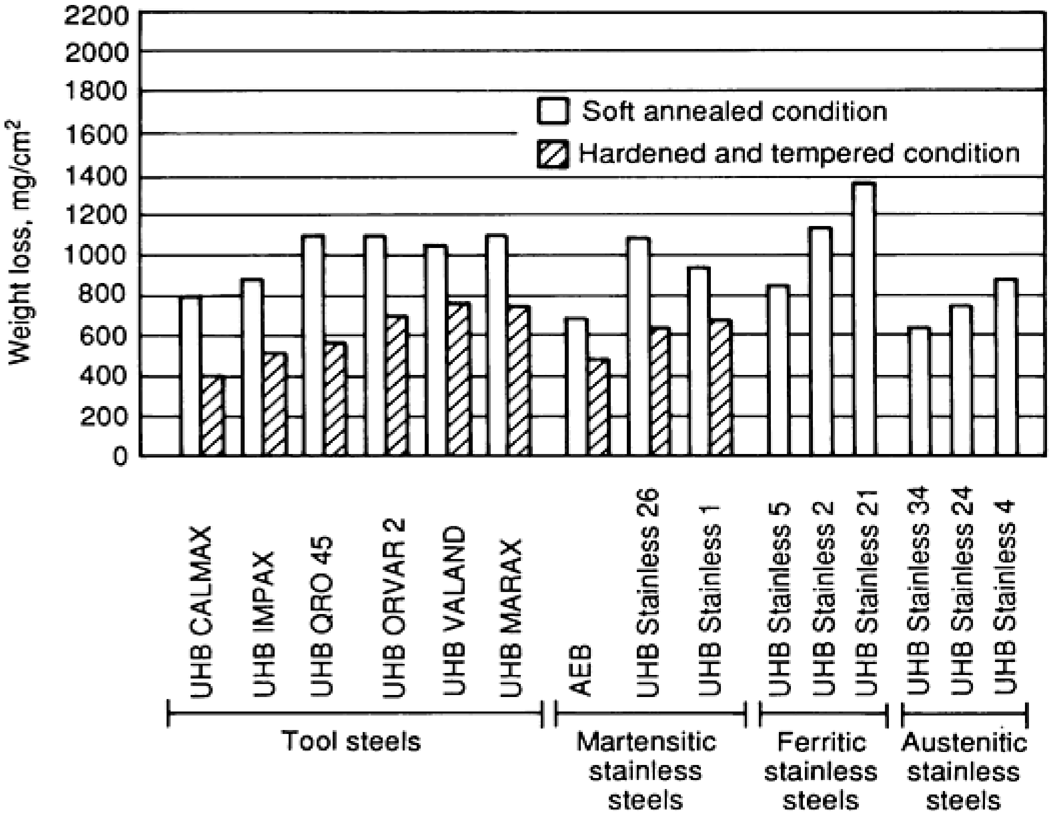

Fig. 9 Weight-loss measurements for different Uddeholm steel grades tested at 735 °C/4 h (1355 °F/4 h) in an aluminum (Al-9.9Si-0.8Fe) melt. Source: Ref 21

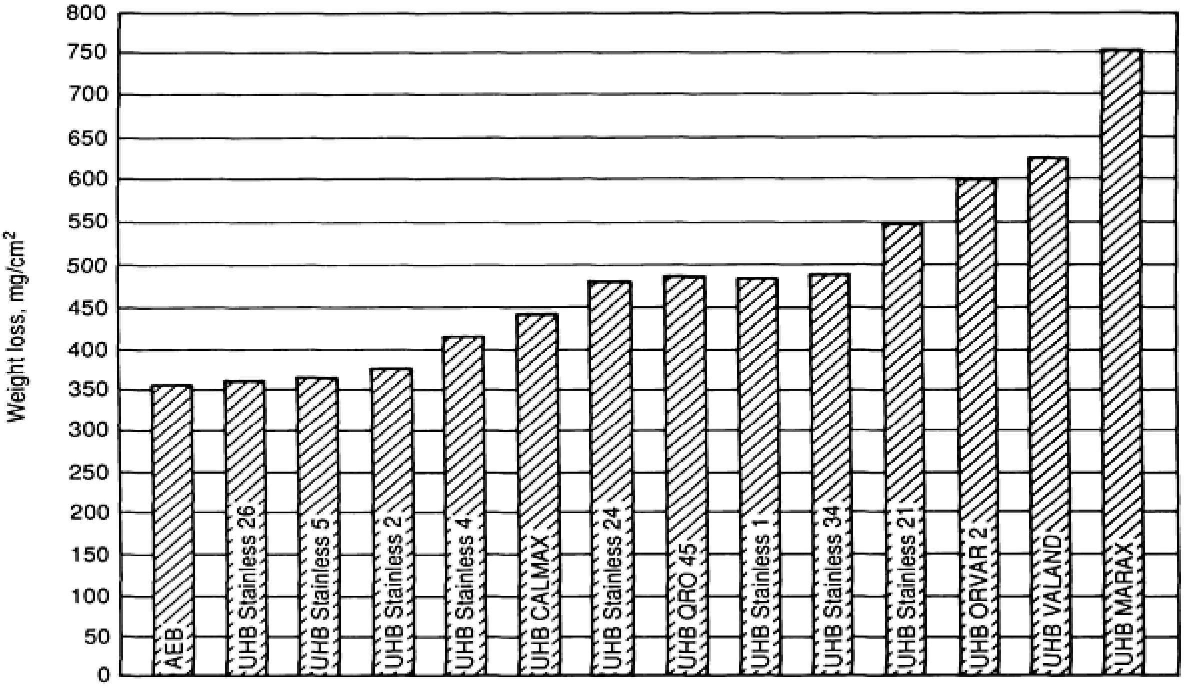

Fig. 10 Weight-loss measurement for different Uddeholm steel grades tested at 950 °C (1740 °F) for 4 h in a brass (Cu-38Zn-1Pb) melt. Source: Ref 21

Soft-annealed and hardened-and-tempered steels were also tested (Fig. 11). Hardened-and-tempered steels showed lower weight losses in zinc and aluminum melts. The higher alloy content in hardened-and-tempered steels reduces molten metal attack.

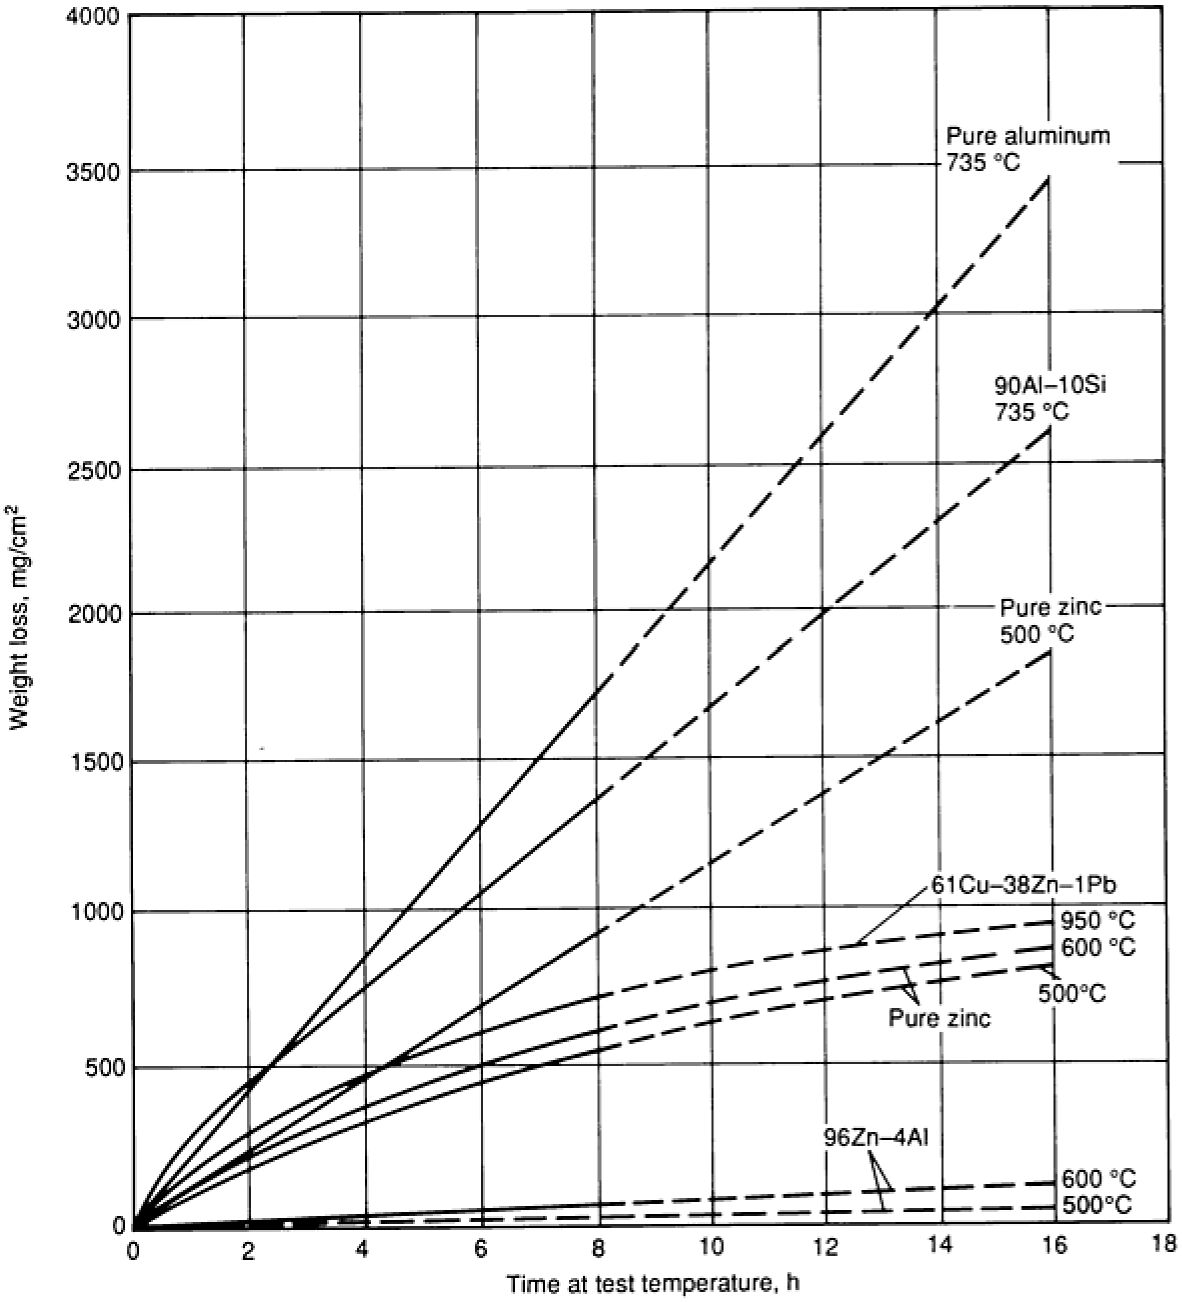

Fig. 11 Erosion rates of soft-annealed Uddeholm UHB Orvar 2 (AISI H13) samples tested in different melts. Source: Ref 21

A large number of different surface coatings were tested. It was found that erosive wear is substantially reduced if the protective oxide layer does not detach from the die surface during the casting process. Similar conclusions are reached with nitrided surfaces.

Melt composition also influences erosion-corrosion. Figure 11 shows large differences in weight loss caused by different melts. In zinc and aluminum melts, wear loss increases rapidly; in the case of brass melts, the wear loss increases gradually with melt temperature and time.

The following general conclusions can be drawn regarding erosion (Ref 21):

- Pure zinc melts are more prone to problems than commercial zinc alloys. The melt composition also seems to be a very important parameter for aluminum and brass melts
- Erosion attack generally decreases with decreasing melt temperature. Melt temperatures should be kept as low as possible, for example, zinc alloys ≤480 °C (≤895 °F), aluminum alloys ≤735 °C (≤1355 °F), and copper alloys ≤1000 °C (≤1830 °F)
- There appears to be no significant difference in erosion loss among different common hot-work tool steels
- Hardened-and-tempered samples generally show smaller losses than soft-annealed samples
- If metallic contact between the tool steel and the melt (such as by an oxide film) can be avoided, the risk of severe erosion attack decreases significantly

Heat checking in die casting is often caused by thermal fatigue, surface stresses, low material strength, and surface irregularities. During the process cycle, alternate heating and cooling leads to thermal fatigue. Mechanical and thermal stress fluctuations initiate fine cracks on the cavity surface that grow larger and ultimately lead to failure of the die. A considerable body of research on the resistance of die materials to heat checking and thermal fatigue has also been generated at Uddeholm Steel. Most noteworthy are a qualitative heat checking rating diagram scale (Ref 21, 30) and a laboratory test for determining thermal fatigue (heat checking) properties of hot-work tool steels (Ref 21, 31, 32).

Materials Resistant to Heat Checking. To resist heat checking, die materials should have a low coefficient of thermal expansion, high thermal conductivity, high hot yield strength, good temper resistance, high creep strength, and adequate ductility (Ref 31). The coefficient of thermal expansion governs the magnitude of strains and stresses produced due to temperature changes and is strongly dependent on the type of microstructure of the die material. All steels with martensitic, bainitic, and ferritic microstructures have approximately the same thermal expansion coefficient. Steels with austenitic microstructure have 50% higher expansion coefficient values and are not suitable for die-casting applications. High thermal conductivity reduces thermal gradients by permitting rapid heat transfer from hot to cold locations. Lower temperature gradients produce lower thermal stresses. The hot yield strength governs the amount of plastic strain for a given temperature cycle. Heat checking, a low-cycle fatigue phenomenon, is controlled basically by plastic strain amplitude. Therefore, high hot yield strength is desirable. To maintain high hot yield strength at prolonged exposure to high temperature, good temper resistance is necessary. Temper softening, which is often accentuated by superposed mechanical loads, can be controlled by good creep strength. Because ductility is a measure of a material's ability to resist plastic strain without cracking, adequate ductility is essential for resistance to heat checking.

Thermal shock is gross cracking due to sudden temperature changes (Ref 30). It is a macroscopic phenomenon and often results in total failure of the dies. Thermal shock is primarily resisted by good material toughness and ductility and, to some extent, by high hot yield strength. A test method developed at Uddeholm Steel for evaluating thermal shock resistance is described in Ref 30 and 31.

Factors Influencing Wear and Failure in Die-Casting Dies

The factors influencing different wear and failure modes can be grouped as follows:

- Geometric factors in the design
- Die material factors, including heat treatment
- Interface factors, including lubrication, surface treatments, and coatings
- Processing factors, including heating and cooling cycles

The geometric factors in die design govern the mechanical stress and thermal gradients that develop in the die. Some important die design considerations are (Ref 31):

- Cavity should not be too large for the die block--there should be enough material left in the die to provide adequate strength and rigidity
- To minimize chilling, the die impression should not be too close to the water-cooling chamber
- Location of gating, venting, offsets, undercuts, deep narrow recesses, cores, and inserts should be optimized to reduce stress or thermal gradients
- Irregular cavity contours and sharp corners should be adequately filleted to reduce stress concentrations
- Location of large areas of molten metal in close proximity to smaller areas should be avoided

Part tolerances also influence die lives. Tighter part tolerances reduce die lives by permitting less wear on the dies. Surface finish requirements of the part can also limit die usage.

Die Material Considerations. In order to resist failure, die materials should have uniform microstructure, no internal defects, good machinability, good polishability, good response to heat treatment, good toughness, resistance to wear, and resistance to heat checking. Because H13 is the most commonly used die steel (H11 and H12 are sometimes used) for die casting, the effect of the material is limited to its manufacturing technique and the heat treatment. Although air-melted steels are less expensive, vacuum arc remelted (VAR) steels have better toughness and higher hot yield strengths (Ref 27). The austenitization and homogenization heat treatments have to be tightly controlled to achieve the most desirable microstructure. Rapid quenching is often prescribed to obtain martensitic microstructure. However, stepped cooling to lower bainite is often preferred because of higher toughness values (Ref 23).

Interface Considerations. Use of commercial die lubricants or mold release agents reduces soldering or sticking of the casting to the die. This subsequently reduces die wear. Some lubricants, however, reduce die life by chemically attacking die steels and also the casting metal adhering to the die surface. An effective lubricant permits easier cleaning of the dies, reduces wear, and allows longer runs between die polishes.

Surface treatments such as nitriding are often used to reduce erosive wear. A nitriding treatment can be substituted for the third, or final, temper of the dies (Ref 30). The surface hardness of H13 when gas nitrided can be 65 to 70 HRC. This extra hardness is desirable for die-casting dies that have been tempered to a lower hardness for increased toughness; the hard surface resists wear but not necessarily heat checking. The original hardness of the interior is not lowered because nitriding is done in the temperature range of 525 to 540 °C (975 to 1000 °F), which is usually below the tempering temperature of H13 steel. However, the nitrided case depth should not exceed 0.13 mm (0.005 in.); deeper cases can result in flaking or spalling damage at parting lines and sharp edges. Spalling of a nitrided surface (which causes undercuts in the spalled area) leads to tearing of the casting during ejection and to damaged cores. The use of a solid release agent lessens soldering, spalling, and abrasion. The use of molybdenum disulfide or colloidal graphite in oil also reduces wear.

Nitriding is especially beneficial in reducing abrasive wear due to sliding of moving components such as ejector pins, slides, and cores (Ref 33). However, the core and slide ends that contact molten metal must be masked against nitriding so as to obtain better resistance against heat checking and spalling. Ejector pins are available made from either nitrided H11 or nitriding steels such as 7140.

Sputtered coatings have also been evaluated for wear and heat checking resistance (Ref 32, 34, 35). Platinum, molybdenum, and tungsten have good resistance to thermal fatigue. They also inhibit oxidation of the substrates, which delays crack initiation. But once the coatings crack, heat checking of the exposed substrate is often higher than that of the virgin material due to the preferential site of metal attack. Carbide coatings such as niobium carbide or vanadium carbide have been successfully applied to die casting dies via the Toyota Diffusion (TD) process. These coatings have reduced die wear substantially in laboratory and selected production tests (see the section on "Surface Treatments and Coatings" in this article).

Processing conditions such as imposed mechanical and thermal loading histories influence die failure modes with more severe loadings resulting in increased wear and failure rates. Die preheating and machine locking power also affect die service lives (Ref 22).

Wear in Sheet Metal Forming Dies

The amount of wear of dies during sheet metal forming is proportional to the distance the sheet metal slides over the die for a given pressure between the surfaces in contact. Thin annealed sheet metal exerts the least pressure and thus causes the least wear; thick hardened sheet metal causes the most rapid wear. However, the rate of wear for different combinations of die/sheet metal pair may vary considerably, depending on material surface characteristics, the speed of forming, and the type of lubrication.

In the forming of parts with dies that produce wrinkles, high localized pressures develop on the tools. In the ironing stage, these wrinkles produce prohibitively high rates of wear and galling.

Sheet metal working consists of blanking or cutting, forming of shallow parts, and deep drawing. Wear of blanking dies will not be considered in this article but wear occurring during shallow forming and deep drawing will both be considered separately. The latter two operations impose different stress fields and wear profiles on the forming dies. Some recommendations are made concerning die material selection based on the expected die lives.

Information provided in this section is primarily from Ref 36 and 37. Reference 38 describes methods for testing mechanical behavior of steel sheet coated with corrosion-resistant coatings (zinc-aluminum); Ref 39 details a method for wear data processing. The topics described in Ref 38 and 39 will not be considered in this section because the focus is on die wear.

Wear in Shallow Forming Dies

To understand wear in shallow forming dies, it is essential to study the mechanics of the process based on the true shape of the parts to be drawn. For this purpose, six sample part shapes are included in Fig. 12, ranging from the simple shapes such as those of parts 1 and 2, to moderately severe shapes such as those of parts 5 and 6.

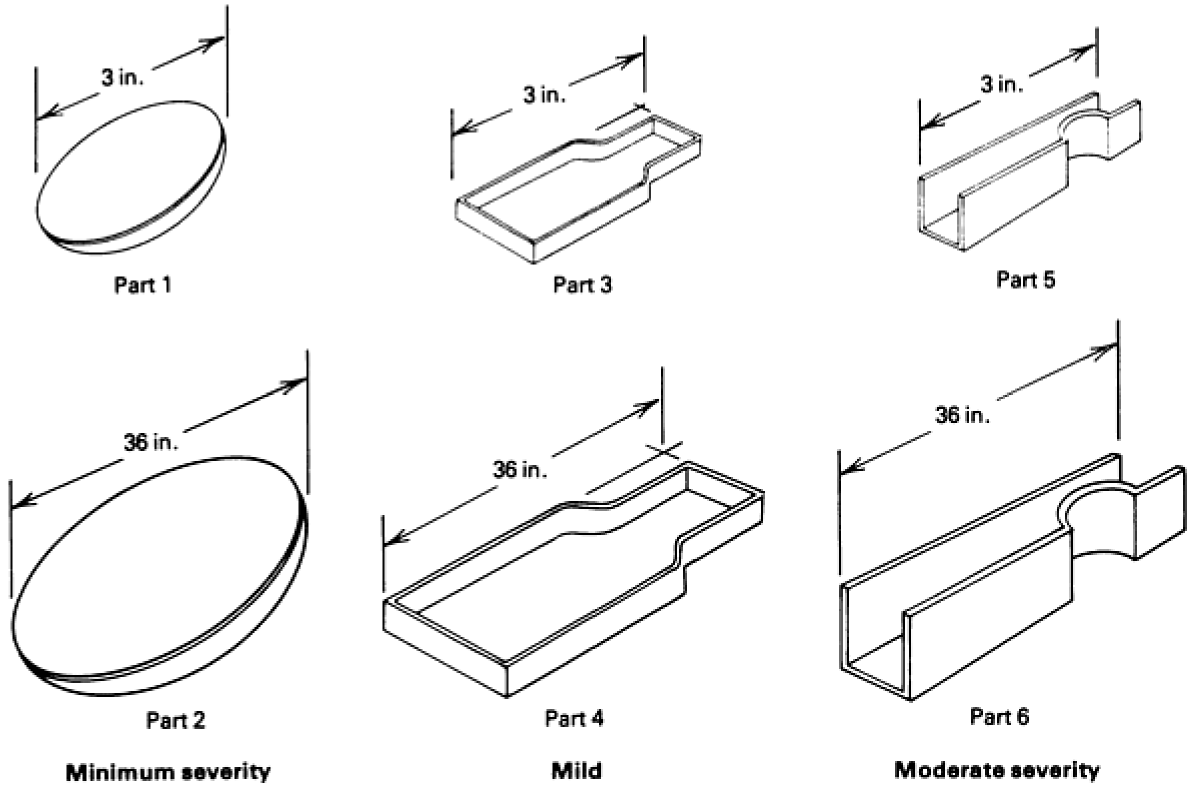

Fig. 12 Parts classified into six classes based on severity of draw. Source: Ref 36

Recommended die materials for these shapes range from plastics for low-quantity production of simple-to-moderate parts, up to the most wear-resistant (nitrided) tool steels for making severely formed parts. Parts of even greater severity, or those run in quantities larger than one million, may require dies or inserts of cemented carbide.

Effect of Part Shape. The tooling for parts 1 and 2 consists of a punch and an upper and lower die. Because there is little deformation of the sheet metal during forming of such simple parts, little or no sliding of the sheet over the lower die, and little movement over the punch, these components have very low wear rates.

Tooling for part 3 consists of a punch and lower die. In forming, the punch pushes the blank through the lower die, which results in sliding on the lower die, but there is little sliding on the punch. Therefore, the punch generally has ten times the life of the lower die made from the same material. However, wear and galling are expected in the areas of moderate shrinkage of this part, particularly when the part is formed on these single-action dies.

Tooling for part 4 consists of a punch and upper and lower die. Without the upper die, excessive wrinkling would be expected at the shrink flanges. As in part 3, a less wear-resistant material is required for the punch and upper die than for the lower die due to greater sliding occurring on the lower die.

The tooling for parts 5 and 6 consists of a punch and lower die with no upper die required because these parts are produced by stretching rather than by shrinking of the metal along the constricted region. The metal envelops the punch with minimal sliding and consequently produces about ten times more wear on the lower die than on the punch. However, the same material can be used for both the punch and lower die for part 5 because of the smaller part size and minor material cost. In the selection of die material for part 6, the critical locations are the wearing edges of the lower die. The body of the lower die could be made of cast iron with wearing edges of tool steel, and the punch could be of a material less wear resistant than tool steel, for example, low-cost alloy cast iron.

Effect of Sheet Thickness. Thick sheets of any metal will exert greater pressure on the dies than thin sheets of the same metal. Therefore, the effect of galling and wear increases as parts are made from thicker sheets, especially parts with shrink flanges. Consequently, for high-production dies working under severe wear conditions and for production of parts to close tolerances, it is often desirable to use an extremely wear-resistant material such as sintered carbide or nitrided D2 tool steel.

Effect of Tolerance Requirements. Tolerance requirements of the part affect the selection of tool material if the part is to be finished without redrawing. When the part is to be redrawn, the material used in the redrawing die is subjected to less wear than the die that performs the primary operation. A major factor in the choice between a wear-resistant material and a less costly and less wear-resistant material is the necessity for maintenance during the production run. If the production run is large and the tolerance requirements tight, costly wear-resistant materials or coated punches have to be considered.

Effect of Sheet Metal. Sheet stock of a higher hardness will usually wear dies more rapidly, but other factors, such as the presence of scale on the surface of unpickled hot-rolled steels, are sometimes of greater importance. However, scales reduce galling, which, on tool materials, may be an even more serious condition than abrasive wear and can result in frequent interruptions for reconditioning the die.

Soft brass or aluminum stock causes less wear and galling than carbon steel, whereas stainless steels and heat-resistant alloys cause more wear and galling. Possible surface treatments include chromium plating of any hardened steel, hardening of alloy cast iron, and nitriding of tool steels such as A2 and D2.

Effect of Lubrication. In low- or medium-production runs, lubricants are often used; in zinc dies, they are a necessity. However, the most effective lubricants are difficult to apply and remove. Efficient application of lubricants is particularly difficult in high-production operations where presses are being fed automatically. In such operations, die materials that are costlier but more resistant to galling (for example, aluminum bronze, nitrided D2 tool steel, and sintered carbides) should be used.

Prevention of Galling. Galling is primarily due to large stretching of sheet metal, poor tool fitting, and rough finish on the surface of tools. For short or medium runs, surface-hardened hot-rolled steel dies can be used that are less costly than tool steel dies. Tool steels are recommended for severe reductions or for forming metals that show a greater tendency to gall, such as austenitic stainless steel.

If galling is encountered, the tool fit and thickness of the stock metal should be checked first to determine whether clearances are adequate. Ironing out wrinkles causes galling. Wrinkles can be prevented by redesign of the tools.

Surface nitriding of dies made from alloy steel or alloy tool steel such as A2 or D2 minimizes galling. But in die steels containing no nitrideforming elements such as chromium or molybdenum, nitrided surfaces may spall on radii smaller than about 3 mm ($\frac{1}{8}$ in.), and plated surfaces may spall on radii less than 6 mm ($\frac{1}{4}$ in.). Hard chromium plating will usually eliminate galling of mild steel, alloy steel, and tool steel dies. But to avoid cracking of the hard coating in operations involving high local pressures, hardened steels such as alloy or tool steels should be used as the substrate. Dirt, grit, and shot fragments on the sheet cause greater damage to nitrided and chromium-plated tools than to hardened tool steels; hard particles may cause minute spalling and small pits, especially at radii in areas of high forming pressure.

Galling is less likely if the die and stock materials are dissimilar in hardness, chemical composition, and surface characteristics (for example, aluminum bronze tools for forming carbon steel and stainless tools for aluminum parts).

Galling is also related to the thermal softening resistance of the die material. Galling and pickup are caused by the extremely high frictional heat generated between the die material and the steel being formed, which results in the softening of the die material and increased pickup.

On the basis of tests conducted by an automobile manufacturer, it was concluded that (Ref 36):

- Metal pickup on the faces of flanging dies is due to the frictional heat generated by two metals rubbing together under high pressure
- Excessive heat is generated if the length of contact is longer than needed to form the flange
- Correct die lubricants should be chosen. For example, when heavy gages are being formed, an extreme-pressure (EP) die lubricant should be used

Wear and galling are less severe with soft stock material, such as aluminum and copper alloys, than with low-carbon steel; they are more severe with high-strength metals such as stainless steels and heat-resistant alloys.

Die Wear and Die Life Studies. The important factors influencing the wear and life of sheet metal forming dies are the composition and hardness of the die material and the part, and the thickness, shape, and quantity of the parts to be formed. Effects of these factors are shown graphically in Fig. 13. The data for Type 4140 steel show the effect of die hardness: its die life increases about 800% when nitrided (Fig. 13a). Effects of the tool material composition and hardness are seen in the forming of the label holder (Fig. 13b), and in the forming of the bushing (Fig. 13c). M4 and D7 at 65 HRC gave more than twice the die life of D2 (61 HRC) in flanging the shredder ring of 17-7 PH stainless steel shown in Fig. 13(d).

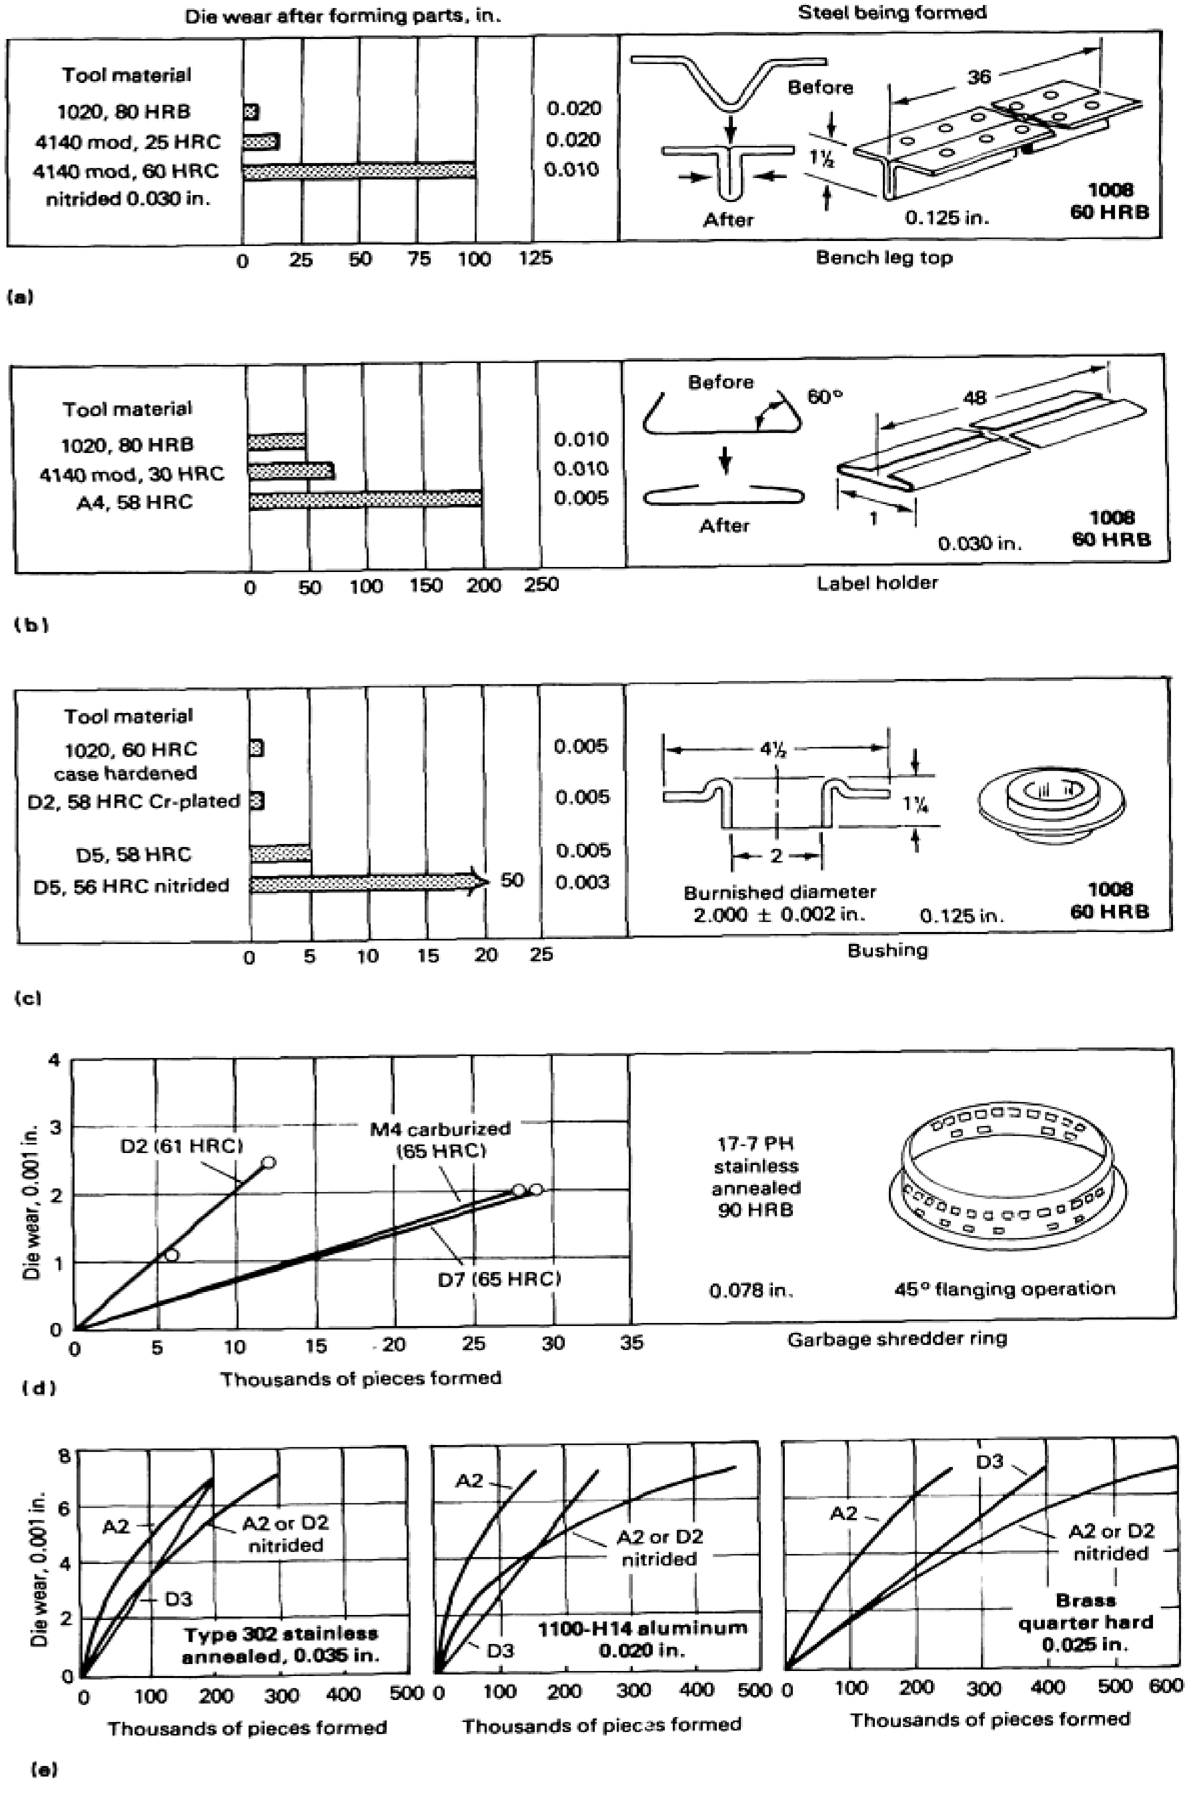

Fig. 13 Data on die wear and die life. The three plots in the bottom row relate to small instrument parts having a maximum area of 19 cm^2 (3 in.^{2}). Source: Ref 36

The plots in Fig. 13(e) show the influence of die and stock material on wear of dies for making parts of similar shape. The wear rate gradually decreases for nitrided steels due to the wearing away of the outer layer (white layer).

Wear in Deep-Drawing Dies

This section deals with the wear of material for dies to draw round and square cup-shaped metal parts in a press, primarily by conventional drawing in which each reduction is made in the same direction. Deep drawing is associated with extension and bending of the sheet over the punch nose, together with the gathering and compression of the sheet metal as it is drawn through the die. For economy of manufacture, the drawn part is always produced in the least number of steps using the least number of dies possible. Ironing is used almost universally in multi-operation drawing and to increase uniformity of wall thickness. Each operation is designed for maximum practical reduction of the metal being drawn; the examples given in this section involve maximum reductions of about 35%.

The performance of a deep-drawing die is determined by the amount of wear or galling during a production run. Wear of a given die is determined largely by the material and thickness of the sheet steel, sharpness of die radii, lubrication, die design, and finish. The amount of wear on die radii can vary by as much as a factor of 20 between the sharpest and most liberal radii.

In drawing square cups, the formation of wrinkles at the corners accompanied by high localized pressures may produce prohibitively high rates of wear. Small corner radii will result in greater wear and shorter life of the dies.

High localized pressures caused by inaccurate fitting of dies during tryout, rough surface on the drawn sheet or on the working surfaces of the die, inadequate lubrication, and poor maintenance (stoning) of dies are typical of uneconomical practice.

Effect of the Thickness of Sheet Metal. In drawing thick sheets of a given metal, the pressure on the dies increases in proportion to the square of the sheet thickness. The die pressure is higher on the draw radius, and increasing sheet thickness will localize the wear in this high-pressure area without a similar effect on other surfaces of the die.

Thick stock will wrinkle less than thin stock; therefore, the pressures required to prevent wrinkling are less than those required for thin stock. However, heavy sheets are often drawn without a pressure pad. Therefore, the wear-resistance requirements for pressure pads used on heavy stock are no greater than those for thin material.

Reference 36 gives recommendations for tool materials for drawing and ironing sheet steel and plate ranging in thickness from 0.38 to 13 mm (0.015 to 0.500 in.). Alloy cast iron is often flame hardened for long runs and thick sheets; for small quantities and thin sheets, it may be used as-cast. For the mildest applications, unalloyed gray iron may be used.

Prevention of Galling. Common causes of galling are stretching sheet metal beyond practical limits, tool fitting with poor alignment or insufficient die clearance for the given sheet thickness, wrinkles, the use of galling-susceptible tool steel, and rough finish on the surface of tools.

Die materials to resist galling can be selected on the basis of their resistance to softening under heat. For example, T15 steel is the die material that has highest resistance to softening and thus the best galling resistance; W1 steel has the poorest resistance to softening and galling.

For parts drawn of carbon steel or nonferrous alloy sheet, the die material can be selected without regard to galling; as a finishing operation, the punch and die should be either nitrided or chromium plated. If chromium-and molybdenum-containing tool steels such as A2, D2, D3, or D4 have been selected, the smoothly ground tools should be nitrided and polished or buffed after nitriding. Otherwise, the tools should be hardened to at least 60 HRC, smoothly finished on the wearing surfaces, hard chromium plated, and the plating polished or buffed. Punches should be plated to a thickness of 0.05 to 0.01 mm (0.0002 to 0.0004 in.). To prevent spalling or flaking of the plate, dies should not be plated more than 0.005 mm (0.0002 in.) thick.

When the parts are drawn from stainless steel or from high-nickel alloy steel, the draw ring material with best resistance to galling is aluminum bronze. The second choice is either D2, D3, or D4 (smoothly ground, nitrided, and polished). The third choice is alloy cast iron (quenched and tempered to 400 to 420 HB).

Punch material is selected without regard to galling and is then chromium plated (as with die materials), unless cast iron is chosen.

Sintered carbide, which is only as efficient as the lubricants used, has proved economical for nonferrous alloys, carbon steel, and stainless steel in many long, continuous runs; however, galling will occur as soon as lubrication becomes faulty.

Effect of Lubrication. Correct lubrication of the parts being drawn is essential to reduce friction, wear, and galling. In fact, deep drawing is impossible without lubrication. In actual practice, die materials are selected after trials employing the production lubricants. If excessive wear or galling occurs, a better lubricant is usually applied. For extremely difficult draws, the best lubricants are usually applied at the outset.

Chromium Plating to Reduce Wear. Chromium plating is used on tool steel draw rings to improve life. On punches, its primary function is to reduce the frictional forces and facilitate removal of the parts from the punch after the sidewalls have been ironed tight to the punch. Usually chromium plating improves punch life somewhat less than it would be improved by the use of the next best tool steel.

For successful performance of tools, chromium plating must always be deposited on a surface harder than 50 HRC, and the thickness of the coating should preferably be 0.05 to 0.01 mm (0.0002 to 0.0004 in.) and never less than 0.0025 mm (0.0001 in.). This gives the required hardness and reduction of friction without excessive spalling or chipping at corners. Chromium-plated dies should be heated to 150 to 205 °C (300 to 400 °F) for a minimum of three hours immediately after plating to minimize the possibility of hydrogen embrittlement.

Die Wear in Hot Forging Dies

In forging steels, die life is often controlled by abrasive wear. Thus, die wear and die life are often thought to be synonymous. However, wear is but one of the several mechanisms by which dies are rendered unusable (Ref 40, 41). Another common mechanism in hot forging is thermal fatigue, or thermal cycling, which gives rise to superficial cracks often known as heat checks. Analogous with thermally induced cracking is mechanical fatigue, or cracking that results from the cyclic application of the forging loads. If the loads are very high or the dies relatively soft, plastic deformation of the dies may occur, making it impossible to impart the desired shape to the workpiece. Although it is not unusual for several of these mechanisms to contribute to die failure, abrasive wear will be emphasized in this section.

Methods of Characterizing Abrasive Wear

The amount of die material removed because of abrasive wear is directly proportional to the interface pressure and the amount of relative sliding, and inversely proportional to the hardness of the metal surface. Most forging dies are typically of rather complex geometry. Therefore, the interface pressure and amount of relative sliding can vary from one area to another. Hence, characterization of abrasive wear in a systematic manner typically makes use of simulative tests of simple geometry.

Most simple die wear studies have made use of upset compression of cylindrical billets (Ref 42, 43, 44, 45, 46). In these tests, measurements of die wear were obtained directly by measuring the surface roughness before and after the tests. Upsetting of cylinders on flat dies may be a convenient way for forging a large number of specimens for the purpose of testing a die steel. While this test may accurately reflect die wear characteristics in some cases, it differs from closed-die forging in some important respects:

- Because the flat-bottomed specimen is placed on a flat die prior to forging, a substantial amount of heat can be conducted from the specimen to the die. Thus, at that interface, the specimen is colder and the die is hotter than would be the case in an actual forging die where the irregularly shaped die makes line and point contact with the billet
- In upsetting a cylinder, the metal flow is all lateral, or in a direction perpendicular to the ram motion. In an actual forging, metal flow will occur in both lateral and longitudinal directions; in some cases, longitudinal flow can be very rapid, exceeding by far the velocity of the press ram. In these cases, the sliding velocity at the interface can be an important factor contributing to die wear

Thus, it must be concluded that only die wear studies conducted with actual forging dies can give reliable results.

Most evaluations of die wear in impression die have made use of dies of simple geometry. These include the investigations of Silva and Dean (Ref 47) and those of Doege, Melching, and Kowallick (Ref 48). The latter workers used an automated heading machine to forge 1045 steel disks into cups via an extrusion-type process. Die heaters were employed to keep the temperature constant. After heading 300 pieces, a surface analyzer was used to measure the wear of the dies, and the average distance between the worn and unworn profile was taken as the measure of wear.

A very extensive series of die wear studies was conducted by Netthöfel (Ref 49), who used the axisymmetric die shown in Fig. 14. Originally, Netthöfel designed and tested an axisymmetric die made of a number of pie-shaped segments. Each segment could be made of a different material and, thus, it would be possible to investigate the wear of several die materials with a single series of forging experiments. However, this approach was not successful. During forging, the segments separated and the forged materials penetrated into the spaces, or "cracks," between the adjacent segments. Consequently, it was decided to use pin-shaped inserts made from the die materials to be investigated. Each pin had a 16 mm (0.63 in.) diameter and was 0.04 mm (0.0016 in.) larger than the hole into which it was placed. The pins were shrink-fitted into the various holes located in the axisymmetric die, as shown in Fig. 14.

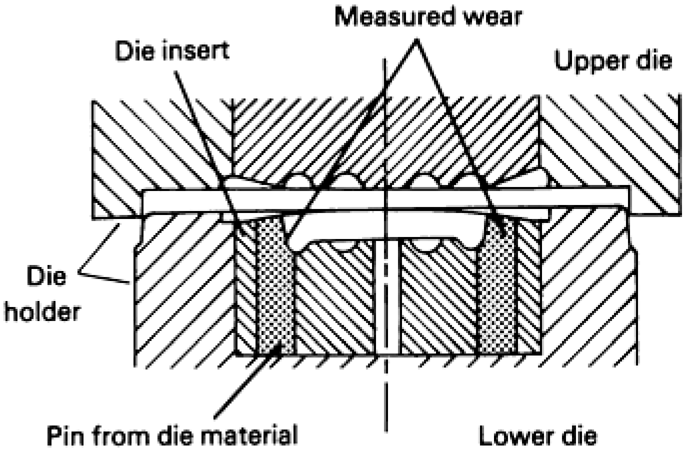

Fig. 14 Cross section of a closed-die forging test setup. Source: Ref 49

Netthöfel used a friction screw press in his studies, and operated it at an initial forging speed of 0.5 m/s (20 in./s). In conducting most of the forging trials, a maximum number of 6000 parts was forged from 0.53% carbon steel (0.54% C, 0.26% Si, 0.7% Mn, 0.02% P, 0.02% S). In order to maintain all of the conditions at approximately constant levels, the die temperatures were controlled by heating the dies with a gas flame and the part was ejected from the lower die using an ejector. The forging cycle was approximately 13 s. The round-cornered square billets were heated inductively to 1200 °C (2190 °F), and flattened in a mechanical press, prior to forging in the screw press with the dies seen in Fig. 14. As a lubricant, Netthöfel used sawdust, which was sprayed over the lower dies and the workpiece material before each blow. Die wear was measured (at the locations indicated in Fig. 14) by taking a cast of the worn die after a number of forgings. In preliminary experiments, not only dies with pin inserts, but also those from full materials were investigated. The results indicated that die wear, as measured in using pin inserts, was identical to that obtained in full material dies under identical forging conditions.

Factors Affecting Abrasive Wear

Die Material. Of all the factors that influence abrasive wear, the one easiest to understand and quantify is that of die material and hardness. In general, increasing alloying content and die hardness both tend to increase the resistance of forging die steels to abrasive wear. As was discussed earlier in this article, low-alloy die steels such as 6F2, 6G, and 6H1 generally have poor resistance to wear as compared to hot-work die steels such as H13 and H26 (Table 1). This is because the microstructures of the latter steels are not only inherently more resistant to wear, but they also tend to be more stable at higher temperatures.

The effect of various alloying elements on wear has been discussed by various authors. Kannappan (Ref 40) summarized results on the wear resistance of several alloy steels and concluded that it increases with increasing contents of carbon and carbide-forming elements. Further, he surmised that the presence of noncarbide-forming elements in martensitic die steels

may even be detrimental. Of the carbide-forming elements, greater wear resistance is developed in the order of chromium, tungsten, molybdenum, and vanadium, with the effectiveness in reducing wear being in the ratio of 2:5:10:40, respectively, when the die temperature is between 250 and 550 °C (480 and 1020 °F). Thus, vanadium and its associated carbides are eight times as effective as tungsten and its carbides in reducing wear. Thomas (Ref 43) made a similar ranking of tungsten, molybdenum, and vanadium, with relative effectiveness in reducing wear being in the ratio of 10:20:40.

The work of Aston, Hopkins, and Kirkham (Ref 46) provides a more detailed insight into the effect of alloying on wear of forging die steels. Their results on eleven die steels tempered to nearly the same hardness (Fig. 15 and Tables 8(a) and 8(b)) were summarized as follows:

- The steel with the lowest alloy content (number 1) has the least wear resistance. It is useful primarily in hammer applications because of its low price, good toughness, and ease of machining
- Steels of moderate wear resistance (numbers 2, 3, 4, 5, and 9) have large amounts of chromium (1.25 to 12%) and molybdenum (0.5 to 1.5%) and some vanadium (0.07 to 1.5%)
- Steels of highest wear resistance (numbers 6, 7, 8, 10, and 5) include those with the highest alloy content. However, several of these die steels (notably, numbers 7 and 10) have only moderate alloying

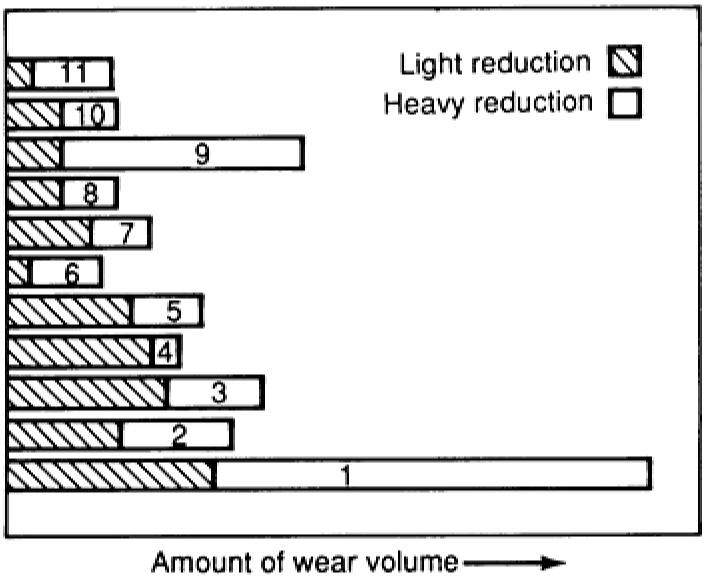

Fig. 15 Results of tests on the effects of alloying on wear of forging die steels. See Tables 8(a) and 8(b) for compositions and heat treatments of steels. Source: Ref 46

From these results, they concluded that good wear resistance is obtained when the total alloy content is in excess of 3%. They remarked on the particularly strong effect of molybdenum on reducing wear (Fig. 16) but noted that quantities in excess of 2% were not needed.

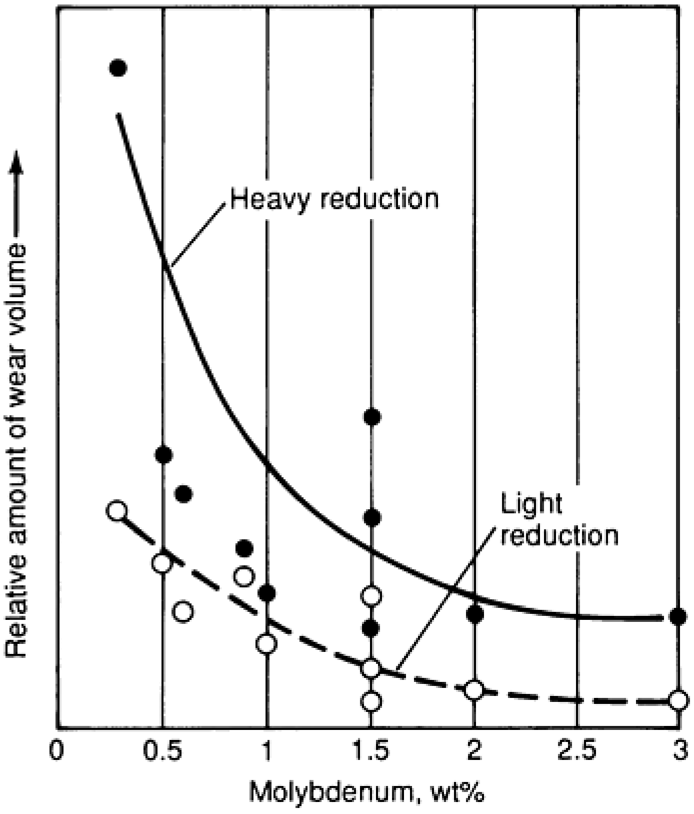

Fig. 16 Effect of molybdenum content on wear resistance of die steels. Data are a cross-plot of results shown in Fig. 15. Source: Ref 46

The results by Thomas (Ref 43) also showed a strong correlation between wear resistance and alloy content (Fig. 17). The low-alloy steel (No. 5 die steel, which is equivalent to steel number 1 in Fig. 15, and 8(a) and Table 8(b)) had relatively poor wear resistance when compared to the 5% Cr hot-work die steel (H12) and the 12% Cr steel. This was true irrespective of the hardness level to which the steels were tempered and even, to a certain degree, of the type of workpiece material.

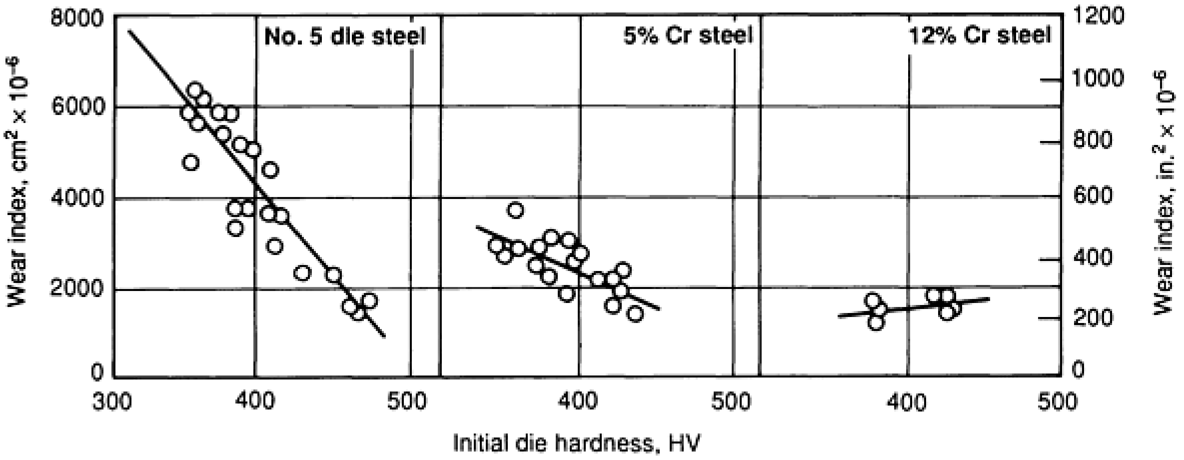

Fig. 17 Influence of initial die hardness on wear of die steels. The wear index is defined as average cross-sectional area of wear depressions in dies. No. 5 die steel: 0.6 C, 0.3 Si, 0.6 Mn, 1.5 Ni, 0.6 Cr, 0.25 Mo; 5% Cr steel: 0.33 C, 0.3 Si, 1.0 Mn, 5.0 Cr, 1.5 Mo, 1.5 W, 0.5 V; 12% Cr steel: 0.1 C, 0.25 Si, 0.7 Mn, 2.4 Ni, 12.0 Cr, 1.8 Mo, 0.35 V. Source: Ref 43

These findings have been verified and further expanded by other researchers. For example, in their carefully controlled forging experiments, Doege, Melching, and Kowallick (Ref 48) and Hecht and Hiller (Ref 50) found low-alloy steels to have far inferior wear resistance as compared to hot-work die steels (Fig. 18) because alloying led to higher hardness and the ability to retain strength at high die temperatures. The work of Netthöfel (Ref 49) is also in agreement with these observations.

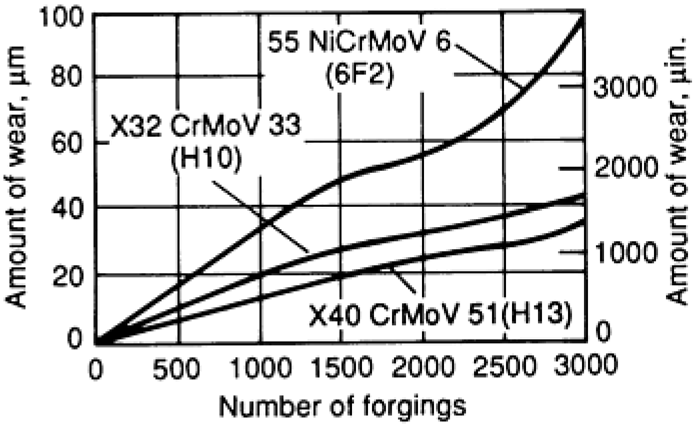

Fig. 18 Amount of wear of hot-work tool steels as a function of the number of forgings. Equivalent steels are in parentheses. Source: Ref 48

Up to now, most of the discussion of alloying has centered on die steels. Several workers have also investigated the wear characteristics of nonferrous die materials. In Netthöfel's (Ref 49) experiments on forging die wear, it was found that the nickel-base alloy Nimonic 90 had a wear resistance between that of an H12 and H19 steel at a die temperature of 255 °C (490 °F). This is an important finding in view of the fact that the nickel-based alloys are generally many times the cost of

the die steel alloys and are also harder to machine. Notthöfel's finding was verified to a certain extent by Ali, Rooks, and Tobias (Ref 42) in their die wear studies in a high-energy-rate forming (HERF) machine (Fig. 19). Although the die were depended on whether the top die or bottom die was examined, it was found that Nimonic 90 was only slightly better than a steel similar to H19 (WEX). Thus, the results reported in Ref 42 and 49 point out the fact that the nickel-base die materials should be reserved for hot-die and isothermal forging applications for which die steels are inappropriate.

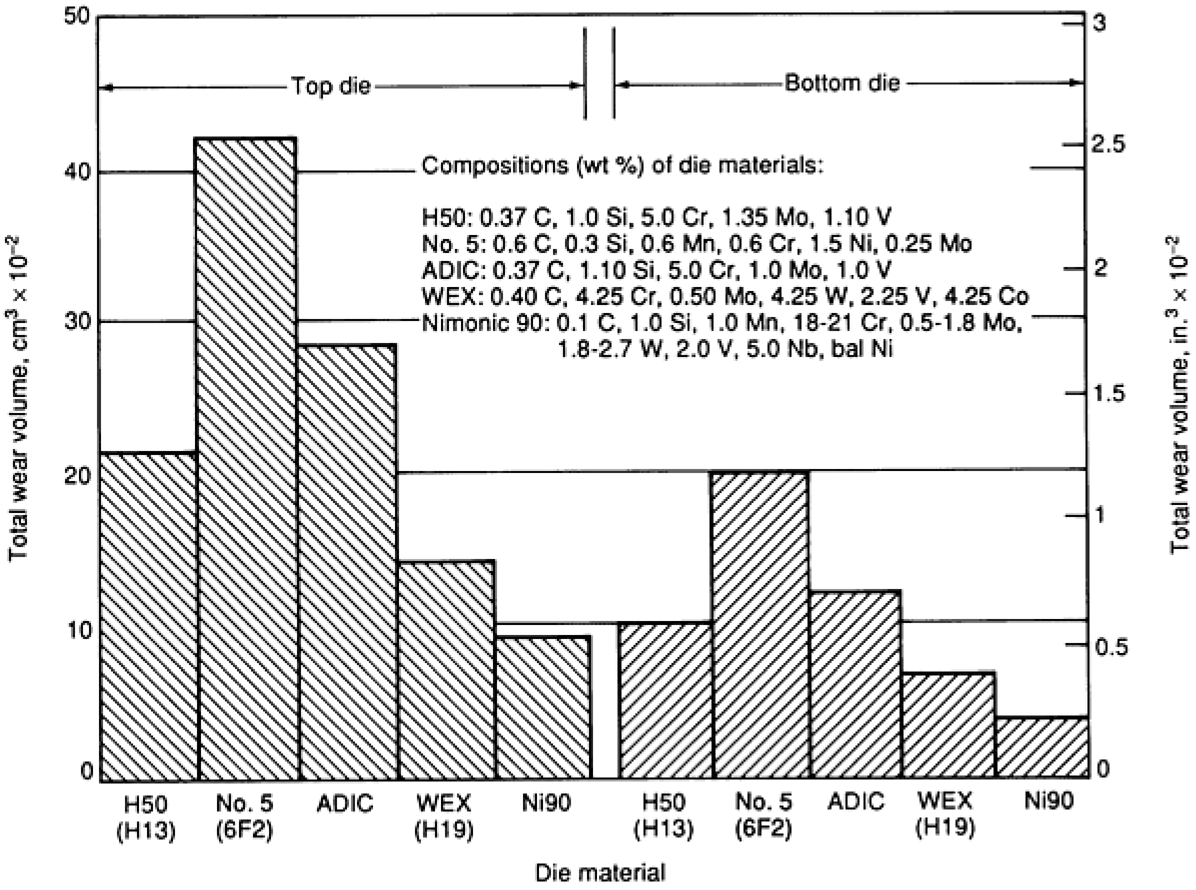

Fig. 19 Total wear volumes for die materials at a mean hardness of 44 HRC. Source: Ref 42

Die Hardness. Die hardness is another factor whose influence on abrasive wear is easy to quantify. The effect of die hardness is best realized through an understanding of the die wear process itself. Misra and Finnie (Ref 51) have summarized a large amount of work on abrasive wear and concluded that two basic processes are involved. The first is the formation of plastically deformed grooves that do not involve metal removal, and the second consists of removal of metal in the form of microscopic chips. Because chip formation, as in metal cutting, takes place through a shear process, increased metal hardness could be expected to diminish the amount of metal removal via abrasive wear. This trend is exactly what has been observed.

The effect of hardness on wear is seen in data on a variety of steels quoted by Kannappan (Ref 40) and by Thomas (Ref 43), which have been discussed previously. From examination of Fig. 17, it is apparent that the dependence of wear rate on hardness is greatest for low-alloy die steels such as 6F2 (No. 5 die steel in Fig. 17). Such a trend has also been reported by Kannappan (Ref 40) in data on several low-alloy and hot-work die steels.

Kannappan (Ref 40) has also discussed the correlation between hardness and wear of die steels with microstructures different from the typical die steel structure of tempered martensite. It has been found that the isothermal heat treatment of steels to produce lower bainite results in better wear resistance (Fig. 20). Supposedly, this effect is a result of the fact that isothermal transformation/hardening causes fewer stresses and microscopic cracks (which promote abrasive failure) than does a thermal martensitic transformation.

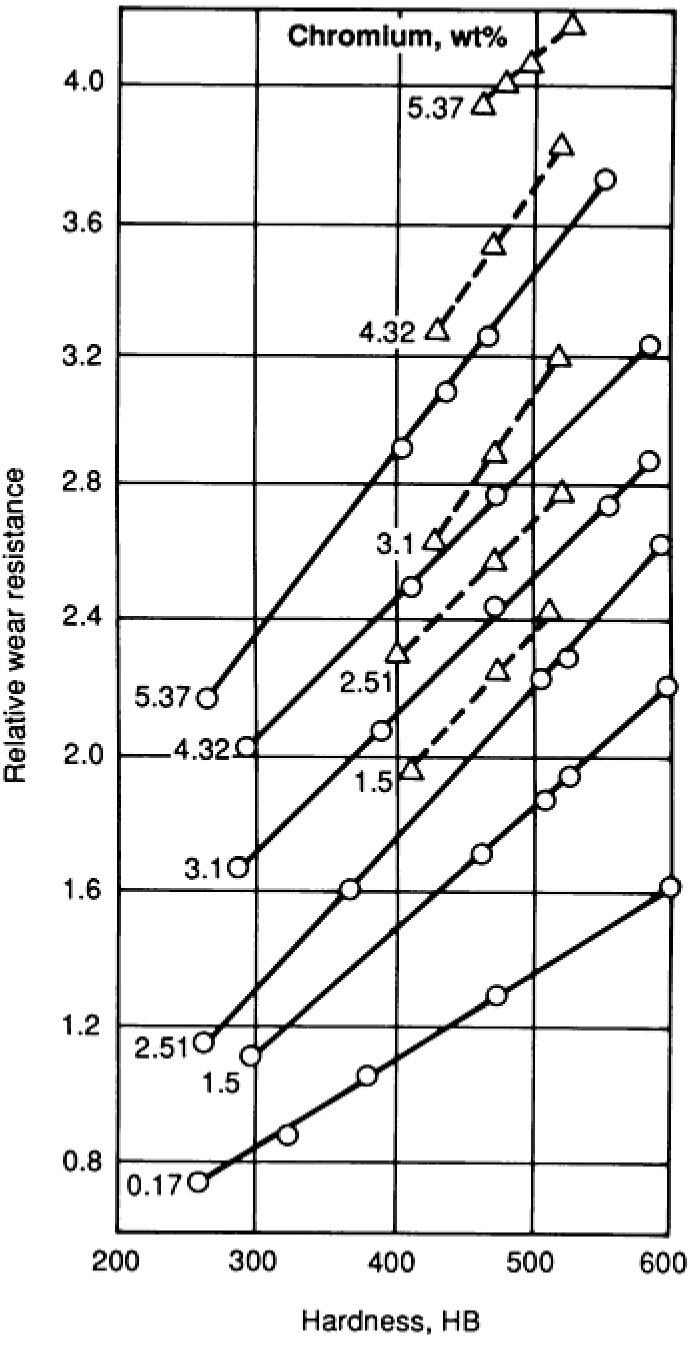

Fig. 20 Relative wear resistance with respect to hardness of selected chromium steels with 0.55% C. Note the difference between the effect of quenching followed by tempering (solid lines) and the effect of isothermal treatment/quenching to a lower bainitic region (dashed lines). Relative wear resistance is defined as a number directly proportional to the applied interface pressure and the amount of relative sliding and inversely proportional to the total wear volume. Source: Ref 40

Workpiece Temperature. Several researchers have commented on the effect of workpiece temperature on die wear. In his investigation of wear of hammer dies, Thomas (Ref 52) found that in forging of steels, wear increased at first with billet temperature up to 1100 °C (2010 °F) and then decreased with increasing temperature (Fig. 21). The initial increase can probably be attributed to the increase in the amount of scale on the billets, which acts as an abrasive during the die wear process. However, above 1100 °C (2010 °F), the flow stress drops off rapidly enough to minimize the interface pressure during forging and therefore decrease the effect of scale. A similar finding was made by Doege, Melching, and Kowallick (Ref 48), who attributed an increase in die wear as the billet temperature was raised from 800 °C (1470 °F) to 1100 °C (2010 °F) to an increase in the die surface temperature and a simultaneous decrease in wear resistance.

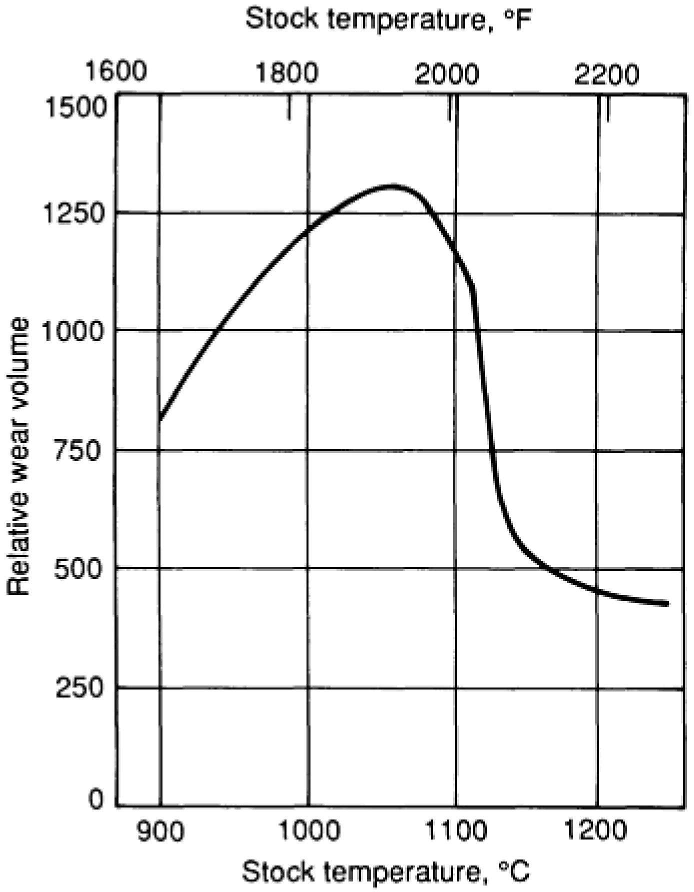

Fig. 21 Effect of workpiece temperature on wear. Source: Ref 52

Lubrication/Die Temperatures. The effects of lubrication and die temperature on die wear have been interpreted in a variety of often-conflicting ways in the literature. This is because lubricants and die temperature influence: lubricity, and hence the amount of metal sliding during forging; the interface pressure during deformation; and the heat transfer characteristics between the dies and workpiece during conventional hot forging. The last item is important not only through its influence on heat absorption into the dies, and thus thermal softening and decreased wear resistance of the dies, but also through its effect on the performance of the die and billet lubricants themselves.

Investigations into the effect of lubrication on die wear in simple upsetting have shown that wear is greatly increased when the dies are lubricated versus when they are not. This effect is shown in the results of Singh, Rooks, and Tobias (Ref 44) from upset tests in a HERF machine (Fig. 22). The same phenomenon has been demonstrated by Thomas (Ref 43), who upset successive lots of 1000 samples each on a flat die in a mechanical press. In these tests, the amount of wear was greater for the lot involving lubricated compression tests (Fig. 23). From these findings, one might conclude that wear increases with lubrication because of increased sliding and that lubrication is detrimental in forging. Thomas clarified this point, however, by calculating the amount of wear for equivalent amounts of metal flow past a given point; he found that lubrication reduces wear by a factor of 3 when compared to forging without lubrication. Moreover, he emphasized that in closed-die forging, the amount of metal sliding is fixed by die and preform design and not lubrication. Thus, the amount of sliding over the flash land, where wear is usually greatest, depends on the amount of flash that must be thrown and not on the efficiency of the lubricant employed. Because the amount of flash will be roughly the same with or without lubrication, employing lubricants in closed-die forging should reduce abrasive wear of the flash land and other parts of the die cavity.

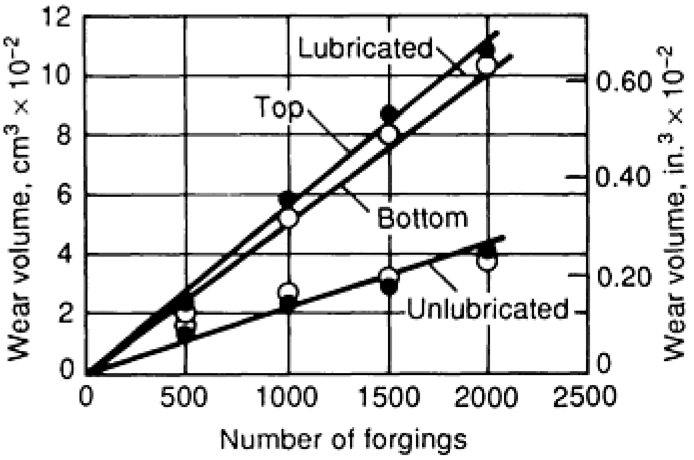

Fig. 22 Effect of lubrication on forging die wear. Source: Ref 44

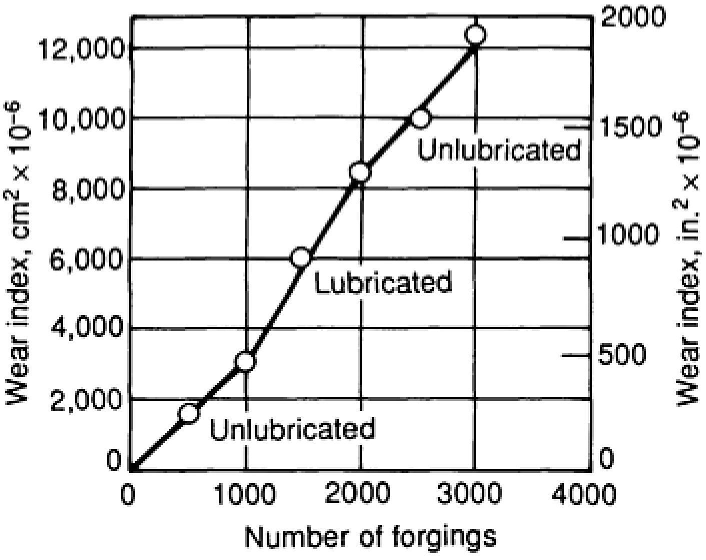

Fig. 23 Effect of lubrication on forging die wear. Wear index is defined as the average cross-sectional area of wear depressions in the die. Source: Ref 43

The interaction of lubrication and die temperature effects was demonstrated by Rooks (Ref 45) in upset tests on a HERF machine. These tests were run with various bulk die temperatures, dwell times, and cycle times. Dwell time in the HERF operation includes a short forging phase, a somewhat longer "bouncing" phase, and an extended "after-forging" phase during which the dies and billet are in contact under low pressure. Results established that die wear after upsetting of 1000 billets decreased with increasing die temperature. This was correlated with decreased amounts of sliding at higher die temperatures due to an increase in the coefficient of friction.

The effects of dwell time and cycle time on die wear were also examined by Rooks (Ref 45). Increasing dwell time increases die chilling. As a result, metal flow is hindered and die wear is reduced. Increased cycle time (time between forgings) tends to have the reverse effect of increasing dwell time (that is, it increases die wear because of lower coefficients of friction and more sliding). However, these effects have been found to be very slight in upset tests, conducted in a HERF machine (Ref 45).

A striking die wear feature that Rooks (Ref 45) and Ali, Rooks, and Tobias (Ref 43) noted concerns the generally higher wear experienced by the top die versus the lower die, which is most noticeable in their lubricated upset tests (Fig. 19). This can be attributed to greater chilling on the bottom die because the hot workpiece was placed on it prior to forging.

This could, therefore, have been expected to lead to greater friction, less sliding, and thus less abrasive wear than the top die experienced.

From a practical standpoint, increased production rate in a forge shop may be expected to lead to lower die life. This is almost certainly a result of increased die temperature. In forging under production conditions, the die surface temperature observed between two consecutive forging blows seems to remain unchanged throughout a production run (Ref 49). During the actual forging operation, the die surface temperatures increase and reach a maximum peak value and decrease again when the dies are separated and the forging is removed. In case the forging "sticks" in one of the dies, the peak surface temperature of that die may increase further and contribute to die wear. Therefore, in conducting die wear studies, it is suggested that an ejector be used to remove the part after forging, so that die temperatures do not increase because a forging sticks in the die. In forging of steel at 1200 °C (2190 °F) with dies at about 250 °C (480 °F), surface temperatures will reach approximately 750 °C (1380 °F) if perfect and ideal contact occurs between the forging and the die. In reality, however, due to scale and oxidation at the die/material interface, the peak surface temperatures during forging reach 500 to 600 °C (930 to 1110 °F) in mechanical presses and 650 to 700 °C (1200 to 1290 °F) in hammers. As an example, die temperatures obtained by Vigor and Hornaday (Ref 53), in forging steel in a mechanical press are given in Fig. 24. It can be seen that the temperature gradient is very large at the vicinity of the die/material interface.

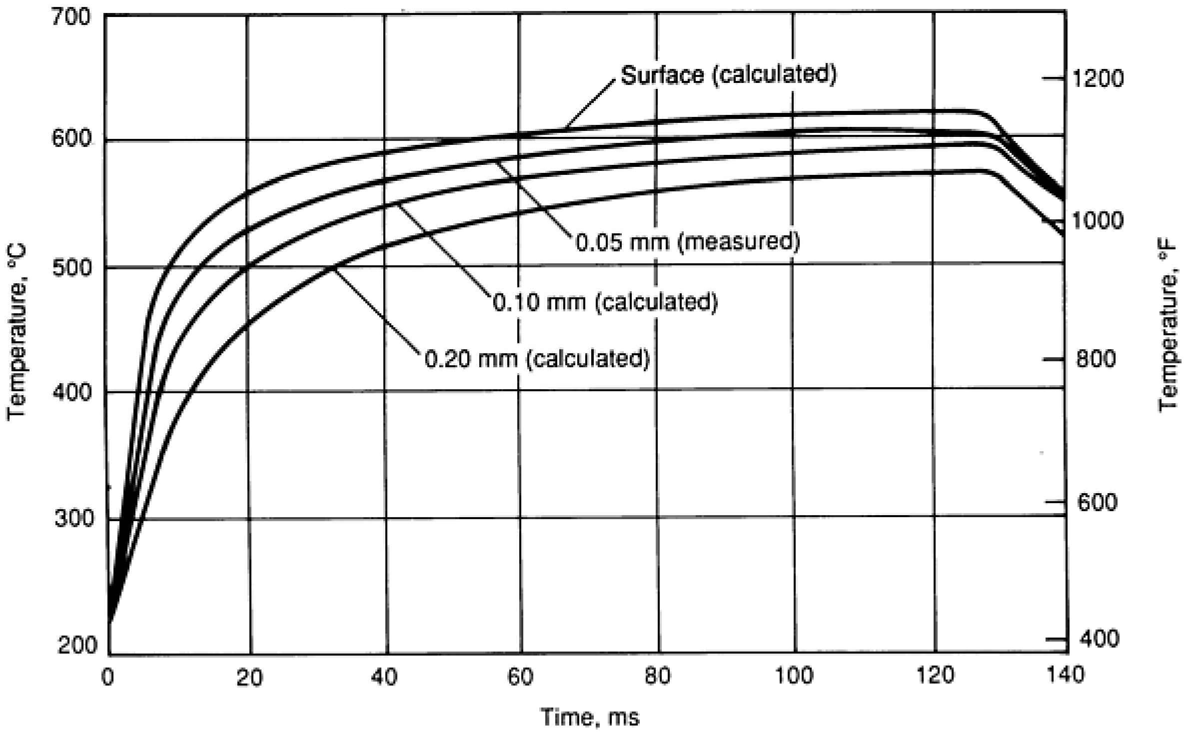

Fig. 24 Temperatures at the surface and at various depths in forging dies obtained during forging 1040 steel without lubricant. Source: Ref 53

The effects of sliding on die wear are also qualitatively well known in forging practice. These effects are taken into account in designing preforms to ensure that more "squeezing" and less lateral flow and sliding action take place during finish forging.

Methods of Improving Resistance to Abrasive Wear

From the discussion of the factors that influence abrasive wear, one can deduce methods to improve die performance controlled by this failure mechanism. Perhaps the most direct method is to employ a die steel that is more resistant to wear, that is, one that is harder and that retains its hardness at high die temperatures (Ref 54). This could mean changing from a low-alloy die steel to a chromium hot-work die steel. The decision to make such a change should be based on the suitability of the new die steel itself in the forging operation and the trade-off between expected increases in die life and increases in material (and machining) costs.

Coating, hardfacing, and surface treatment of forging dies often can be employed to improve wear resistance as well. Information regarding specific coating and hardfacing alloys (and the methods of their application) and surface treatments such as nitriding and boriding is contained in the following section of this article and will not be reviewed here. However, there are numerous instances of such methods increasing die life. These include the use of chromium and cobalt-base coatings (Ref 48, 55), weld deposits of higher-alloy steels onto low-alloy steels (Ref 56), weld deposits of nickel and cobalt hardfacing alloys on die steels (Ref 57, 58, 59), ceramic coatings (Ref 60, 61), and surface nitriding (Ref 54, 62, 63).

Another means of reducing wear in the forging of steel involves reducing the scale on heated billets; scale acts as an abrasive during the sliding that occurs between the dies and workpiece. Thomas (Ref 52) estimates that poor control of scale can reduce die life as much as 200%. Methods of reducing scale are relatively obvious and include the following:

- Using a reducing, or inert, furnace atmosphere
- Using a billet coating to prevent oxidation
- Minimizing time at temperature in the furnace or using induction heating

One final means of decreasing the problem of wear is through improved redesign of the blocker shape. This is an important consideration because wear is strongly dependent on the amount of sliding that occurs on a die surface. Thus, it is possible to reduce sliding, thereby reducing wear, by redesigning the blocker shape.

Thermal Fatigue

Thermal cycling of the die surfaces during conventional hot forging results in the second most common reason for rejecting dies, namely heat checking. Thermal cycling (thermal fatigue) results from the intermittent nature of forging production.

The major factors influencing heat checking are:

- Die surface temperatures
- Surface stresses and strains
- Damage accumulation in thermal fatigue
- Microstructural effects of fatigue

Die Surface Temperatures. Information on die temperatures is best obtained from direct measurements. Surface temperatures for dies used in a mechanical press have been found to reach about 600 °C (1110 °F) in forging of steel cylinders that were preheated to approximately 1175 °C (2150 °F) and upset to 75% reduction in height (Fig. 24). Similar measurements have been made by Kellow, *et al.* (Ref 64), who upset medium-carbon steel samples in a slow hydraulic press and a HERF machine. Surface thermo-couples were placed at various distances from the axis of the 25 mm (1 in.) diameter billets. Experimental results showed that the temperatures obtained along the initial contact area of the workpiece and the die do not differ significantly between low- and high-speed forging. However, the temperatures obtained outside the initial contact area, where the billet surface extends during deformation, were significantly higher in high-speed forging (900 °C, or 1650 °F) as compared with low-speed hydraulic press forging (550 °C, or 1020 °F). These results are mainly due to differences in heat generation due to friction, which serves as one means of dissipating the energy produced by the forging machine.

Other measurements of die temperatures away from the die surfaces themselves demonstrate that large temperature gradients, as well as high temperatures, are induced in forging dies. These measurements include those of Voss (Ref 65), who measured temperatures in low-alloy (6F3) and chromium hot-work steel (H10, H12) radial forging dies preheated to 100 °C (210 °F) before forging (Fig. 25). Measurements away from the surface (at 0.5 mm, or 0.02 in., from the surface) show large temperature gradients. By comparing die temperatures during forging to those between forging blows (Fig. 25), it is apparent that very large temperature changes at the surfaces of forging dies may be expected as well. For this reason, large stresses and large strains due to temperature effects are experienced by the surface layers of forging dies.

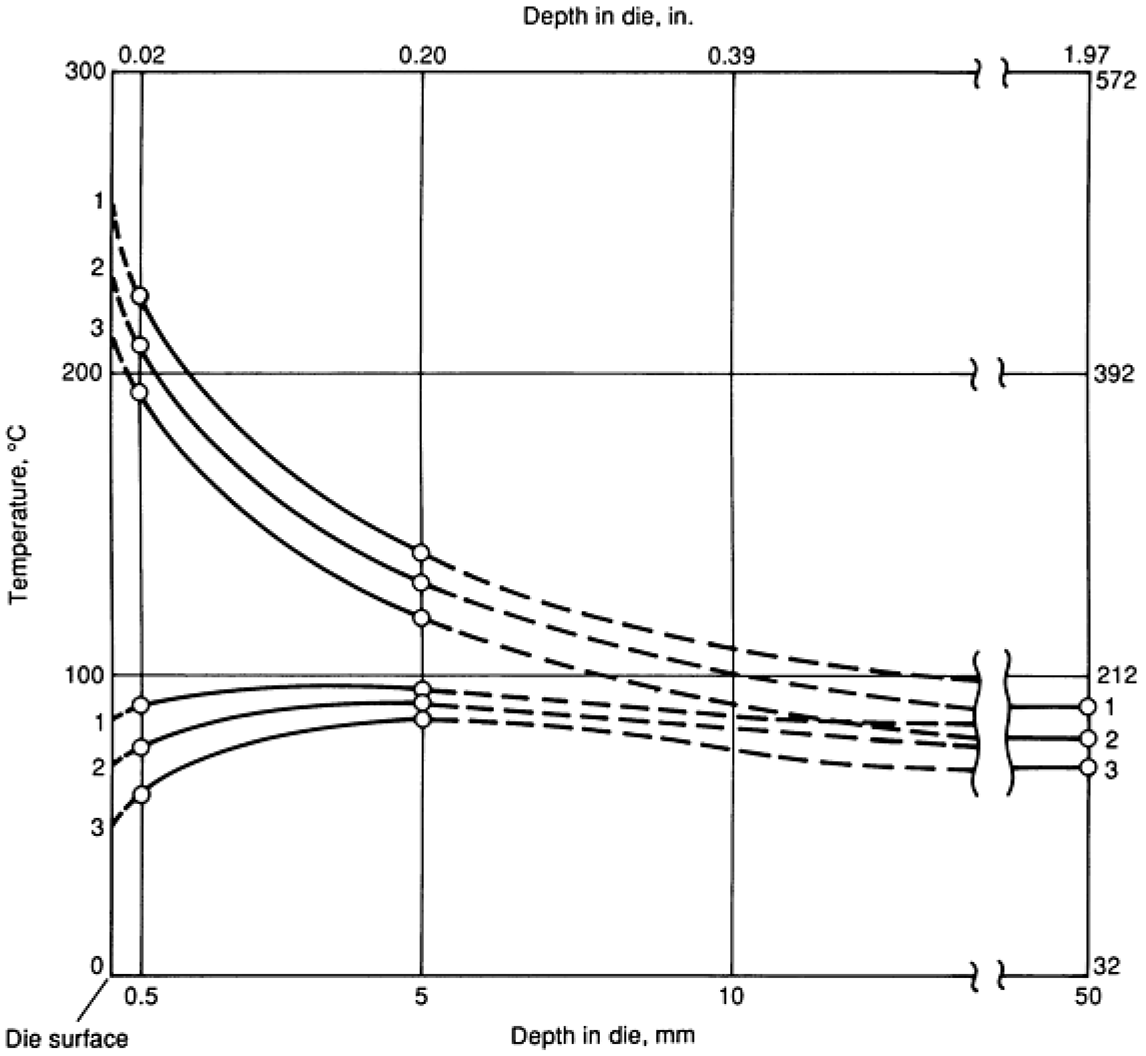

Fig. 25 Temperatures in dies with air-water cooling of the dies between blows. Initial die temperature: 100 °C (210 °F). Initial stock temperatures: (1) 1150 °C (2100 °F), (2) 1050 °C (1920 °F), (3) 950 °C (1740 °F). Upper curves are the temperatures achieved during forging; lower curves are the temperatures reached between forging blows. Source: Ref 65

Materials with high conductivity are less likely to develop large thermal gradients and fail by thermal fatigue than those with poor thermal conductivity. Although conductivity data for the various die materials are scarce, available measurements do show, for instance, that the tungsten hot-work die steels with higher conductivities should be more resistant to heat checking than the chromium hot-work die steels.

Surface Stresses and Strains. The stresses and strains that result from the temperature cycles experienced by the forging dies have two main sources: (1) thermal expansion and contraction, and (2) phase changes brought about by temperature cycling. The first of these is probably the easiest to quantify. This is because the thermal stresses and strains are approximately proportional to the maximum temperature difference (T_{max} - T_{min}) experienced by the dies and the thermal expansion coefficient of the die material. Most die steels have similar thermal expansion coefficients. Therefore, the thermally induced deformation of the dies is controlled primarily by the magnitude of T_{max} - T_{min}.

As might be expected, the tendency to heat check can be decreased by reducing T_{max} - T_{min}. This can be done in two ways. First, T_{min}, or the bulk die temperature, can be increased. However, such a change may adversely affect resistance to other forms of die failure. Alternatively, T_{max} can be decreased. The easiest way to do this is by decreasing the workpiece temperature or by using a lubricant with better thermal insulating properties.

Figure 26 shows the effects of increasing T_{min} or decreasing T_{max} on the fatigue life (in terms of number of cycles to produce a crack of certain length) of mild steel. It is seen that a 100 °C (180 °F) decrease in T_{max} is much more beneficial in extending the fatigue life than a similar increase in T_{min}. This result is generally true for die steels as well, and can be attributed to the greater reduction of the strain amplitude by decreasing T_{max}.

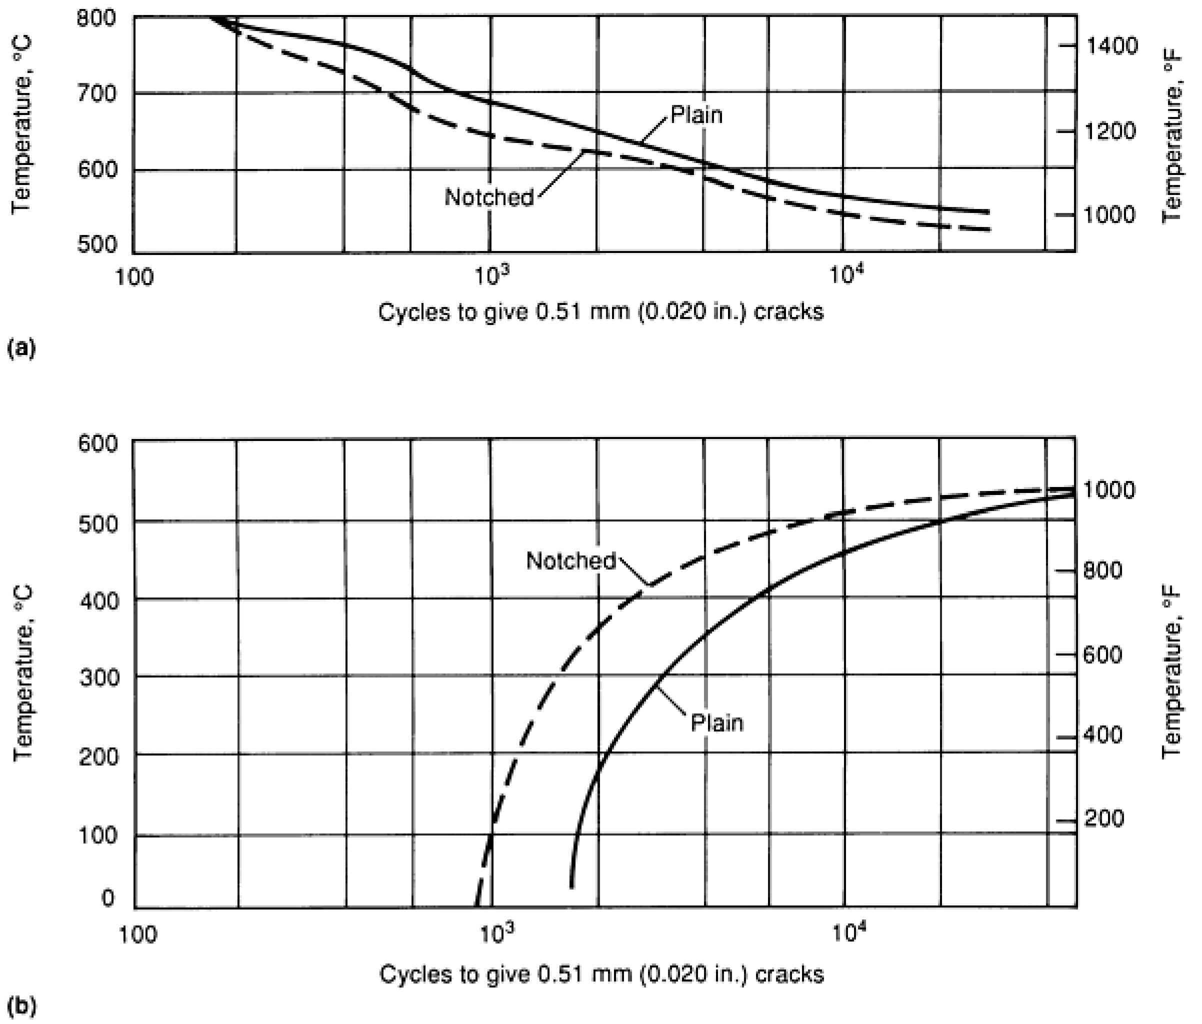

Fig. 26 Effects of maximum (a) and minimum (b) temperatures on the fatigue life of En 25 mild steel. Source: Ref 40

The effects of phase changes on thermal fatigue of forging dies has been examined by Rooks, Singh, and Tobias (Ref 66) and Okell and Wolstencroft (Ref 67). Both sets of investigators have concluded that die surface heating and cooling may lead to reversion of the tempered martensite to austenite and subsequent transformation back to martensite. Because austenite and martensite have different densities, such phase changes lead to strains and stresses that are imposed by subsurface layers of the dies that do not undergo the transformation.

As with the thermally induced strains, transformation-induced strains can be reduce either by keeping the maximum die surface temperature below the Ac_1 temperature (the temperature at which austenite forms, which is ~800 °C, or 1470 °F), or by keeping the minimum die surface temperature above the martensite start, M_s, temperature, which depends greatly on alloy composition, typical values being ~280 °C (~535 °F) for H11 and ~380 °C (~715 °F) for H21. Okell and Wolstencroft (Ref 67) suggested the latter possibility, but specified that it should only be used for the more highly alloyed die steels, which have good hot hardness because they resist overtempering.

Microstructural Effects on Thermal Fatigue. Because ductility has a large effect on the number of thermal cycles a forging die can undergo prior to forming cracks, microstructure can have a significant impact on the frequency of heat checking. The most important microstructural variables are cleanliness, grain size, and microstructural uniformity. Die

steels that are clean resist crack initiation inasmuch as inclusions act as nuclei for crack initiation. Thus, the use of a slightly more expensive steel that has been refined to remove inclusions may be a wise investment. Grain size can also affect thermal fatigue resistance because grain size has a large influence on crack initiation, with fine-grained material tending to perform better in this respect. Lastly, steels whose chemistry and microstructure are uniform (that is, free of segregation) tend to have uniform thermal properties (thermal expansion coefficients) and thus are able to resist thermal stresses and strains that may be developed due to such variations in a uniform temperature field.

Methods of Improving Resistance to Thermal Fatigue. The resistance to thermal fatigue can be improved by materials selection, lowering the maximum die temperature variations, or surface treatments.

Use of a Steel with Higher Yield Strength. Because thermal fatigue crack growth is controlled by the amplitude of the plastic strain increment, die steels with higher yield strengths, and thus higher elastic limits, are more resistant to thermal fatigue under a given set of process conditions.

Lowering the Maximum Die Temperature. Because thermal stresses and strains are related to the temperature changes that the die surfaces experience, decreasing the maximum temperature to which the die surface is exposed is beneficial. This can be accomplished by lowering the workpiece temperature or by using lubricants, such as glasses, that act as thermal insulators. Lowering the maximum die surface temperature is also helpful in avoiding transformation-induced strains, which, in conjunction with thermal strains, may cause thermal fatigue problems.

Raising the Bulk Die Temperature. Thermal stresses and strains and the tendency for heat checking can also be reduced by preheating the dies to higher temperatures. Use of this technique should be limited to die steels with good retention of hot hardness, such as the molybdenum hot-work die steels (H41 to H43).

Use of High-Quality Die Steel. Die steels that are clean, of fine grain size, and homogeneous in microstructure resist the initiation of fatigue cracks that are thermally or mechanically induced.

Use of Special Surface Finishes or Treatments. By eliminating machining marks, which act as stress concentrators, fatigue crack initiation can sometimes be avoided or delayed. Surface treatments such as nitriding or shot peening may also reduce thermal (and mechanical) fatigue problems by inducing residual compressive stresses into the surfaces of forging dies.

Mechanical Fatigue

Unlike thermal fatigue, the literature on mechanical fatigue of die steels is sparse. Perhaps the largest amount of data on this failure mechanism has been gathered by Thomas in a series of three-point bending experiments (Ref 68). Variables that he investigated included imposed load (of greatest importance in controlling fatigue behavior), hardness, material, position in the die block, strain rate, and temperature.

Methods of Improving Resistance to Mechanical Fatigue. Methods of minimizing failure due to mechanical fatigue fall into one of two categories. The first of these relates to die design and loading. In this area, redesign of dies (flash design) or performs to lower die stresses may totally eliminate problems of mechanical fatigue. Also, because of the logarithmic nature of fatigue-failure behavior, often only a slight decrease in applied loading can result in markedly improved fatigue lives. Such a reduction in load may be obtained, for example, through better control of the forging energy in hammers and slight modification of the flash configuration in die design.

The second major category of methods to improve fatigue resistance comes under the heading of material modification. Modifications include treatments (such as shot peening) that put the surface layers of the dies into compression. Another alternative is a total change of die material to one with a higher fracture toughness. Such a material can support larger fatigue cracks before total fracture occurs.

Catastrophic Die Failure/Plastic Deformation

The last two forms of die failure, catastrophic die failure and failure due to plastic deformation, will be discussed only briefly here. The first of these, catastrophic die failure, can be considered a special case of mechanical fatigue failure in which the fatigue life is only one cycle. It is usually a result of excessive forging stresses or improper die material/heat treatment selection or improper assembly of the die insert in the die holder. Forging stresses may be high because of excessive forging energy or because of the general shape of the forging die cavity (Ref 69). With regard to the former,

once the dies have come together in a forging operation, excessive forging energy can only be dissipated by elastic deformation of the dies themselves. Therefore, the fracture stress may be reached at points of stress concentration. Among the details of the forging die cavity that affect stresses are the draft angles and corner radii.

Improper die material selection can also result in catastrophic die failure. Dies for hard-to-work materials or in which there are points with high stress concentrations require die steels with good fracture toughness. These steels include low-alloy steels (such as 6F3 and 6F7) and some of the chromium hot-work die steels (such as H11). When the more highly alloyed die steels (such as H19 or H21) are employed (because of their wear resistance, for example), they should be tempered to lower-than-normal hardness in order to increase toughness if the dies are susceptible to catastrophic die failure.

Failure of forging dies to perform properly because of plastic deformation can be measured by hot hardness or yield strength. In general, the yield strengths of steels decrease with increasing temperature. However, yield strength is also dependent on the prior heat treatment, composition, and hardness. The higher the initial hardness, the greater the yield strength at various temperatures. In addition, the yield strengths of different die steels increase with alloy content--the tungsten hot-work die steels are harder than the chromium hot-work die steels, which are themselves harder than the low-alloy steels (Fig. 2 and 3). Not shown in Fig. 2 and 3 is the fact that the molybdenum hot-work die steels are even harder than the tungsten ones and thus manifest the greatest resistance to plastic deformation as far as die steels are concerned.

Surface Treatments and Coatings

A variety of die coatings and surface treatments are available to extend the lives of dies limited by wear. Among the most common coatings are plated chromium and cobalt-alloy deposits, which adhere to the die surface via a mechanical bond, and weld fusion deposits, which entail a metallurgical bond. The latter can be used in rebuilding excessively worn dies as well. Recently, the use of ceramic coatings (for example, carbide and nitride coatings) applied by processes such as chemical vapor deposition (CVD) have been found to extend forming die lives.

The surface layers of ferrous forming dies can also be hardened by alloying them with nitrogen or boron. Nitriding is the most common of the surface treatment techniques and can be accomplished using a gaseous, liquid, or plasma medium. The plasma technique (ion nitriding) appears very attractive because the formation of brittle white layers, which are unavoidable in other nitriding processes, can be eliminated or at least minimized. Boriding of die surfaces can also be accomplished using a variety of media, and increases in die life of the same magnitude as those obtained with nitriding have been reported.

Coatings have been used extensively in net shape forming to reduce friction and wear. Coatings can be applied to either the workpiece or the die. In the case of the workpiece, the coatings are made of soft material with good adhesion, lubricity, and low shear strength. In cold forming, for example, phosphate coatings are used to reduce interface friction and die wear (Ref 70). Resin-bonded coatings containing solid lubricants have also been successfully used (Ref 71, 72, 73). In hot-forming applications, hard coatings are generally used. They are applied to the die or mold surface by mechanical, thermal, or chemical means.

A hard surface layer reduces the frictional force and the wear rate when sliding against a relatively soft workpiece material if the coating/workpiece material pair is chemically stable and the coating is well bonded and mechanically compatible with the substrate (die material) (Ref 74). The role of the hard layer is to prevent plowing, whereas chemical insolubility is needed to ensure minimal dissolution. Hard coatings are especially useful when the dominant wear mechanism is abrasive wear.

Typical hard coating materials are oxides, carbides, nitrides, borides, and amorphous glasses. One of the main considerations in the choice of a coating material is the quality of bonding between the coating and die material (substrate). The bonding could be chemical, mechanical, or both. Chemical bonding is caused by a reaction or diffusion of atoms between the coating and the substrate to form a solid solution at the interface.

Alloying Surface Treatments

The lives of steel forming dies limited by wear can often be increased by various surface treatments in which the structure of the surface is alloyed with, for example, nitrogen, carbon, or boron. Other common methods of surface hardening of steel (for example, flame hardening and induction hardening) have not been reported in the literature as having been used

for forming dies. This is perhaps due to the large loss in toughness and distortion of the die cavity that these methods may cause.

Nitriding is probably the most common treatment for hardening the surface layers of forging dies. It is useful for applications in which the surface temperature does not exceed 565 to 595 °C (1050 to 1100 °F) in service. As with most of the surface treatment processes, nitriding finds its greatest application for press-forming dies in which strength and wear resistance are more important than toughness. However, there are reports of nitriding being successful in impact applications such as hammer forging (Ref 75). Wear rates have been reduced by as much as 50% using nitriding (Fig. 27) (Ref 75, 76).

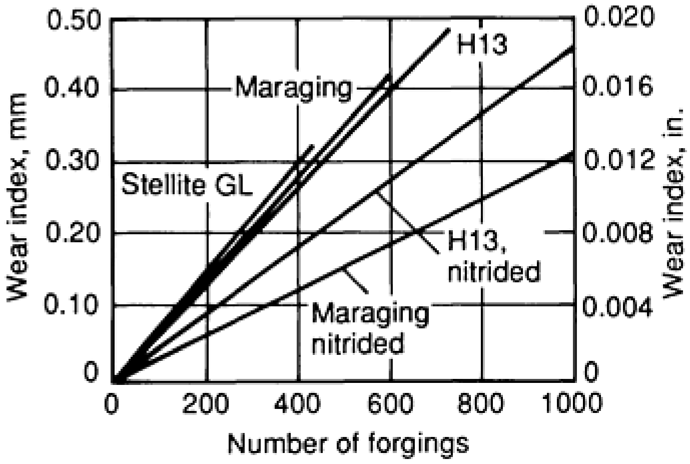

Fig. 27 Relative wear rates of nitrided ad non-nitrided tool steels used in extrusion forging Source: Ref 75

Nitriding processes are performed at temperatures between 495 and 565 °C (925 and 1050 °F). It is important that tempering of the die steel be performed at a temperature exceeding the nitriding temperature prior to nitriding in order to optimize the property combination of the core and the surface of the dies. Also, because of the low nitriding temperatures, there is generally little distortion from this heat-treating process.

Although the depth and hardness of the nitride case depends a great deal on the nitriding time, these properties (particularly the hardness) are sharply dependent on the composition of the steel as well. Die steels containing large amounts of strong nitride formers such as chromium, vanadium, and molybdenum form shallow, very hard surface layers. On the other hand, low-alloy chromium-containing die steels (such as 6G and 6F2) form deeper surface layers that are tougher, but not as hard.

Detailed information on specific techniques for nitriding--gas nitriding, liquid (salt bath) nitriding, and ion nitriding--can be found in Volume 4, *Heat Treating,* of the *ASM Handbook.*

Boriding and Carburizing. Boron can be added to surface layers by a diffusion treatment that can be carried out in either gas, molten salt, or pack media at a temperature between 900 to 1100 °C (1650 to 2010 °F), depending upon the process and the material to be borided. Extremely hard surface layers with low coefficients of friction are formed, provided the base metal forms borides. The process does not require quenching. If the base material has to be heat treated, the heat treatment can be done after boriding, although care is required to reduce quenching stresses to prevent spalling of the borided layer.

Very little is known about the usefulness of boriding forming dies. Vincze (Ref 77) claims a 70% increase in die life with dies surface treated by boriding compared to untreated dies. In this study, boriding was carried out by filling the die impression with a mixture of 10% B_4C, 40% sodium borate, and 50% hardening salt, and heating the pack at 900 °C (1650 °F) for 3 h. This diffusion heat treatment was followed by quenching and tempering. Burgreev and Dobnar (Ref 78) also report large increases in hammer forging die life when boriding is used.

Boriding of steels is also done electrolytically. Boron atoms are electrodeposited onto the metal from a bath of molten salt containing fluorides of lithium, sodium, potassium, and boron. The dies are borided in the 800 to 900 °C (1470 to 1650 °F) temperature range in an atmosphere of argon or a mixture of nitrogen and hydrogen. Thickness of coating is from 0.013 to 0.05 mm (0.0005 to 0.002 in.), and treatment lasts 15 min to 5 h (Ref 79).

It has been stated that boriding results in undesirable interaction with alloying elements of hot-work die steels (H series) and develops a soft layer (Ref 78). Porosity in the borided layer can develop for steels that require postboriding heat treatment. For this reason, it is preferable to limit boriding to those alloys that do not require further high-temperature treatment. For example, A6 air-hardening steel can be hardened from the boriding temperature by cooling in air, and only requires tempering. This steel, therefore, can be safely borided.

Carburizing of hot-work die steels is uncommon and not popular for two main reasons (Ref 80). As with boriding, the high temperatures required for carburizing (815 to 1095 °C, or 1500 to 2000 °F) lead to distortion of the dies on cooling. Secondly, the high-carbon surface layer, although it greatly increases hardness, can drastically reduce the toughness of the dies.

Additional information on boriding and carburizing can be found in Volume 4, *Heat Treating,* of the *ASM Handbook.*

Ion implantation is an alloying surface treatment that has been recently applied to forming dies. The process was first developed in the late 1960s to introduce electrically active elements into semiconductors of microelectronic devices. Now, more than 2000 commercial ion implantation systems are being used worldwide for semi-conductor processing (Ref 81).

Ion implantation research has increased steadily since the first publication of Hartley, *et al.* (Ref 82). The description of the process, its advantages and shortcomings, and the industrial application of the process have appeared in several review articles (Ref 83, 84, 85, 86, 87, 88, 89). Some ion implantation applications in forming are discussed below.

Ion Implantation of Stamping and Cutting Tools. The number of applications involving the reduction of wear in stamping and punching tools probably exceeds all other uses of ion implantation for metals. The dominant cause of failure in high-speed tool steels used in metal stamping is adhesive wear. Ion implantation of titanium and carbon has provided the optimum treatment for such tools. For example, the life of punches and dies for manufacturing aluminum beverage cans has been improved by 6 to 10 times as compared with that of untreated tooling. Similarly, punches for pressing powders into pellets have lasted twice as long after being treated. These applications range from forming pharmaceutical pills to more demanding service such as pressing ceramic pellets. Selected examples are listed in Table 9.

Table 9 Examples of extending tool life via ion implantation

Tool	Material	Application	Results
Chasers	Tool steel	Cutting threads in 380 aluminum	5× life
Draw die	D2	Drawing 3.5 mm (0.140 in.) hot-rolled steel	22× life before polishing
Flanging ring	D2	2 mm (0.080 in.) hot-rolled steel (flywheels)	80× life before polishing
Forming dies	W1	1 mm (0.042 in.) cold-rolled steel	Pickup reduced, improved finish on part
Forming	D2	Forming electrical connectors	At least 60% longer life
Pierce punches	M2	13 mm ($\frac{1}{2}$ in.) hot-rolled steel	12× life
	M2	1.3 mm (0.050 in.) Hastelloy (jet engine part)	30% longer life
Pilot pins	M2	0.08 mm (0.003 in.) 301 stainless steel	5× life
Plastic forming	Stainless steel	Shaping vinyl siding	Wear rate reduced for dies
Plug gage	O6	Gaging powdered metal part	At least 2× life
Reamers	Carbide	Finish reaming gray cast iron	2× life
Slitters	Carbide	Cutting rubber (belts)	Friction reduced 30%
Sprue bushings	P20 (chromium plated)	Injection molding thermoset (20% glass)	At least 4.5× life
Taps	M2 (chromium plated	Tapping cold-rolled steel nuts	8× life
Thread form taps	M2	Tapping 380 aluminum	2× life
Ultrasonic electrodes	D2	Welding aluminum to steel	2.5× life (mechanical wear)
Wire compacting	Inconel, M2	Compacting copper-base composite wire	At least 16× life

dies

Source: Ref 90

Ion implantation has also been used on a variety of low-temperature (to 200 °C, or 390 °F) cutting and slitting tools. Knife blades for cutting synthetic fibers have been implanted with titanium and carbon to improve wear resistance. Other applications include slitting blades for cutting rubber, hay baling cord cutters, plastic bandage cutter tools, corn-husking blades, paper slitters, and paper punches. Typical life improvements of 6 to 10 times have been reported for most of these applications.

Ion Implantation of Injection Molds. Another of the better-known application areas for the ion implantation process is that of injection molds for plastics and metal powders. Simple implantation with nitrogen has provided several-fold improvements in the life of these tool steel molds, along with improved mold-release characteristics and reduced corrosion from chemical additives. Molds used for powder metallurgy have also shown less tendency to fracture than untreated molds.

Ion Implantation of Extrusion and Wire-Drawing Tools. Ion implantation has proved effective in treating components such as spinnerettes for nylon or rayon fibers, which have numerous tiny orifices. The usual failure mechanism in these tools is a combination of corrosion and abrasive wear. Implantation of titanium and carbon into the spinnerettes (usually made from stainless steel) has improved the resistance to the abrasive particles (titanium oxide) that are added to the synthetic material. The treated spinnerettes have also been more resistant to the corrosive conditions encountered during the cleaning process. Ion implantation of wire-drawing dies (up to 25 mm, or 1 in., in diameter) has not only increased the life of the dies, but also improved the surface finish of the drawn wire.

References 90, 91, 92, 93, 94, 95 deal specifically with application of ion implantation in forming. Additional information can also be found in the article "Ion Implantation" in this Volume.

Plasma source ion implantation (PSII) is an ion implantation technique recently developed by J.R. Conrad of the University of Wisconsin--Madison (Ref 96). Objects to be implanted are placed directly in a plasma source and then pulse-biased to a high negative potential. A plasma sheath forms around the target and the ions bombard the entire target simultaneously (Ref 97, 98, 99).

Carbide Coating by Toyota Diffusion Process. Good surface covering and strongly bonding carbide coatings, such as VC, NbC, and Cr_7C_3, can be formed on die steel surfaces by a coating method developed at Toyota Central Research and Development Laboratory, Inc. of Japan (Ref 34).

In the Toyota Diffusion (TD) process, metal dies to be treated are degreased, immersed in a carbide salt bath for a specific time period, quenched for core hardening, tempered, and washed in hot water for the removal of any residual salt. The borax salt bath contains compounds (usually ferroalloys) with carbide-forming elements such as vanadium, niobium, and chromium. The bath temperature is selected to conform to the hardening temperature of the die steel. For example, the borax bath temperature would be between 1000 and 1050 °C (1830 and 1920 °F) for H13 die steel.

The carbide layer is formed on the die surface through a chemical reaction between carbide-forming elements dissolved in the fused borax and carbon in the substrate. The carbide layer thickens due to reaction between the carbide-forming element atoms in the salt bath and the carbon atoms diffusing into the outside surface layer from the interior of the substrate.

The thickness of the carbide layer is varied by controlling the bath temperature and immersion time. An immersion time of 4 to 8 h is needed for H13 steel to produce carbide layers with satisfactory thickness (5 to 10 μm) for die-casting applications. Dies are then removed from the bath and cooled in oil and salt or air for core hardening followed by tempering.

The salt bath furnace consists of a steel pot with heating elements; no protective atmosphere is needed. Selective area coating is accomplished by the use of copper or stainless steel masking, plating, thermal spraying, or wrapping with foils. The type of carbide coating can be changed easily by using a different bath mixture or more than one pot, each containing different carbide mixtures.

The process is applicable to most steels and some nonferrous metals. Satisfactory results have been obtained for H12 and H13 steels, which are the most widely used steels for die-casting dies. Coated steels exhibit high hardness and excellent resistance to wear, seizure, corrosion, and oxidation. In addition, resistance to cracking, flaking, and heat checking is claimed. Hardness of the coating depends on layer composition; 3500 HV for vanadium carbide, 2800 HV for niobium carbide, and 1700 HV for chromium carbide.

Additional information on the TD process can be found in Ref 100 and in Volume 4, *Heat Treating,* of the *ASM Handbook.*

MetalLife Treatment

A new surface treatment for dies and molds, MetalLife, utilizes a controlled micropeening method to develop rough texture and beneficial compressive stresses on the surface of dies and molds (Ref 101, 102, 103, 104). Rough texture increases die-lubricant retention characteristics and the residual compressive stresses inhibit the initiation of fatigue microcracks due to the mechanical or thermal cycling of die surfaces during operation.

Shotpeening of surfaces is not a new concept, but the conventional process is not very suitable for die and molds because it results in pitting and stress raisers on the surface that can result in premature tooling failure. Uncontrolled use of a smaller blasting media can result in erosive and abrasive wear. The key variables that need control are the media size, concentricity, angle of impingement, velocity, and dwell time for each media used. Sometimes multiple treatments have to be performed.

Punch and die life increases of 6 to 10 times are claimed using the MetalLife treatment. Drawing and forming dies have shown life improvements of 10 to 20 times in certain cases. In the field of die casting, MetalLife has been used to close heat-checking cracks and increase the life of dies.

Ceramic Coatings

There are a number of ceramic coatings that can be applied by various means to metal parts to improve their service properties; these ceramic materials are electrically nonconductive, have up to 20 times the abrasion resistance of metals, and can withstand temperatures in excess of 2480 °C (4500 °F) (Ref 105). Among the many ceramic wear-resistant materials available for coatings are titanium carbide, titanium nitride, and chromium carbide. These materials can be applied to chromium hot-work steels and the air-hardening tool steels by the chemical vapor deposition (CVD) process (Ref 106). In this process, the metal part to be coated is placed in a special reactor vessel after which it is heated and reacted with gas containing coating materials species. Selection of suitable coatings and metals depends strongly on the compatibility of the two from a thermal expansion viewpoint. If the expansion coefficients are widely different, the coating may crack when the part is cooled to room temperature. Because a surface interdiffusion layer is also produced, the possibility of forming soft or brittle compounds must also be considered. From previous discussions, it is known that these considerations are also important from the perspective of expected performance during forging. A good match of thermal properties is required to prevent heat checking, and tough, hard surface layers are needed to offer resistance to wear and brittle fracture. Besides being hard, these coatings generally have good lubricity. However, because of oxidation problems, they must be used at temperatures below 650 °C (1200 °F), which is above the typical operating temperature of forming dies made of hot-work die steels. To date, CVD coatings have been used for forging dies to a limited extent only. In one application, use of a TiN coating on H26 press-forging dies increased die life from approximately 18,000 (uncoated) to 51,000 pieces, as compared to a die life of 36,000 pieces using chromium-plated dies (Ref 107). The use of these coatings is sure to increase in the future, particularly in applications where life is limited by abrasive wear.

Evidence that ceramic surface coatings can extend the life of hot-forging dies has also been demonstrated in die wear trials on H12 (Ref 108, 109). In these trials, die life increases in excess of 10% were reported.

Other ceramic coatings that may find hot-forming application include alumina, zirconia, chromium oxide, and magnesium zirconate. All of these coatings have excellent wear resistance, especially chromium oxide, which has a diamond pyramid hardness of 1200 kg/mm^2 with a 300 g load; aluminum oxide has a slightly lower hardness, 1100 kg/mm^2 with a 300 g load (Ref 105). Several ceramic coatings provide excellent thermal resistance in excess of 2480 °C (4500 °F). Zirconia has a melting point close to 2480 °C (4500 °F) and is extremely resistant to thermal shock. Magnesium zirconate, with a melting point near 2150 °C (3900 °F), and yttria-stabilized zirconia, with a melting point near 2650 °C (4800 °F), are used as thermal barrier coatings.

Ceramic coating application requires the following steps:

- Cleaning
- Roughening
- Undercoating
- Coating
- Finishing

Surface preparation (cleaning, roughening, and undercoating) is the most critical step and determines application success. Mechanical, metallurgical-chemical, and physical bondings play an important role in coating adherence and strength.

Coatings are applied on the substrate by four common methods (in addition to the CVD method described above):

- Oxygen acetylene powder
- Oxygen acetylene rod (welding)
- Plasma spraying (torch)
- Detonation gun

In the oxygen acetylene powder method, the powder is fed into a flame at 2760 °C (5000 °F) and sprayed on the substrate by compressed gas. The coatings produced by this method are generally porous with low adhesion. This process is of moderate costs.

In the oxygen acetylene rod method, fused ceramic material in a rod form is introduced into a 260 °C (500 °F) oxyacetylene torch. Molten ceramic is sprayed at speeds up to 170 m/s (550 ft/s) via compressed gas on the target. This results in a coating with high cohesive bonding.

In plasma spraying, ceramic powder is introduced into a plasma (ionized gas) at temperatures as high as 16,650 °C (30,000 °F). The high-pressure plasma gas accelerates molten particles on the target. This method produces well-bonded high-density coatings, but is very expensive.

Extremely dense coatings are produced by the detonation gun process. This process is preferred when tungsten carbide coatings are to be applied. An explosion of oxygen and acetylene gases produces 3315 °C (6000 °F) temperatures, melting the ceramic and producing a molten jet that impinges the target at speeds up to 760 m/s (2500 ft/s).

A novel method for coating metalworking dies with refractory metals has been patented by a group of researchers at United Technology Corporation (Ref 110). In this method, a refractory metal coating is sprayed by a plasma gun and subsequently compacted under conditions of minimum shear stress. Refractory metals selected include molybdenum, niobium, tantalum, tungsten, rhenium, and hafnium because they have melting points in excess of 2200 °C (4000 °F) and sufficient ductility for compaction. The compaction of the coating is achieved by processing a workpiece, which has previously been formed to the end shape, through the die. This pressing of a preformed workpiece reduces the metal flow and shear stresses to a minimum, thereby avoiding shear and spall of the coating. Refractory-coated H13 tool steel dies have exhibited significant improvements in wear resistance.

Electroplating

Chromium Plating. Chromium is usually applied to metal pieces using electroplating baths composed of chromic acid and some sulfate or fluoride compound (Ref 111). Bath temperatures are between 45 and 65 °C (110 and 145 °F). The kind of plating used for forging dies is called hard chromium plating and results in surface deposits typically between 25 and 500 μm (1 and 20 mils) thick. After application of the plating, the die cavity is ground to finish dimensions.

Chromium plating has been used to a modest extent on industrial forging dies, but there is conflicting evidence as to its value. Dies with deep cavities, sharp corners, or projections that show cracking due to thermal or mechanical fatigue should not be chromium plated. This may be due to the tendency of hard chromium platings to contain microcracks that

open during cyclic loading. On the other hand, dies for thin forgings that must be discarded because of wear (especially at the flash land), and best suited for chromium plating (Ref 112)

Cobalt Plating. As with chromium, various cobalt alloys have been applied to hot-forging die steels, primarily to extend life through reduction of die wear (Ref 113, 114, 115, 116, 117). Typically composed of alloys of cobalt and tungsten or cobalt and molybdenum, these coatings are applied in electroplating baths using so-called electroplating brushes, which allow a small or selected area to be plated. Besides offering improvements in wear resistance, it appears that these coatings also possess a low coefficient of friction and can in some cases solve problems involving sticking of the workpiece. Many of the criticisms often leveled against coatings, namely loss of adhesion or flaking due to poor resistance to shock loading, appear not to apply to these coatings. Hence, it is not surprising that increases of die life up to 100% in press-forging operations are not uncommon with the use of these coatings. The kinds of parts for which these improvements have been obtained are varied and include gear levers, turbine blades, and suspension end-sockets for cars.

Hardfacing

Hardfacing is a weld fusion process that produces deposits which are metallurgically bonded to the substrate. In the early days, hardfacing was used for repair and maintenance of die and molds. It is now being used increasingly as an inexpensive means for depositing a hard layer on localized wear-prone die areas.

For dies and molds, these deposits have the following applications:

- Deposits of identical material onto a die block to repair it or to allow resinking of it
- Deposits of higher-alloy steels (for example, chromium hot-work steels) onto the die surface of low-alloy steels to improve the service performance of the dies
- Deposits of hard or high-temperature materials (usually cobalt- or nickel-base alloys) onto low-alloy or hot-work steels to improve the service performance of the dies. These alloys come under the general heading of hardfacing or hard-surfacing alloys

Hardfacing Processes. Before discussing specific alloys, the processes by which they are deposited will be briefly reviewed. The first step in any of the hardfacing processes should be the annealing of the die block into which the rough impression has been sunk (Ref 118). This relieves residual stresses and helps prevent cracking during welding of the surface layer. After annealing, the die block should then be reheated to a temperature of 325 to 650 °C (600 to 1200 °F), which is also necessary to minimize cracking due to thermal gradients set up between the surface and the interior during welding. The application of the surface layer can then be performed by one of a number of welding processes (Ref 119, 120):

- Gas torch welding (combustible gas welding)
- Manual arc welding
- Submerged arc welding
- Gas shielded arc welding (TIG or MIG)
- Open arc welding
- Thermal spraying
- Fusion treatment
- Plasma spraying (plasma arc welding)
- Transferred arc plasma
- Flame plating
- Deposition process (electroslag welding)

Together with the solidification conditions, the amount of melted base material and base-material dilution is important for wear properties. Hardfacing methods differ considerably from each other and also compare with powder spray methods, which show almost no base-material dilution due to mixing.

Combustible-gas welding offers many advantages in depositing smooth, precise surfaces of high quality. This is done by using a carburizing flame that causes "sweating," or welding of a thin surface layer that spreads freely and prevents metal

buildup. For repair of dies, the shielded metal arc method is preferred. It allows high productivity and has the advantage of low heat input and thus minimal distortion of the die cavity.

After welding, the die block must be cooled to room temperature to prevent cracking of the weld deposit. The die impression is then finished, machined, and ground. Heat treatment (austenitizing, quenching, and tempering) of the die block is performed last. Once again, differences in thermal properties between the base metal and surface deposit are critical insofar as thermal cracking is concerned. Because this is also an important consideration in the performance of forming dies, it is not unusual that welding alloy suppliers are sometimes hesitant about recommending many combinations of die block material and hardfacing alloy (Ref 121).

Hardfacing Alloys. For hardfacing, welding alloys are generally based on iron, cobalt, or nickel. Hard phases are formed by addition of carbon (in iron) or boron (in nickel). The volume fraction of hard phase is very important for the wear resistance in the weld deposit. Often there is no proportional dependence and the best wear resistance is not achieved by the highest hard-phase concentration.

Various ferrous alloys are used to repair steel dies or to lay down deposits with better wear and heat resistance than the substrate. These alloys are very similar to the low-alloy and hot-work tool steels in composition. Austenitic and austenitic-ferritic materials are preferred for wear resistance under heavy loads.

The use of nickel- and cobalt-base alloys in hardfacing offers a considerable cost savings over die blocks made of these alloys. In a typical hardfacing operation, a one- or two-alloy layer, each about 0.25 to 1.25 mm (0.010 to 0.050 in.) thick, are deposited on the die. If a large amount of buildup is desired or required, however, it is advisable to apply layers of stainless steel or low-alloy filler metal first rather than many layers of the more expensive nickel or cobalt hardfacing materials.

Detailed information on the methods for depositing hardfacing alloys and their resistance to wear can be found in the article "Friction and Wear of Hardfacing Alloys" in this Volume.

Electro-spark deposition (ESD) is a variation of hard surfacing that has been used extensively in Europe for improving the galling resistance of material (Ref 122). Electrodes of WC, TiC, and Cr_3C_2 materials have been deposited on type 316 stainless steel and other substrates. The ESD process has been found to be effective in fusing metallurgically bonded coatings to the substrate at low heat with the substrate remaining near the ambient temperature.

Hard Coatings for Cold Extrusion

In the cold extrusion of steel, compressive loads up to 3000 MPa (435 ksi) and tensile loads up to 1500 MPa (220 ksi) are not unusual. Core hardening (or through hardening) of the tool steel makes the punches brittle, leading to early failures. The highly stressed tools, therefore, either should be made from tungsten carbide (a costly material) or they should be hard coated.

A very detailed study of chemical and physical treatments for backward can extrusion has been reported by Westheide, *et al.* (Ref 123). They divided the surface treatments used into reaction- and coating-layer processes (Fig. 28). In the reaction layers, the layer element diffuses into the substrate (die material); in the coating layers, the primary adhesion mechanism is mechanical interlocking. Figure 28 also identifies the type of coating that can be deposited on the substrate.

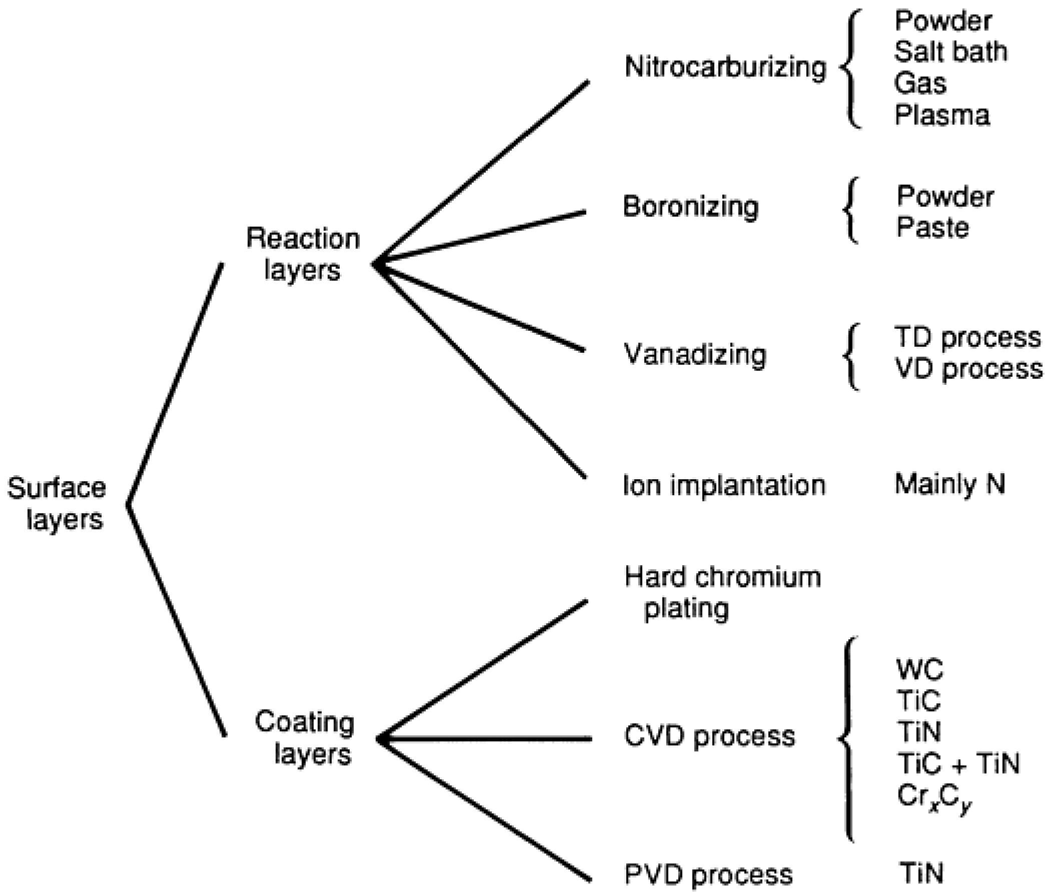

Fig. 28 Coating processes carried out on die materials used for cold extrusion. Source: Ref 123

In this study, billets of case hardening steels (similar to AISI 5120) were used. Punches were either made of a cold-working tool steel (similar to AISI D2) or of high-speed tool steel (similar to AISI M2); the former hardened to ~62 HRC and the latter to ~64 HRC. Backward can extrusion experiments were carried out on a 630 kN (70 ton) press at 40 strokes/min. The billet height to internal diameter ratio was unity and soap was used as the lubricant.

A comparison of treatments for backward can extrusion is given in Fig. 29 for 10,000 extrusions. Lowest wear rates were obtained for PVD TiN coatings and TD vanadium carbide (vanadized) coatings.

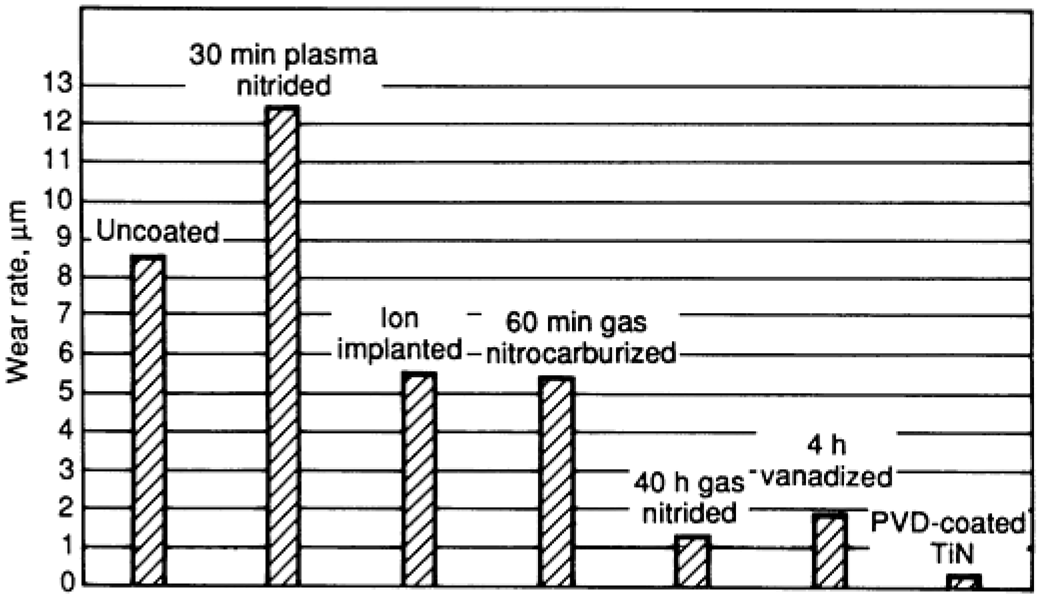

Fig. 29 Comparison of coatings for backward can extrusion. Source: Ref 123

The application of TiN coatings in cold extrusion is reviewed in Ref 123 and 124. Some of the cold extrusion applications where TiN coatings have proved beneficial are hexagonal socket press tools, tools for spur gear teeth, and hydraulic valve stem housings (Ref 123). Vanadium carbide coatings deposited by the TD process have been applied to extrusion dies in rubber forming. Die life increases from 30 h for hardened steels to 900 h for coated steels have been found in the production of rubber window seals (Ref 104).

Surface Treatments and Coatings for Cold Upsetting

Westheide (Ref 123) also carried out similar studies on protective wear-resistant coatings for upsetting dies. A qualitative comparison of various coatings is provided in Table 10. Hard chromium plating and TiC coatings via CVD were found to have excellent wear resistance.

Table 10 Comparison of selected coatings for cold upsetting

Coating	Surface after coating	Wear reduction	Layer adhesion	Remarks
Nitriding and nitrocarburizing	P	G	M	Chipped off
Vanadizing	M	M	G	Layer polished, uncertain measurement
Ion implantation	E	G	E	B^+ implantation = unsuccessful
Hard chromium plating	E	E	E	. . .
CVD-W_2C	P	G	P	Layer chipped off
CVD-TiC	P	E	E	. . .
PVD-Ti*X*	M	M	P	Layer chipped off due to interruption of coating

Note: E = excellent, G = good, M = moderate, and P = poor.

Friction and Wear in the Mining and Mineral Industries

D.L. Olson and C.E. Cross, Center for Welding and Joining Research, Colorado School of Mines

Introduction

THE PRACTICE of mining and mineral processing, by its nature, involves severe mechanical interactions between metals, as well as between abrasive nonmetallic and metallic materials. The abrasive nature of most ores can cause significant wear to both handling and processing equipment.

Various wear processes are involved, depending on the nature of the abrasive material, type of loading, and the environment. The direct impact of metallic components with the earth requires alloys that have excellent ductility and work-hardening properties. The transport of ground material across a surface, such as chutes, requires high surface hardness. The crushing or fragmentation of ore requires even higher hardness values. Performing mechanical operations in corrosive environments, such as mineral slurry pumps, requires that the material exhibit both corrosion and wear resistance.

To properly select wear-resistant materials, careful analysis of the material application is necessary. This selection should consider a very broad range of alloys, including high-strength steels, white irons, austenitic alloys, and high-chromium/high-carbon stainless steels.

Types of Damage

Abrasive wear, the most common form of damage in the mineral industry, can be classified as being due to low-stress, high-stress, or impact abrasion (Ref 1, 2). The material-ore interaction is considered a low-stress abrasion application when the wear process does not involve a fracture of the abrasive material.

An example is the movement of fragments of ore traveling across a high-strength steel surface (Fig. 1a). Low-stress abrasion is not accompanied by significant impact. The damage is the result of either scratching or a micrometal removal process. Sharp, angular abrasives result in the highest wear rate. For this case, materials with high hardness are used to minimize the metal removal rate. Abrasion-resistant (AR) steels, alloy cast irons, and ceramic tiles are often used for these applications.

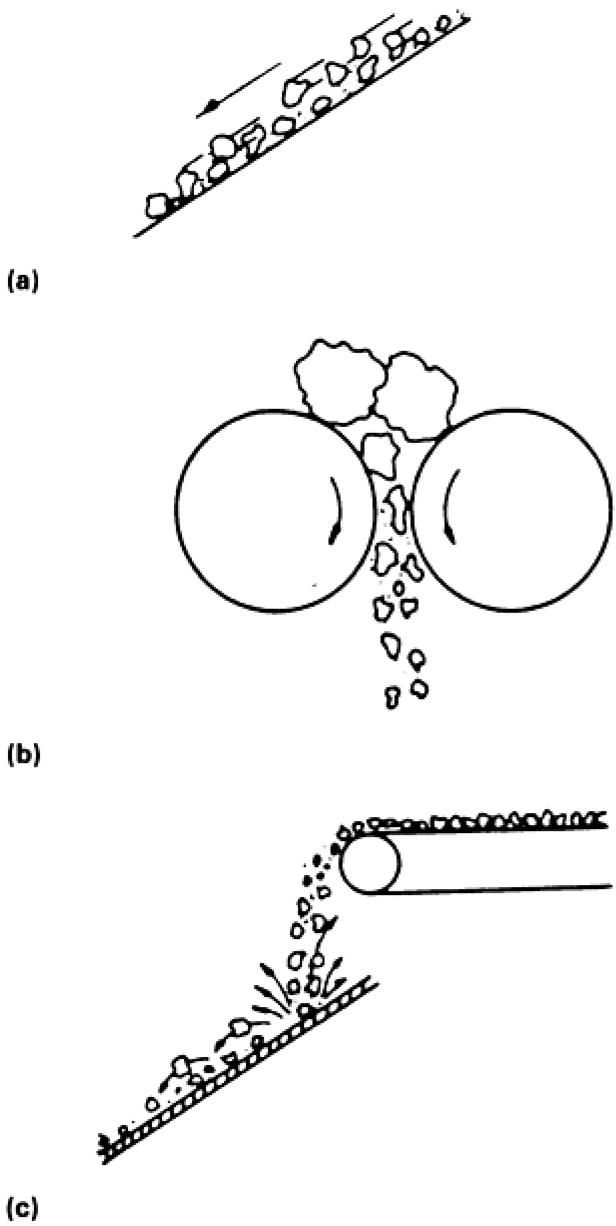

Fig. 1 Three types of abrasive wear, (a) Low stress. (b) High stress. (c) Impact. Source: Ref 1

High-stress abrasion results when abrasive materials are caught between two normally loaded surfaces. The loads are commonly sufficient not only to cause particle penetration of the loading surfaces, but can also fragment the abrasive material. This damage is common to ball mills, rock drills, and rock crushers (Fig. 1b). Surface damage is due to a combination of scratching and plastic deformation, commonly resulting from fatigue. The damage can be minimized by the selection of materials with both high yield strength and hardness.

Some sites on mining equipment will be subject to direct impact, which requires those sites to have both hardness and toughness. The high localized pressures on impact cause the abrasive materials to cut into the wearing surface, resulting in very apparent large gouges and scratches. This type of damage (Fig. 1c) is common to the impact areas of chutes, pulverizing mills, and shovels (Ref 1). The material of choice is often an austenitic alloy that has high toughness and progressively increase in hardness with use through work hardening (Ref 3, 4). High-manganese steels with greater than 14 wt% Mn (known as Hadfield alloys) are examples of traditional impact-resistant austenitic alloys.

Corrosive Wear. Wear is primarily the removal of surface metal by mechanical action. Often, the mining and mineral processing environment is wet, which cause a chemical action that affects the mechanical wear (Ref 5 , 6, 7, 8, 9). This corrosion effect either increases or decreases the metal removal rate, depending on the natures of both the mechanical

interaction and the corrosion product. The synergistic effect of mechanical and chemical interaction causes considerable variation in reported wear rates on mining and mineral processing equipment.

Adhesive wear between one metallic part and another is also a common form of damage in the mineral industry. It results from the surface tearing of materials that became bonded because of rubbing (Ref 1). The damage involves scoring, galling, or seizure. The adhesive wear rate is usually larger when the interacting materials have similar compositions and crystal structures, and it usually occurs under load with little or no lubrication. A common location for adhesive wear is at a surface where wire rope rubs against spools and pulleys, for example. Figure 2 illustrates adhesive wear on a steel spool that has been interacting with wire rope.

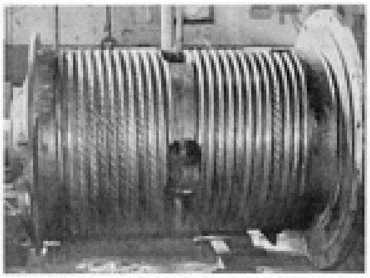

Fig. 2 Cable wear on large spool, a form of adhesive wear. Source: Ref 10

Testing for the types of wear damage described above is often performed according to ASTM test procedures (Ref 11, 12, 13), as well as other special tests designed by specific corporations to evaluate special conditions (Ref 14, 15, 16, 17).

Methods to Improve Wear Resistance

Wear resistance can be increased on mining and mineral processing equipment through proper material selection and equipment design, and through the use of wear plates, as well as hardfacing deposition. The method selected will depend on the type and use of the part and the economics associated with operation of the equipment.

Material Selection. A variety of materials that provide wear resistance are commercially available (Ref 18, 19). Some material types are shown in Fig. 3 relative to service and environmental needs.

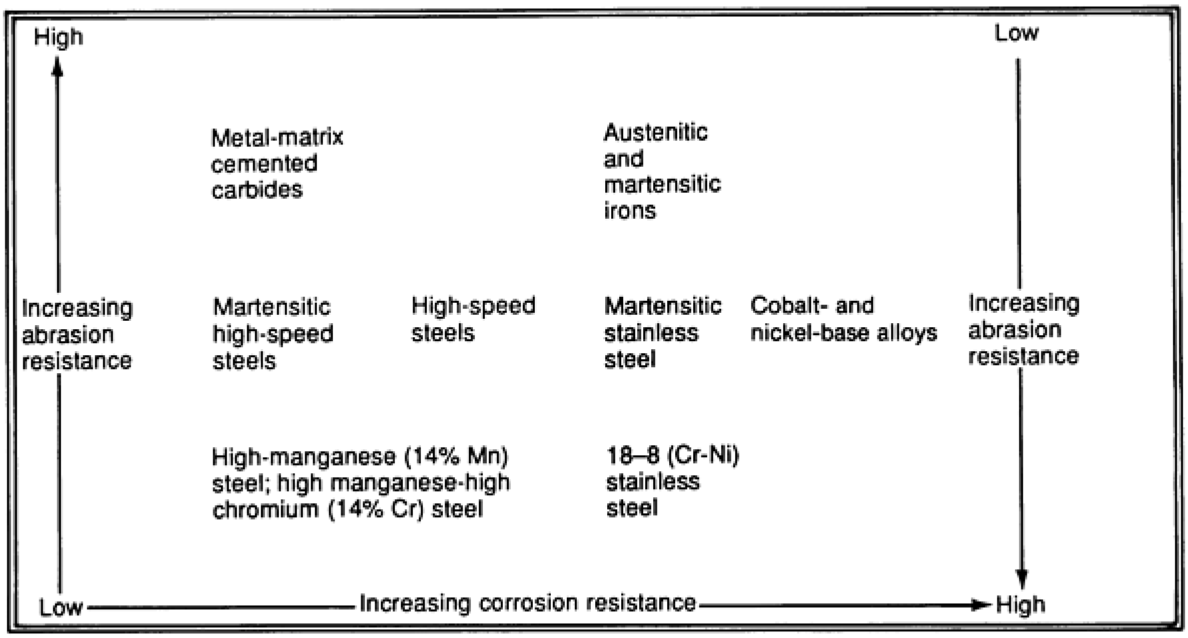

Fig. 3 Relative placement of various wear-resistant alloy systems when considering abrasion, impact, and corrosion resistance. Source: Ref 20

High impact resistance with low abrasion and corrosion resistance can be achieved with high manganese ferrous alloys. A Hadfield alloy (14Mn-1C) is a traditional material for impact resistance. In both the as-cast and as-welded conditions, the Hadfield alloy shows good ductility. Additionally, the alloy work hardens with impact and deformation, resulting in increased strength and hardness levels (Ref 21). For more corrosive environments, impact resistance can be achieved with the 18-8 (18%Cr + 8%Ni) stainless steels. Austenitic stainless steels, such as the 18-8's, also work harden with service, but have the disadvantage of high material cost.

Abrasion-resistant plate steels, similar to armor-grade steel, have a unique combination of desirable properties: high hardness, good toughness, and weldability (Ref 22). Abrasion resistance is achieved using a water quenched and tempered martensite, which is often low enough in alloy content (that is, has a low carbon equivalent) to avoid the concerns of weld underbead cracking with proper welding practice. Vacuum degassing and desulfurization during steelmaking is required to minimize inclusions and thus improve toughness in the short transverse direction.

As the abrasion resistance increases from a low-stress to high-stress application, the selected material must increase in hardness from martensitic alloy steel to high-carbide materials, including alloyed white irons. Applications for martensitic steels of various hardness levels are given in Table 1.

Table 1 Materials for surfacing, build-up, and hardfacing

Types of Materials	Advantages	Applications
Low hardness		
Pearlitic steels	Low cost, crack resistant	A build-up material to restore dimension or as a low-cost base for surfacing applications
Mild steels	An excellent base for hardfacing	
Low-alloy steels	Some toughness for build-up of worn areas	
Austenitic steels	Excellent for heavy impact, tough	For metal-to-metal wear under heavy impact conditions
Low-carbon Ni-Cr stainless	Good corrosion resistance	Corrosion-resistant surfacing of large tanks, nuclear vessels
High-carbon Ni-Cr stainless	Oxidation and hot wear resistant	Furnace parts, red heat frictional wear
14% Mn, Cr-Ni	High yield strength austenitic	Build-up, crack repair, joining manganese alloys or manganese to mild steel
14% Mn, 1% Mo	Fair abrasion and corrosion resistance, work	Railways track build-up

	hardens	
14% Mn, 3% Ni	Work hardens	Build-up and joining of manganese parts
Semiaustenitic steels	Low-cost crack-resistant materials	Hardfacing applications
Copper alloys	Resistance to seizing under frictional wear conditions	For build-up of bearing surfaces
Medium hardness		
Nickel-base alloys	Good corrosion resistance and excellent hot hardness	For applications where hot hardness is important
Nickel-chromium	Resistance to oxidation	For corrosive wear conditions
Nickel-chromium-molybdenum	Resistance to exhaust gas corrosion	For hardfacing truck, bus, and aircraft engine valves
Nickel-chromium-molybdenum tungsten	Corrosion-resistant properties	For surfacing applications
Nickel-chromium-boron	Corrosion-resistant as well as abrasive-resistant properties	Pumping service applications, especially in the oil fields
Martensitic alloy irons	Excellent abrasion resistance	For overcoming abrasive wear where light or no impact is involved
Chromium-molybdenum	Abrasion resistance while withstanding light impact	For the build-up of machine parts subject to repetitive metal-to-metal wear with or without light impact
Chromium-tungsten	High compressive strengths	
Austenitic alloy irons	Better crack-resistant properties than the martensitic alloy irons	Where erosive wear with or without light impact is present
Chromium-molybdenum	Good crack-resistant qualities	Pump and turbine build-up
Nickel-chromium	Crack resistant, light impact	For erosive wear with light impact
Martensitic steels	Abrasion resistance with medium impact	For a variety of abrasive wear conditions where there may also be involvement with medium impact
Low carbon (up to 0.30% C)	Least expensive, tough	
Medium carbon (0.30-0.65% C)	Good resistance to medium impact	
High carbon (0.65-1.7% C)	Fair abrasion resistance	
High hardness		
High-chromium irons	Excellent erosion-resistant properties	For general use where hot gases or materials are involved
Austenitic	Good abrasion-resistant qualities	For farm and earth-moving equipment working in sandy soils
Martensitic	Ability to be rehardened after annealing	As a hardfacing in steel mills and refineries where hot erosion (595 °C, or 1100 °F) is a wear problem
Tungsten-molybdenum alloys	High red hardness	For hardfacing of coke oven parts as well as other hot (425-650 °C, or 800-1200 °F) steel mill applications
Chromium-tungsten cobalt alloys	High red hardness, high hot strength and creep-resistant qualities	For most hardfacing applications, but best suited to those applications where hot wear and abrasion (above 650 °C, or 1200 °F) are involved (jet engine turbine blades, gas engine exhaust valve)
Low carbon (up to 1.0% C)	Good oxidation resistance, tough	
Medium carbon (1.4% C)	Resistant to abrasion and oxidation	
High carbon (2.5% C)	Good abrasion resistance, brittle	
Tungsten carbides	The ultimate in abrasion-resistant qualities	A variety of materials used for hardfacing to meet an extremely wide range of severe abrasive conditions, especially oil well drill bits, tool joints, rock drill bits
Fine-grain tubular rods	A relatively smooth, extremely wear-resistant surface, gas weld	
Coarse granular tube rod	Develops a rough cutting surface as the deposited binder wears away	
Granules or inserts	Develops an extremely rough abrasive cutting surface as granules or inserts become more exposed. Highly abrasive, but brittle under impact conditions	

Source: Ref 23

The role of carbon content in steel and iron to promote abrasion resistance is illustrated in Fig. 4, which indicates the position of various alloy types relative to their gouging wear rates. Figure 5 correlates wear rate to hardness for the various alloys experiencing abrasion wear.

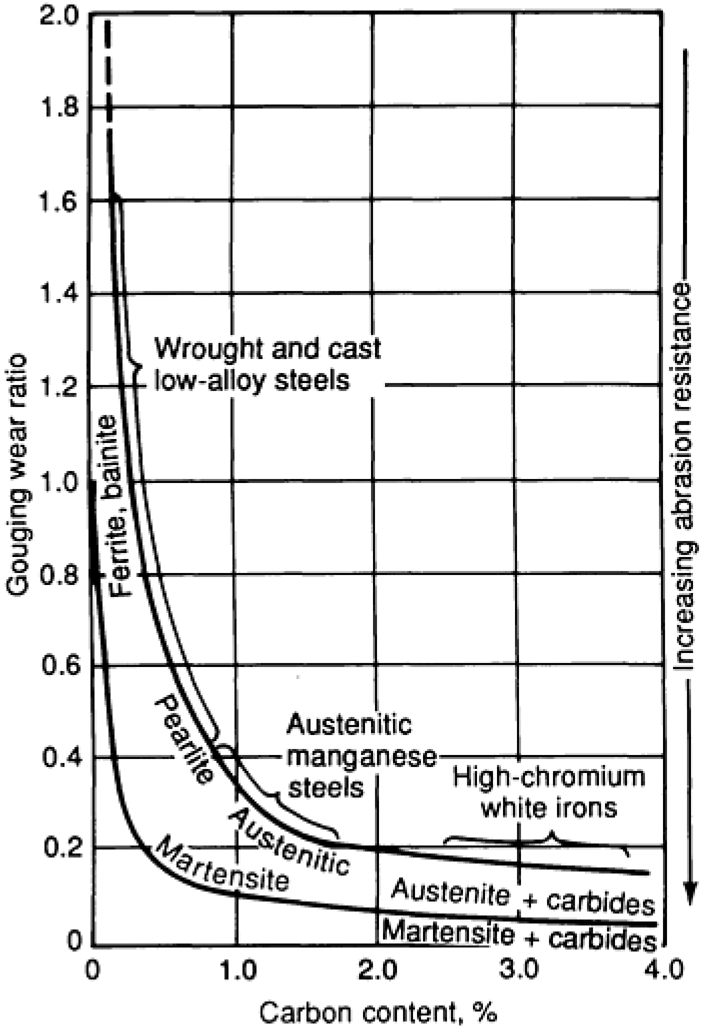

Fig. 4 Relative placement of various alloys as function of carbon content and abrasion resistance, as measured by gouging wear ratio. Source: Ref 24

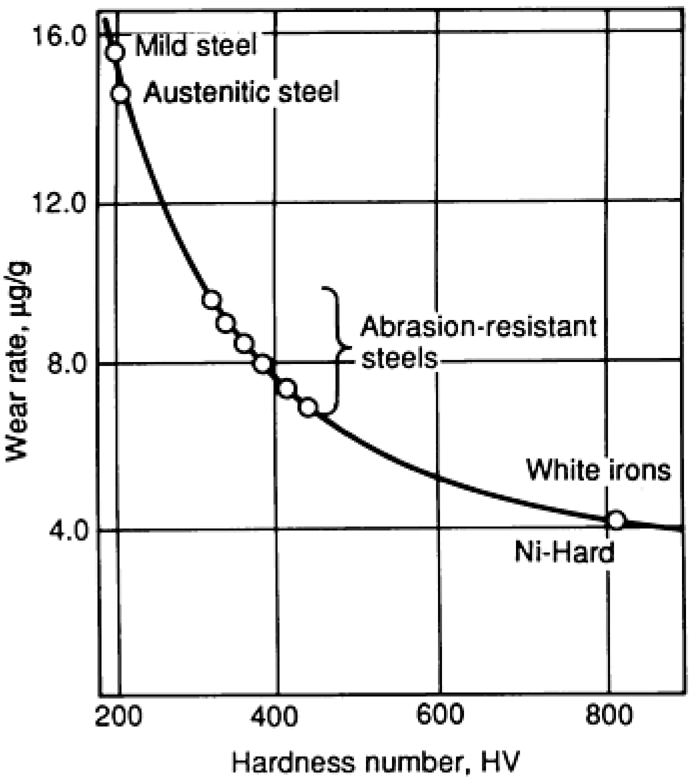

Fig. 5 Abrasion resistance of various alloy systems, comparing wear rate to hardness. Source: Ref 25

Use of Wear Plates. A part that experiences major wear should be designed for easy replacement to prevent excessive processing downtime. Figure 6 shows high-manganese steel wear plate castings that are welded into the bucket of a large shovel. These castings were made with properly spaced holes, which alloys easy shielded metal are welding of the cast plates to the shovel. Similar wear plates are used as working surface in crushers (Ref 26, 27) and pulverizers.

Fig. 6 High-manganese steel-casted wear plates plug welded to inside of large shovel. Source: Ref 10

Figure 7 illustrates the use of wear plates in medium-sized buckets. Often, an easily weldable steel plate or strip that is considered expendable is used. A typical practice is to incur significant wear in a new bucket to reduce its weight prior to welding these wear plates to it. Bucket weight is an important consideration in the efficiency and economics of earth-moving processes.

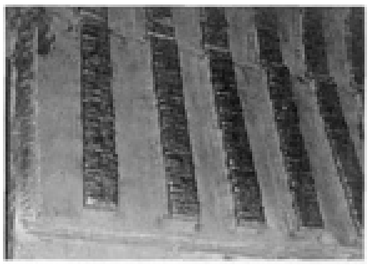

Fig. 7 Steel strips welded onto surface of shovel and hardfacing deposition placed on top of steel strips to give abrasion and impact resistance for a rack consisting of large racks. Source: Ref 10

Table 2 lists the various ferrous alloys used for mill liners. They include a broad range of high-carbon steel and alloyed white irons.

Table 2 Ferrous materials for grinding mill liners

Item	Material	Composition range, %(a)							Hardness range, HB(b)	Relative wear rate(c)

Source: Ref 26

(a) The composition range from an individual supplier will normally be narrower than the ranges given in the table. Production of certain compositions falling within the above ranges may involve proprietary rights covered by patents or trademarks.

(b) Hardnesses listed are on the unworn surface of the liners. Austenitic and martensitic alloys tend to work harden on wearing surfaces.

(c) Relative wear rate as determined when wet grinding minus 10mm ($\frac{3}{8}$ in.) feed to minus 48 mesh on ore containing about 65% quartz, 25-30% feldspar, and 3% pyrite as the principal abrasives, in primary ball mills at Climax, Colorado.

(d) A composition containing about 1.0% C, 5-6% Cr, and 1.0% Mo was used as a comparative standard in all tests and assigned a relative wear rate of 100.

(e) Wear rates in the Climax mills could not be determined on this material, because of spalling and breakage.

Use of Hardfacing Deposition. Three primary methods are used to deposit hardfacing materials in the mineral industry (Ref 28, 29, 30, 31, 32, 33, 34, 35): arc welding, oxy-fuel gas welding, and thermal spraying. Filler metals are available in rod, wire, and powder form.

The most traditional process is shielded metal arc (SMA) weld deposition, which involves low capital investment, can be used in all positions, and is an excellent field welding process. It is considered a low deposition rate process. A large selection of commercial electrode compositions exist.

The gas-metal arc welding process is used to make wear-resistant depositions. The gas-metal arc wire electrode process increases deposition rate and productivity, but usually requires more equipment setup. This gas-metal arc weld deposition process is more flexible than the submerged arc welding process, but it is more difficult than shielded metal arc welding in terms of moving the welding equipment, including the necessary gas supply for protective cover.

The submerged arc welding process deposits in either the flat position or on top of a rotating round part and is capable of high deposition rates. It is a fully automatic process that needs to be performed in a stop. A wide range of alloy consumables are available, including strip electrodes.

Flux-cored electrodes that introduce flux and carbide-forming ingredients to the weld deposit, by additions to the core of the welding wire, are available. These flux core additions can also contain generators of plasma and shielding gas which can produce a wire welding process that is self shielding and therefore does not require additional supplied shielding gas.

Hardness is commonly used as a measure in the selection of hardfacing materials. The abrasion resistance of martensitic alloys is expected to increase with increasing hardness, whereas impact resistance would be obtained from materials of low hardness. An extensive list of hardfacing and surfacing materials is given in Table 1, along with their specific advantages. The alloy compositions and AWS designations for these various hardfacing materials are given in Table 3.

Table 3 Classification and Composition of typical hardfacing alloys

Use of Design. The geometric pattern of hardfacing deposition also has a role minimizing the wear rate. Figures 8, 9, 10, 11, 12, and 13 illustrate various patterns in which hardfacing deposits can be laid. Figure 9 suggests that the flow of fine material be perpendicular to stringer bead deposits, whereas with coarse ore, it is common to align the flow of ore with the stringer bead deposits. The larger rocks tend to knock off the perpendicular beads. Ores with mixed sizes require the spaced weave pattern. The general concept is for the interspaces to be filled with fines, which allow the ore to grind upon ore, thereby reducing metal loss. The spacing between deposits is directly related to the size distribution of the ore.

(c) Hardfacing just top of tooth, which is recommended practice that results in self-sharpening of tooth use. Source: Ref 32

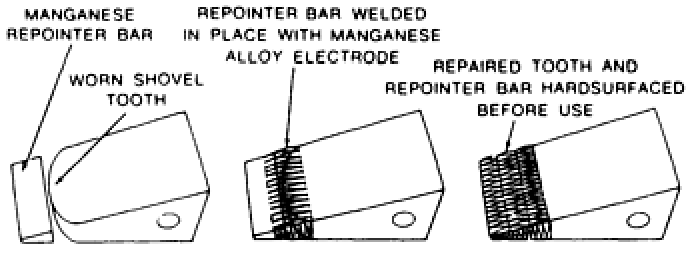

Fig. 13 Worn shovel tooth often rebuilt by welding a new repointer bar, usually made of high-manganese steel, onto end of tooth prior to depositing hardfacing materials. Source: Ref 32

For locations that experience impact loading, it is common to use complete coverage of the hardfacing deposits. Scoop buckets are commonly hardfaced on the digging edge using overlapping stringer beads, with the side of the bucket having a diamond bead pattern, as shown in Fig. 10 and 11.

Special rules are used for hardfacing deposits on scraper teeth. The teeth become blunt, either without hardfacing or with hardfacing on both the top and bottom of the teeth (Fig. 12). Shovel teeth should be hardfaced when they are new. Hardfacing should be deposited with close spacing, if not overlapped, from the point of the tooth back to 50 mm (2 in.) from the point (Fig. 9). The proper method is to deposit hardfacing material only on the top of the tooth. This practice will allow the tooth to preferentially wear, resulting in a self-sharpening effect (Fig. 12). If the point breaks off, then it is often built up with either steel or 14 wt% manganese steel (Fig. 13).

Hardfacing materials commonly have thermal expansion coefficients that are very different from the substrate material on which they are deposited. This thermal expansion mismatch causes residual stresses. The hardfacing materials commonly have thermal expansion values that are larger than the base structural material, which promotes longitudinal tensile stresses in the deposit.

In many hardfacing materials, it is common to have cross-checking, which is a form of transverse cracking that is desirable because it relieves the stresses produced by thermal expansion mismatch between weld deposit and base metal (Fig. 14a). If cross-checking does not occur during hardfacing, then the combined residual and externally applied stresses can cause hairline cracks under the weld deposit in the heat-affected zone of the base material (Fig. 14b), which can result in spalling during service.

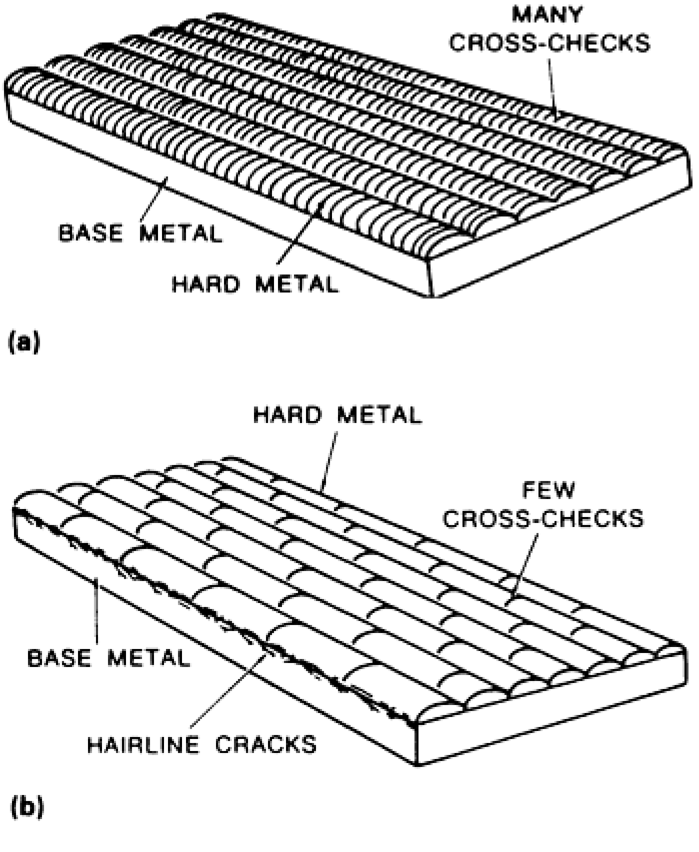

Fig. 14 (a) Sufficient cross-checks. (b) Insufficient cross-checks. Source: Ref 32

In situations where crack-free hard surface deposits are necessary, welding practice that involves a carefully selected welding electrode with preheat and post-heat treatments is necessary (Ref 32). Recommended practices are available from many of the harfacing electrode manufacturers.

Ball and Rod Grinding Media

Grinding media, in the form of balls and rods, are made of various alloys (Ref 3, 24, 36, 37, 38, 39, 40, 41). The mining industry consumes cast steel, Ni-hard, and high-chromium white iron grinding balls. Grinding rods are commonly hot-

rolled high-carbon steel (AISI 1080 to 1095), as well as AISI 52100 steel. The grinding media need to be harder than the ore to be ground. The composition and hardness of typical steel and white iron grinding media are compared in Table 4.

Table 4 Composition and hardness of typical steel and white iron grinding media

Type of ball	Hardness, HB	Composition, %					
		C	**Si**	**Mn**	**Cr**	**Ni**	**Mo**
Forged steel	650	0.80	0.26	0.60	. . .	. . .	0.29
Pearlitic white iron	460	2.75	0.30	0.75	. . .	. . .	. . .
Martensitic white iron	600	3.23	0.62	0.64	1.89	4.26	. . .

Cast iron grinding balls are iron-carbon alloys that contain free carbides. In unalloyed cast iron balls, iron carbide is the phase that influences hardness. With up to 10 wt% chromium, these cast iron balls have mixed carbides, including $(Fe,Cr)_3C$, and hardness values from 800 to 1200 HV. At levels above a 10 wt% chromium addition, $(Fe,Cr)_7C_3$ carbide is also present, resulting in hardnesses that ranges from 1300 to 1800 HV. The nature of these carbides is significant to the wear rate of the grinding media (Ref 38).

Low-alloy pearlitic white iron grinding balls offer a lower-cost alternative to alloyed irons and can be used with many ore types. Pearlitic white irons can have up to 2 wt% chromium content and their hardness values are not extremely high, usually ranging from 450 to 600 HV. They are available in either as-cast or stress-relieved conditions (Ref 38).

Heat-treated martensitic white iron balls are also available. These alloys are usually alloyed with nickel and chromium to allow the formation of a martensitic matrix during the normal cooling process. An example of this type of white iron is Ni-hard cast iron, which has from 2.5 to 4.5 wt% nickel and from 1.5 to 2.5% wt% chromium. Ni-hard cast iron balls have hardness values ranging from 600 to 750 HV, depending on ball size and carbon content (Ref 38).

Martensitic ductile iron balls with hardness values between 600 and 700 HV offer high hardness with higher toughness than is commonly found with pearlitic and martensitic white iron balls. The microstructure consists of a discontinuous carbide network and small graphite nodules in a martensitic matrix. The graphite nodules assist in controlling the amount of free carbides and in promoting the discontinuous carbide network. Martensitic ductile irons are cast to yield carbides and then water quenched to produce a martensitic structure. The toughness can be improved by tempering (Ref 38).

Friction and Wear of Medical Implants and Prosthetic Devices

Duncan Dowson, The University of Leeds (England)

Introduction

SYNOVIAL JOINTS are remarkable bearings. In man they generally operate as dynamically loaded bearings subjected to about 10^8 cycles of loading in a 70-year lifetime. They are self-contained and subjected to the oscillatory motion associated with the requirements of human locomotion and their position in the skeletal frame.

The natural synovial joint exhibits the features of many engineering plain bearings. It consists of layers of bearing material (articular cartilage) mounted on relatively hard bones forming the skeletal frame (Fig. 1). The lubricant (synovial fluid) is a water-based fluid containing a additive (hyaluronic acid) that not only produces a tacky, viscous fluid which ensures adequate fluid-film lubrication under most conditions in healthy joints, but also combines with protein to form a very effective boundary lubricant. The slipperiness of cartilage-coated bone ends is well known, and this led to the early concept of boundary lubrication in synovial joints. However, carefully conducted experiments (Ref 1, 2) suggested that fluid-film lubrication prevailed in natural joints, and recent theoretical work (Ref 3, 4) has confirmed this possibility. It appears that natural recognized the merits of elastohydrodynamic and microelastohydrodynamic lubrication long before engineers appreciated the phenomena and adopted the to advantage in machine design.

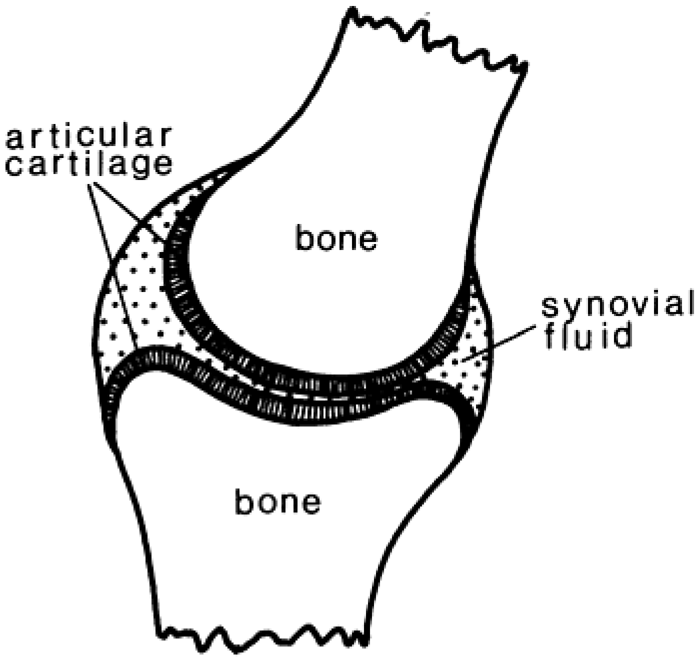

Fig. 1 Schematic showing key components of a natural synovial joint

In tribological terms, the major load-bearing natural synovial joints, such as the hip and the knee, operate with average coefficients of friction of about 0.02 and wear factors of about 10^{-6} $mm^3/N \cdot m$. Like many bearings, they tend to deteriorate with time, and in due course the bearing material roughens, fissures, and wears away to expose the underlying bone. This process, which represents but one form of the rheumatic diseases, is known as osteoarthrosis and is generally associated with a restriction or loss of movement, increased stiffness, and pain. In severe cases, surgical intervention may be necessary. It is at this stage that the materials scientist and the tribologist are called upon to work alongside the surgeon in the design and development of satisfactory total replacement joints.

Historical Background

Total joint replacement is widely regarded as the major achievement in orthopedic surgery this century. Arthroplasty, or the creation of a new joint, is the name given to the surgical treatment of degenerate joints aimed at the relief of pain and the restoration of movement. This has been achieved by excision, interposition, and replacement arthroplasty and by techniques that have developed over about 170 years.

Early Excision Arthroplasty

In excision arthroplasty, which developed in pre-anesthetic and pre-antiseptic times, bone is divided, remodeled, and removed. One of the earliest approaches to excision arthroplasty is attributed to Anthony White, who operated successfully on a 9-year-old boy at the Westminster Hospital in London in 1822 (Ref 5). Shortly afterwards, a planned excision arthroplasty for a hip deformity was reported by J.R. Barton of Philadelphia (Ref 6).

Interposition Arthroplasty

One of the main objectives of arthroplasty is to re-establish movement in the joint, but this can readily be defeated by arthrodesis--the subsequent fusion and fixation of the bones. Interposition arthroplasty attempts to overcome this problem by interposing foreign materials between the bone ends. The procedure developed in the mid-19th century, with notable contributions being reported by Gluk (Ref 7) in 1885, Jones (Ref 8) in 1902, Hey-Groves (Ref 9) in 1926, and Smith-Peterson (Ref 10, 11) between 1923 and 1938.

A remarkable range of materials was interposed between the bone ends, including muscle, wood, ivory, gold foil, celluloid, pyrex, phenol-formaldehyde resin, and a cobalt-chromium-molybdenum alloy known as Vitallium then used in

dentistry. In many of the initial cases, the insert was simply interposed between the surfaces, but in most of the latter devices the material was shaped into a cup, which allowed some movement between it and both the femoral head and the acetabulum. Interposition arthroplasty was adopted for hundreds of patients prior to the widespread introduction of total joint replacements in the 1950s and 1960s.

Replacement Arthroplasty

The origin of replacement arthroplasty is generally associated with Philip Wiles (Ref 12), who, while working at the Middlesex Hospital in 1938, designed and introduced a stainless steel total replacement hip joint. The acetabular cup and femoral head were ground to fit together accurately, and the femoral head was mounted on a bolt that passed down the neck of the femur. If appears that the six operations carried out achieved some success, but the work was disrupted during World War II and all records were lost. It nevertheless appears that this pioneering development represented the first effective introduction of metal-on-metal total replacement joints.

Femoral Head Replacements. It was not until the 1950s that further progress was reported on total replacement joints, but in the meantime a number of interesting femoral head replacements were introduced. Notable among these were the acrylic prosthesis developed by the Judet brothers in Paris in 1946 (Ref 13) and the cobalt-chromium alloy prosthesis introduced by Austin Moore in the United States in 1950 (Ref 14). The Judet prosthesis was received with some enthusiasm, but by 1954, when some 850 patients had been operated upon by the Judet brothers, there was concern about the incidence of fracture and severe abrasion of the acrylic head. Nylon was tried as an alternative material, but excessive wear took place and the wear debris was associated with acute tissue reaction. The Austin Moore implant did not suffer such wear problems, and many operations were carried out, but concern was expressed for the migration of the acetabulum and the penetration of the femoral head into the pelvis. An interesting feature of the later forms of the Austin Moore femoral implant was the fenestrations of the intramedullary stem, since it appeared that cancellous bone grew into the foramina to effect anchorage of the prosthesis.

Total Hip Replacements. Two English surgeons made outstanding contributions to the development of total hip replacements in the 1950s.

Metal-on-Metal Implants. In 1951, G.K. McKee of Norwich introduced a metal-on-metal prosthesis in which both the femoral and acetabular components were made of stainless steel (Ref 15). The acetabular cup was initially fixed into the pelvis by means of screws, but because these came loose within a year, no doubt due to the excessive friction associated with a stainless steel ball seated within a close-fitting acetabular cup, the material of construction was changed to Vitallium, a cobalt-chromium-molybdenum alloy. McKee then adopted a modified form of the Thompson femoral component developed in the United States and a cloverleaf form of acetabular cup that was again fixed by a screw. A success rate of about 50% was reported in the period of 1956 to 1960, but it became clear that success depended primarily on the metallic components remaining tight in the bone. In 1960, when McKee and his colleague Watson-Farrar introduced methyl-methacrylate as a cement to hold the components in place, the success rate rose to an encouraging 90%. By 1967, the outer surface of the cup was studded to assist fixation in the cement, as shown in Fig. 2 (Ref 16). McKee wrote confidently of the excellent chance of his total replacement hip joints lasting for 10 to 20 years. He also wrote of the "lapped-in" Vitallium components:

> ". . .the frictional resistance is small, the bearing surfaces are hard, and wear is reduced to a minimum."

McKee also recognized that the rubbing together of identical metals was tribologically unsound, but necessary in total replacement joints to avoid electrochemical corrosion:

> ". . .If metal is used in the body in the manufacture of an artificial joint, then both components must be of the same metal, otherwise an electrolytic reaction would be set up and corrosion would occur. Although this is contrary to usual engineering principles, it is essential in replacement joint surgery and it is also important to use a material, metal or other substance, which is inert even in a finely particulate form".

There has been some reawakening of interest in metal-on-metal prostheses in recent years, and it is therefore important to recognize the major contributions of McKee some 30 or 40 years ago.

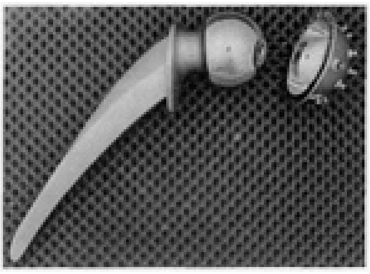

Fig. 2 McKee-Farrar total replacement hip joint incorporating lapped-in Vitallium femoral and acetabular cup components. Stud-shaped projections facilitate installation of cup into hip bone of patient.

Metal-on-Polymer Implants. The outstanding success of modern replacement joint operations is undoubtedly attributable to the late Professor Sir John Charnley. He recognized that is was necessary to combat loosening of the components by reducing the frictional torque generated by the articulating surfaces. It appears that a factor which directed him to this conclusion was the chance encounter with a patient fitted with a Judet femoral head replacement that squeaked! The outcome was his concept of a "low-friction arthroplasty" based upon a small-diameter metallic femoral head engaged in a polymeric acetabular cup. The frictional torque was thus reduced by a combination of sound biomechanics and tribology.

Charnley studied the lubrication of natural and total replacement synovial joints. He concluded that whereas synovial fluid was an exceptional lubricant for natural joints, it was not at all well suited for any of the replacement materials then considered. In 1958, he concluded that:

> ". . .the only chance of success in lubricating an artificial animal joint would be by using surfaces which were intrinsically slippery on each other; in other words, self-lubricating irrespective of whether tissue fluid were present or not."

This philosophy prompted Charnley to introduce polytetrafluoroethylene (PTFE, or Teflon) acetabular cups and stainless steel femoral stems in 1959. The early results with this remarkably low-friction polymer were spectacular, but the very poor wear characteristic of the material led to rapid penetration of the cup wall by the metallic femoral head after only 2 or 3 years (Fig. 3). Some 300 replacement hip operations were carried out between 1959 and 1961 before PTFE was abandoned.

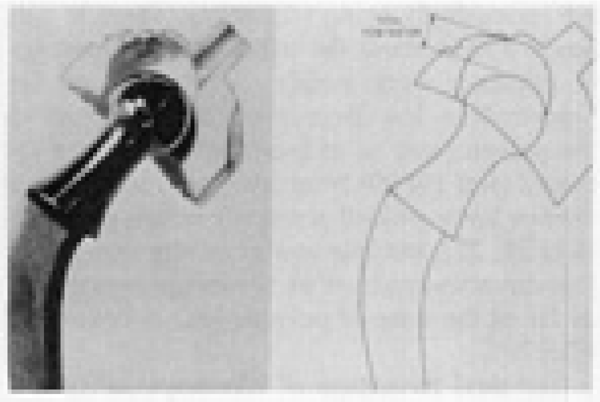

Fig. 3 Excessive penetration of PTFE acetabular cup by a stainless steel femoral stem approximately 2 to 3 years after implantation of a vintage Charnley joint in the early 1960s

Attempts were made to improve the wear resistance of the polymer by introducing fillers into the PTFE, but the improvements noted in laboratory tests were not reproduced in the body. In 1961, Charnley turned to ultrahigh molecular

weight polyethylene (UHMWPE) as the cup material. This material exhibits a higher coefficient of friction than PTFE, but a vastly enhanced resistance to wear. Its introduction was astonishingly successful, today, some 30 years later, it is still the dominant polymeric material in total replacement joints.

Alternative Metals

Strength requirements have ensured the use of metals for the femoral components of both hip and knee replacements. The range of metals used include stainless steel (such as 316L), cobalt-chromium-molybdenum alloys (such as Co-28Cr-6Mo), and titanium and titanium alloys (such as Ti-6Al-4V). Ti-6Al-4V, originally developed for the rotor and stator blades of aircraft gas turbine engines, rapidly replaced high-purity titanium, which failed to provide adequate strength for load-bearing joints (Ref 17). Stainless steel and the harder cobalt-chromium-molybdenum and titanium alloys appear to be the dominant metals in current metal-on-polymer implants.

In some cases, there has been a return to the concept of metal-on-metal prostheses, based on highly polished cobalt-chromium-molybdenum components (Ref 18). Careful design and manufacture can undoubtedly lead to very low wear rates, but there is still some concern regarding the relatively high friction and the deleterious effects of metallic wear particles.

Ceramics

High-purity aluminum oxide is potentially an attractive implant material for total replacement synovial joints, because it is bioinert and can be prepared to present an excellent counterface to polyethylene. A high-density, fine-grained Al_2O_3 is generally preferred, and hip joints in the form of polyethylene acetabular cups, ceramic femoral heads, and metallic femoral stems are increasingly being implanted. There is still much debate about the tribological advantages of ceramics over metals as counterfaces for polyethylene, but decreases in the wear rates of the polyethylene of at least 50% have been reported (Ref 19, 20) from laboratory tests. Other studies have yielded a more confusing picture (Ref 21, 22), but it is now generally recognized that ceramics can have an advantage over metals as far as the wear of polyethylene is concerned (Ref 23).

The dual advantage of biocompatibility and excellent wear resistance prompted the introduction of ceramic-on-ceramic hip replacements in the 1970s and 1980s (Ref 24, 25, 26, 27). It is necessary to produce an excellent surface finish on such implants and to hold fine tolerances on the important dimensions during precision manufacture. The unforgiving nature of the materials also calls for precise surgical techniques and careful consideration of strength requirements. Some of these implants failed due to fatigue and surface fracture, and recent clinical reports have sounded cautionary notes (Ref 28, 29).

Current Status

Total hip replacement is now a well-established orthopedic procedure, with about 400,000 hip joints being replaced by man-made alternatives each year worldwide, mainly in Europe and the United States. Knee prostheses are developing rapidly, and considerable progress will likely be reported in this field in the next decade.

The primary limitations are no longer tribological, although there is considerable evidence to suggest that tissue reaction to wear debris is associated with implant loosening, and current prostheses have achieved remarkable success as replacement rubbing bearings in the human body. Other aspects of material and implant performance, such as fixation, corrosion, mechanical strength, and surface variations, lie beyond the scope of this article and will be discussed only insofar as they affect the tribological characteristics of prostheses.

There are various types of metal porous surfaces on prostheses now. Some surfaces have additional coatings of hydroxyapatite (the mineral part of bone) to enhance initial ingrowth and to provide a more natural barrier between the bone and the implant.

Additional information can be found in the article "Corrosion of Metallic Implants and Prosthetic Devices" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Properties of Implant Materials

It has been noted in the previous section that the most common materials used in total replacement synovial joints are metals, ceramics, and UHMWPE. The principal physical properties of these materials will be summarized before focusing on their tribological characteristics.

Metals. The introduction of chromium-containing "stainless" steels into the manufacturing industry in the early 20th century was followed by their use in orthopedic surgery from about 1926. They remain the major implant alloys in general orthopedic surgery to the present day, although specifications and manufacturing techniques have changed and they recently have been joined by the harder and more corrosion-resistant cobalt-chromium-molybdenum and titanium alloys. In the United States, 316L is not currently used very extensively for permanent implants.

Typical compositions of the implant metals used in orthopedic surgery are given in Table 1; their physical and mechanical properties are listed in Table 2. Full accounts of the biocompatibility and general physical and mechanical properties of implants metals have been presented in Ref 30, 31, 32, 33.

Ceramics. High-density, fine-grained Al_2O_3 has proved to be the most widely used bioceramic in total replacements thus far. Body fluids can reduce the mechanical strength of ceramics, primarily through the ingress of liquid into the pores of low-density material; therefore, it is necessary to use high-density materials in orthopedic implants. Listed below are representative properties of alumina ceramics used in implants:

Chemical composition, %	>99.5 Al_2O_3
Density, g/cm^3 (lb/in.^{3})	>3.9 (>0.14)
Average grain size, μm	<7
Microhardness, GPa (kgf/mm^2)	23 (2.3 × 10^3)
Compressive strength, MPa (kgf/mm^2)	>4 × 10^3 (>400)
Flexural strength, MPa (kgf/mm^2)	>400 (>40)
Young's modulus, GPa (psi × 10^6)	38 (5.5)
Impact strength, MPa (kgf/mm^2)	>0.40 (>0.04)
Corrosion resistance (Ringer's solution), mg/m^2 per day	<0.1

Ultrahigh Molecular Weight Polyethylene. It is worth recalling that it was only in 1939 that ICI Ltd. produced low-density (specific gravity, 0.91 to 0.935) polyethylene (LDPE) by the polymerization of ethylene gas and that high-density (specific gravity, 0.94 to 0.97) polyethylene (HDPE) was first produced in Europe and the United States in the 1950s. Thus, the introduction of UHMWPE into orthopedic implants early in the 1960s represented a very rapid application of a new biomaterial, which necessarily meant that many of its tribological characteristics under physiological conditions were imperfectly understood. Indeed, a comprehensive picture of the biotribological features of this remarkable material is only now emerging (Ref 34). The tensile and physical properties of UHMWPE are listed in Table 3.

Table 3 Tensile properties of RCH 1000 surgical-grade UHMWPE plastic at selected strain rates

RCH 1000 has the following physical properties: molecular weight, 3.5 × 10^6 to 4.0 × 10^6; density, 0.94 g/cm^3 (0.034 lb/in.^{3}); hardness (at 20 °C, or 70 °F), 5.3 ± 0.3 HV; bulk shear stress, 24 MPa (3.5 ksi).

Tensile property	Strain rate	
	3.28 × 10^{-3} s^{-1}	**3.28 × 10^{-2} s^{-1}**
Gage length, mm (in.)	25.4 (1.0)	25.4 (1.0)
Yield stress, MPa (ksi)	20.3 (2.94)	24.9 (3.61)
Fracture stress, MPa (ksi)	28.4 (4.12)	30.6 (4.44)

Tribological Characteristics of UHMWPE

The wear characteristics of UHMWPE have been studied extensively ever since the material was first introduced into orthopedic implants some 30 years ago. There have been three major types of investigations during this period:

- Studies of the basic wear mechanisms on standard laboratory machines (for example, pin-on-disk and pin-on-plate configurations)
- Evaluations of complete implants in joint simulators
- *In vivo* assessment of the performance of total replacement joints

Pin-on-Disk Experiments

The general form of a tri-pin-on-disk friction and wear measuring machine is shown in Fig. 4. One of the test materials, usually the metal or ceramic, is machined in the form of a disk and located on pegs on a turntable driven at constant speed in an environmental chamber. Three test pins, usually the polymer, are mounted in a frame and loaded against the turntable by means of static weights or a hydraulic system. The frame is prevented from rotating by means of three cantilever arms, whose deflection indicates the friction torque on the frame.

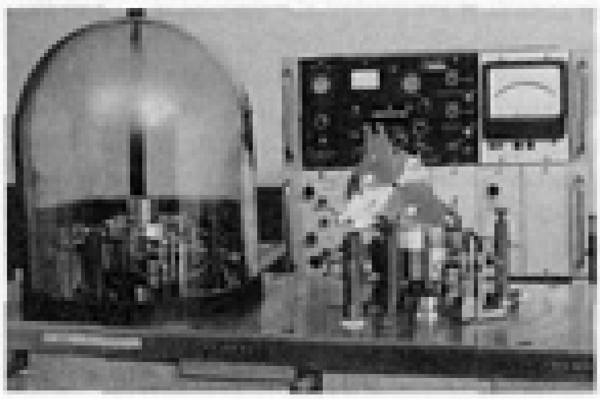

Fig. 4 Typical tri-pin-on-disk friction and wear testing machine that measures wear under stable speed, load, and environmental conditions

The wear pins are generally cylindrical in form, with flat, spherical, or truncated conical ends. The latter configuration, shown in Fig. 5, has the advantage of offering a substantial foundation for the wear face, while permitting wear to take place over a relatively small area.

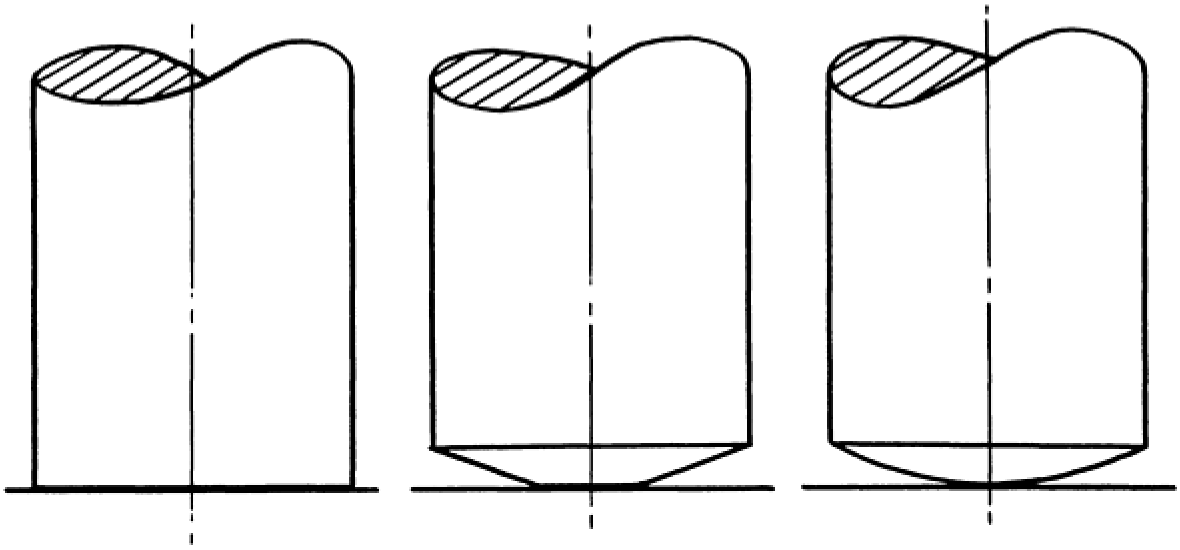

Fig. 5 Schematic showing typical geometry of wear pins evaluated on a tri-pin-on-disk friction and wear testing machine. (a) Flat end. (b) Truncated conical end. (c) Spherical cap end

Wear can be measured by monitoring dimensional changes, such as the diameter of the wear face of the length of the pin, or by measuring weight loss. The former method has much appeal, but with polymers the results generally exhibit considerable scatter. The reason for this is that the dimensions being measured are influenced by both temperature and humidity. Therefore, the measurement of weight loss is generally preferred, although even with this method considerable care has to be exercised to measure small changes in the liquid content of the polymer specimens associated with the lubricant or the humidity of the atmosphere.

A great advantage of the pin-on-disk machine is that it enables wear to be studied under stable conditions of speed, load, and environment. If the weight or volume changes associated with wear are monitored periodically and plotted against sliding distance, a linear relationship is generally observed. This enables the wear factor (k) to be ascertained from the simple relationship between wear volume (V) and the load (P) and sliding distance (X):

$$V = kPX \qquad \textbf{(Eq 1)}$$

The wear characteristics of different combinations of materials can thus be quantified and compared using the wear factor, *k*, enabling initial screening of potential sliding pairs of materials to be made for a particular application. Furthermore, the transfer film that is formed by the polymer on the hard counterface under many conditions can be studied throughout the test, and the surfaces of both the monolithic polymeric specimens and the transfer film can be subjected to surface analysis and examination by electron microscopy after testing.

A valuable and early summary of wear test methods and a compilation of wear rates and factors from many source has been presented by Dumbleton (Ref 35). It is generally recognized that short-term tests can be misleading, since the generation of a reasonably steady form of transfer film takes a finite time. Furthermore, there is evidence that surface fatigue plays a major role in determining the long-term wear rate of polyethylene sliding against steel (Ref 36, 37), and this characteristic might be totally missed in short-term tests. Dowson (Ref 37) has reported increases in the wear factor of about 60 to 70% following the onset of surface fatigue in the polymer in steady-state sliding wear in a tri-pin-on-disk machine under dry (atmospheric) conditions.

Wear factors for UHMWPE sliding on very smooth (R_a = 0.013 to 0.036 μm) EN58J stainless steel disks were found to be of the order of 10^{-7} mm^3/N · m under dry conditions and 10^{-9} to 10^{-8} mm^3/N · m in the presence of distilled water. It should be noted that the counterface roughness was exceptionally good, and certainly better than that achieved in most metallic implants. It was also reported that when UHMWPE slid on itself under dry conditions, the wear factor was much higher (about 10^{-4} mm^3/N · m).

Perhaps the most important feature of these early wear factors obtained for UHMWPE was their exceptionally low values, indicating very good resistance to wear. Indeed, the values were so low that they were inconsistent with the *in vivo* performance of total replacement hip joints, thus casting doubts on the value of pin-on-disk measurements of wear as far as implant performance was concerned. The measurement of the very small wear rates of a UHMWPE was subsequently discussed further by McKellop *et al.* (Ref 38), Clarke (Ref 39), and Dumbleton (Ref 35). An equally important observation was the evidence of surface fatigue in the polymer after a significant sliding distance (Ref 36).

Pin-on-Plate (Reciprocating) Experiments

Human joints experience oscillatory sliding conditions, and thus much research has been carried out on reciprocating pin-on-plate, rather than steady-speed pin-on-disk, machines. Such testing still does not simulate the exact motion encountered in synovial joints, but it does include the essential feature reversals in motion and hence in surface shear stresses. A six-station pin-on-plate friction and wear machine is shown in Fig. 6.

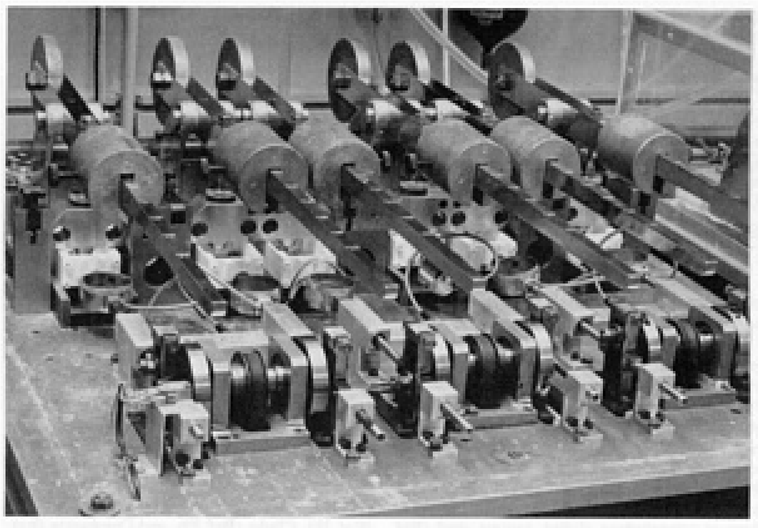

Fig. 6 Six-station reciprocating pin-on-plate friction and wear machine used to evaluate prosthetic implant materials

This type of testing machine is very useful for the initial screening of many potential implant materials. It has also proved to be particularly valuable in revealing important aspects of the role of the counterface roughness and the environment. Typical sets of data for the deduced wear factors for UHMWPE pins loaded against EN58J stainless steel in both dry (atmospheric) and wet (distilled water) environments are shown as functions of counterface roughness in Fig. 7. It is clear the long-term wear factor exhibits a minimum at a counterface roughness slightly less than 0.1 μm. Furthermore, the presence of water increases the wear factor substantially, typically by an order of magnitude, for counterface roughnesses representative of many implants (R_a values of 0.05 to 0.1 μm). Because replacement joints appear to enjoy a measure of lubrication, it thus appears from these pin-on-plate reciprocating tests that wear factors on the order of 10^{-6} m^3/N · m can be expected in implants.

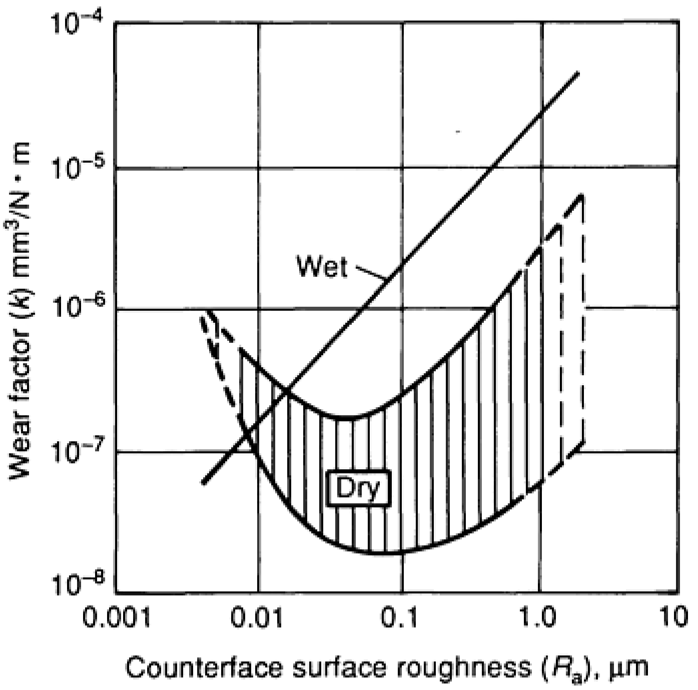

Fig. 7 Plot of UHMWPE plastic wear factor versus stainless steel counterface surface roughness evaluated under both dry (atmospheric) and wet (distilled water) conditions

Joint Simulators

It is customary to evaluate the performance of engineering tribological components in machine simulators prior to their introduction into products, yet the use of joint simulators is a relatively recent development. There are still few satisfactory joint simulators in service, but it is increasingly important that new biomaterials and new implant designs be fully tested in the laboratory before their release for clinical evaluation.

Hip Joint Simulators. Modern forms of hip joint simulators, such as that shown in Fig. 8, subject the implant to the dynamic loads and the complex motions experienced in walking or some other simple, specified motion. The computer-controlled load components are usually applied hydraulically, in mutually perpendicular directions, with a feedback mechanism to ensure that the specified load is indeed applied. Joint simulators need to be robust; otherwise, the long-duration tests become critical evaluations of the seals, bearings, and hydraulic and mechanical components of the testing machine, rather than of the total replacement joints themselves.

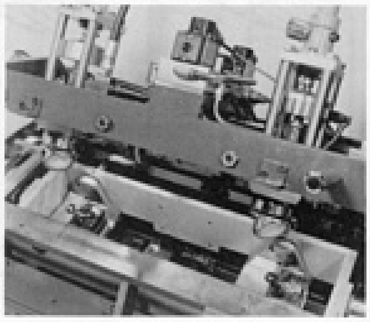

Fig. 8 Multistation hip joint simulator duplicates walking and other human motions typically encountered by prosthetic implants

The evaluation of wear in implants tested in joint simulators is more difficult than in the simple forms of laboratory friction and wear testing machines described earlier, because the component being evaluated, the acetabular cup, is a good deal heavier than the simple wear pins used in pin-on-disk or pin-on-plate machines. This use of heavy components makes it difficult to achieved adequate accuracy in the determination of small weight changes. Furthermore, the acetabular cups are usually embedded in a heavy metallic holder, probably with acrylic cement, in order to replicate as closely as possible the *in vivo* situation.

Dimensional changes thus feature much more prominently than weight loss determination in the evaluation of penetrations of femoral heads into acetabular cups in joint simulators. Casting and shadowgraph techniques have been described in Ref 40, while coordinate measuring machines (Ref 41) have been shown to offer great advantages. It should also be noted that dimensional changes reveal the total penetration of the femoral head into the acetabular cup, and that this represents a combination of wear and creep. Some simulators (Ref 40) thus include a separate creep station, in which the dynamic loading cycles are applied to the implant without articulation. The resulting creep penetration can then be deducted from the total penetration attributable to wear plus creep in order to establish the relative contributions of each process to the overall penetration. Total penetration, of course, is of primary concern to the patient and the surgeon, but the separate contributions of wear and creep are of interest to the tribologist and the materials scientist.

An early account of the use of a hip joint simulator was reported by Duff-Barclay and Spillman (Ref 42), while Dumbleton provided an excellent account of the state of the art in the early 1980s (Ref 35). Further accounts of joint simulator studies can be found in Ref 43, 44, 45, 46.

Knee Joint Simulators. Relatively little work has been done on the development of knee joint simulators, but accounts of the principles involved can be found in Ref 35 and 47. A typical knee joint simulator, designed to operate on principles similar to those outlined for the hip joint simulator, is shown in Fig. 9. Detailed accounts of the application of holographic measuring techniques in the evaluation of the magnitude and distribution of wear in various forms of total replacement knee joints tested in the simulator can be found in Ref 48 and 49.

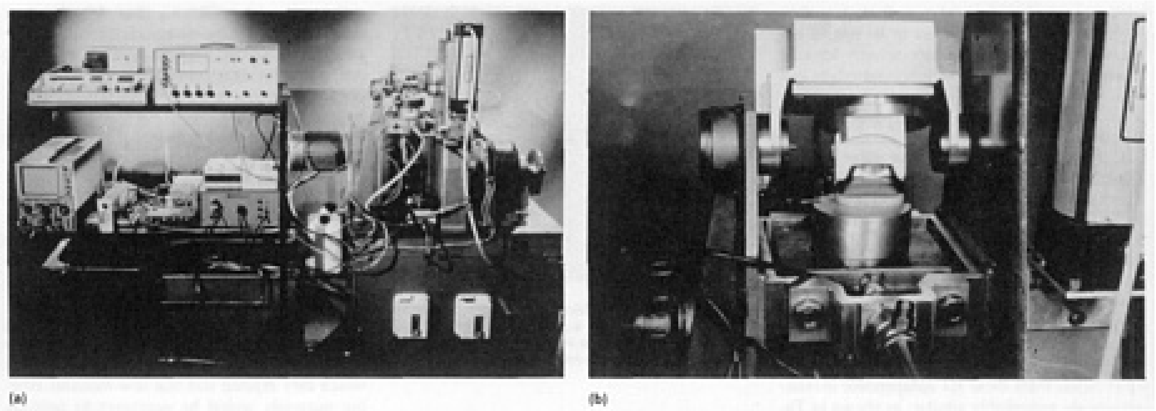

Fig. 9 Knee joint simulator used to evaluate magnitude and distribution of wear in a total replacement knee joint. (b) Closeup view of test cell showing knee joint implant being evaluated while it is held in position in a test fixture

In Vivo Assessment of Total Joint Replacement Performance

The penetration of femoral heads into the acetabular cups of total replacement hip joints can be assessed by radiographic studies *in vivo* or by direct measurement of explanted prostheses at the time of revision surgery or postmortem. Charnley (Ref 50) and his colleagues pioneered the former approach, and with Halley in 1975 (Ref 51) he found an average rate of penetration of 0.15 mm/year for 72 patients operated on in 1962 and 1963. Griffith *et al.* (Ref 52) subsequently assessed 491 hips from patients operated on between 1967 and 1968, and in a much-quoted paper they recorded an average rate of penetration of only 0.07 mm/year. The mean follow-up period was 8.3 years (a range of 7 to 9 years), while a few (4%) of the sockets exhibited penetration rates as high as 0.24 mm/year. An interesting feature of the measurements was that the rate of penetration generally decreased with time in the body.

More recent studies of the rate of penetration of femoral heads into UHMWPE acetabular cups in Charnley prostheses (Ref 53, 54) have confirmed that average values range from 0.07 to 0.15 mm/year. Implants removed during revision operations appear to exhibit rather larger penetration rates, typically 0.2 mm/year, as reported by Atkinson *et al.* (Ref 55). This increase may well reflect inadequate biomaterial, surgical, or mechanical factors associated with the implant and be one of the prime indicators for revision surgery.

Dumbleton (Ref 35) reviewed radiographic measurements of penetration, and in recent years many reports have been made for different forms of prostheses. Useful records are provided in Ref 56 and 57.

Dowson and Wallbridge (Ref 58) compared their laboratory wear data with a retrospective assessment of the clinical performance of early Charnley prostheses based on PTFE acetabular cups. They adapted the simple wear equation (Eq 1) to account for creep and the dynamic loading and motion cycle encountered in the hip joint:

$$k_{\text{clinical}} = \left[\pi r^2 P\left(1 - \frac{C}{100}\right)\right] \Big/ N \int L \cdot dx \qquad \textbf{(Eq 2)}$$

where P is the annual linear penetration rate in millimeters per year, r is the radius of the femoral head in millimeters, C is the percentage of the penetration attributable to creep, N is the number of loading cycles per annum, L is the instantaneous load in newtons at any point in the cycle during which the corresponding sliding distance (dx) is in meters. For the loading cycle revealed by Paul (Ref 59) for level walking and a 22 mm diam Charnley prosthesis, the denominator on the right-hand side of Eq 2 can be written as:

$$N \int L \cdot dx = 1.188\, NBd \qquad \textbf{(Eq 3)}$$

where the units are N · m/year and where B is the body weight in newtons and d is the diameter of the femoral head.

An important unknown variable in such analyses is patient activity, but on the assumption that the number of loading cycles on a 60-year-old patient fitted with a replacement hip joint would be about 1.5 million per year, the authors found that the clinical wear factor equivalent to the recorded average penetration rate for the early Charnley implants of 2.26 mm/year was 3.7×10^{-5} $mm^3/N \cdot m$. This compared favorably with the average wear factor for PTFE sliding on stainless steel of 3.4×10^{-5} $mm^3/N \cdot m$ in pin-on-disk experiments. This comparison was made on the basis of zero creep, which is now known to be incorrect, and rather thin data on patient activity, but it provided welcome support for the view that clinical performance of implants could indeed be predicted from laboratory wear data.

An assessment of the walking activity of both normal subjects and patients fitted with total replacement hip joints has been provided by Wallbridge and Dowson (Ref 60). They found that the number of loading cycles applied to each hip joint per annum (N) was related to age (A) in years by the approximate relationship:

$$N = (3.29 - 0.032A) \times 10^6 \quad \textbf{(Eq 4)}$$

When Atkinson *et al.* (Ref 55) attempted to repeat the exercise for the later range of UHMWPE Charnley implants, the agreement between laboratory and clinical performance was somewhat less satisfactory. The average clinical wear factor derived from measurements on 25 explanted prostheses was 2.9×10^{-6} $mm^3/N \cdot m$, which the results ranging from 0.9×10^{-6} to 7.2×10^{-6} $mm^3/N \cdot m$. The average surface roughness was found to be 0.054 μm, and the corresponding laboratory wear factor for this roughness was 1.2×10^{-6} $mm^3/N \cdot m$, a mere 41% of the average deduced clinical wear factor.

It was at this stage that the role of surface blemishes in the form of fine scratches on the hard metallic counterface upon the wear of the polyethylene was recognized. It had previously been shown (Ref 61) that for isotropic counterface roughness, the relationship between the wear factor (k) and the roughness average (R_a) of the hard counterface was given approximately by:

$$k = (4.0 \times 10^{-5})\, R_a^{1.2}\ mm^3/N \cdot m \quad \textbf{(Eq 5)}$$

This was the relationship used to indicate the extent of the agreement between the clinical and laboratory wear factors, but the disproportionate influence of a single blemish was revealed in Ref 62. It was shown that the piled-up edge material associated with a single transverse scratch on the stainless steel counterface could increase the wear rate by about one order of magnitude, which immediately explained why scratched femoral heads could penetrate the acetabular cups at a greatly enhanced rate. Barium sulfate in the acrylic cement appears to be one of the abrasive substances that may scratch femoral heads. The selection of the hard counterface in a total joint replacement must thus represent a balance between hardness and a good surface finish.

Ceramic femoral heads have attracted considerable attention in recent years. They exhibit excellent biocompatibility and good bearing surfaces for rubbing conditions. The wear rate of UHMWPE against well-polished Al_2O_3 does indeed appear to be lower than that against the metals currently employed in orthopedic implants, not only in the laboratory (Ref 19, 20) but also *in vivo* (Ref 63, 64, 65, 66, 67, 68). The ratio of the rates of penetration of the femoral heads into the UHMWPE acetabular cups for ceramic and metallic heads from these six independent investigations are remarkably similar, as shown in Table 4, and totally consistent with the laboratory studies reported in Ref 19 and 20. The indications that ceramic femoral heads will take roughly twice as long as metallic femoral heads to penetrate to a given extent into UHMWPE acetabular sockets are now firmly established. An example of a Charnley low-friction prosthesis with either metallic (stainless steel) or ceramic (Al_2O_3) femoral heads and a UHMWPE acetabular cup is shown in Fig. 10.

Table 4 Ratio of penetration rates of ceramic and metallic femoral heads into the UHMWPE acetabular cup component of Charnley prostheses

Penetration rate of femoral head material into acetabular socket		Ratio of penetration rates of femoral heads into acetabular cups[a]	Ref
Ceramic, mm/year	**Metallic, mm/year**		
. . .	. . .	0.56	63
0.23	0.30 (0.31)	0.77 (0.74)	64
0.08	0.20	0.40	65
0.098	0.247	0.40	66
0.025	0.043	0.58	67
0.08	0.14	0.57	68

(a) Penetration rate ratio = Ceramic penetration rate/Metallic penetration rate

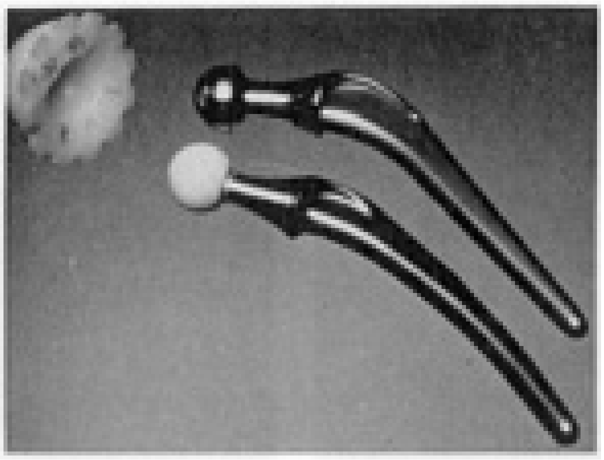

Fig. 10 Charnley low-friction hip joint prosthesis equipped with a polymeric UHMWPE acetabular cup and either a stainless steel (top) or an Al_2O_3 ceramic (bottom) femoral head

Friction. The wear of acetabular cups and the resulting penetration of both metallic and ceramic femoral heads into the sockets in the pelvis have been emphasized thus far. Brief reference should also be made to friction. The frictional torque exerted on both natural and total replacement joints has been studied in pendulum machines and joint simulators.

Natural synovial joints enjoy a mixture of fluid-film and mixed lubrication (Ref 69), but a representative coefficient of friction is 0.02. All current forms of total replacement joints rely on boundary or at best mixed-film lubrication, and their coefficients of friction are therefore inevitably higher than those of their natural counterparts. Some care has to be exercised in quoting coefficients of friction, because such values are usually derived from torque measurements and normalized in terms of the radius of the femoral head. Fricker (Ref 70) has presented a clear statement of the problem. Dumbleton has reviewed measurements of coefficients of friction for prosthetic materials (Ref 35) and shown that the value for UHMWPE and various counterfaces range from 0.02 to 0.25, with a typical value being about 0.07. Detailed investigations of the friction of prostheses have also been reported in Ref 71, 72, 73. Friction in itself does not appear to limit the succesful operation of total joint replacements, but it can be a major factor in loosening of the implant and subsequent loss of function.

Alternative Materials and Future Prospects

Because penetration rates of the femoral head into the acetabular cup in current forms of total replacement joints are typically in the range of 0.1 to 0.2 mm/year, and overall migrations of the head of 2 or 3 mm can generally be accommodated in current designs, the wear lives of implants should be in the range of 10 to 30 years. There is growing evidence to support this prediction, which means that many elderly patients can receive joint replacements with much relief and confidence. The primary problem is no longer wear, but joint loosening. However, there is increasing concern

about the role of wear debris in promoting implant loosening, and thus tribologists are being called upon to reduce the volume of wear debris substantially.

The metals, ceramics, and UHMWPE currently used in prostheses have established a sound basis for satisfactory implant performance. Indeed, it is unlikely that major advances can be expected in the reliable tribological performance of rubbing bearings for the body. The basic wear mechanisms in total replacement joints are now well understood. If the counterfaces are rough (Ref 61) or damaged (Ref 62), the basic abrasive and adhesive wear mechanisms dominate, but as the counterface roughness is improved, subsurface fatigue plays an increasingly important role. This has been clearly revealed by birefringent techniques (Ref 74) applied to implant wear by procedures originally outlined by Gibbons (Ref 75). There is much interest in the prospects for alternative structural materials, such as composites (Ref 76) and isoelastic arrangements designed to have properties similar to the bone into which they are implanted (Ref 77).

If substantial improvements are to be made in the tribological performance of synovial joints, it seems likely that new concepts will be necessary, rather than incremental improvements in rubbing bearings. One possibility that is attracting some interest would be to design an implant that would generate a fluid film between the bearing surfaces and thus emulate nature in promoting fluid-film lubrication (Ref 69). It has been pointed out that the mechanical properties of current forms of implant materials are quite different from those of the natural materials which they replace and that low-modulus bearing materials would be necessary to promote fluid-film lubrication. This concept is known as the "cushion bearing" (Ref 78).

Friction and Wear of Dental Materials

John M. Powers, University of Texas Health Science Center; Stephen C. Bayne, University of North Carolina

Introduction

HUMAN HARD DENTAL TISSUES (enamel, dentin, and cementum), restorative materials (metals, ceramics, and polymers), and dental instruments (burs, curettes, and endodontic files) used to abrade tooth structure are all subject to friction and wear processes. Table 1 summarizes some typical dental materials susceptible to wear; Table 2 presents typical mechanical properties of these same materials.

Table 1 Simplified composition or microstructure of some typical dental materials susceptible to wear and friction

Material	Simplified composition or microstructure
Alloys	
Alloy crown	Au-Ag-Cu (single phase), Au-Pd, Ni-Cr
Amalgam (admixed)	Ag_2Hg_3, Cu_6Sn_5, Ag_3Sn-Cu_3Sn-Zn (unreacted), Ag-Cu (unreacted)
Amalgam (unicompositional)	Ag_2Hg_3, Cu_6Sn_5, Ag_3Sn-Cu_3Sn-Zn (unreacted)
Endodontic instruments	Stainless steel, carbon steel
Orthodontic wire	Austenitic stainless steel, Ni-Ti-Co, Ti-Mo-Zr-Sn
Ceramics	
Cements:	
Zinc oxide-eugenol	Zinc eugenolate and zinc oxide (unreacted)
Zinc phosphate	Zinc phosphate and zinc oxide (unreacted)
Glass-ceramic inlays and crowns	Glass with crystalline alumina or fluoride-mica glass ceramic
Gypsum dies	$CaSO_4 \cdot 2H_2O$
Porcelain (PFM)	Pottassium-sodium alumino-silicate glasses
Porcelain denture teeth	Quartz particles in a glass matrix
Polymers	
Cements:	
Glass ionomer	Acrylic or maleic acid copolymer and calcium aluminosilicate matrix with aluminosilicate glass (unreacted) or silver-glass cermet (unreacted)
Zinc polyacrylate	Acrylic polymer and zinc oxide (unreacted)
Composites (hybrid)	Aromatic or urethane diacrylate matrix with silanated filler (quartz, borosilicate glass, lithium aluminum silicate, barium aluminum silicate, or colloidal silica)
Composites (microfilled)	Aromatic or urethane diacrylate matrix with colloidal silica
Denture acrylics	Poly(methyl methacrylate) with pre-polymerized PMMA or rubber-reinforced acrylic beads
Pit and fissure sealants	Aromatic or urethan diacrylate matrix with silanated filler
Plastic denture teeth	Poly(methyl methacrylate) matrix and beads

Source: Ref 1

This article will review the friction and wear of various dental materials that have been studied by fundamental wear measurements, simulated service wear measurements, and clinical measurements (Ref 2, 3). Correlations of properties such as hardness, fracture toughness, and wear will be described and wear mechanism such as sliding adhesive wear, two-body abrasion, three-body abrasion, erosion, and fatigue identified.

Human Dental Tissues

The destruction of hard dental tissues by wear is categorized conveniently as physiologic wear, pathologic wear, prophylactic wear, and finishing procedure wear (Ref 4). In of these types, the actual wear situation may vary considerably because of different substrates, opposing wear surfaces, lubrication systems involved, and third-body abrasives. An overview of different circumstances is provided in Table 3.

Table 3 Classification of wear situations in dentistry

Intraoral wear event	Type of wear	Lubricant	Substrate	Opponent	Abrasive
Physiologic causes of wear					
Noncontact wear	3-body	Saliva/food	Tooth/restoration	. . .	Food
Direct contact wear	2-body	Saliva	Tooth/restoration	Tooth/restoration	. . .
Sliding contact wear	2-body	Saliva	Tooth/restoration	Tooth/restoration	. . .
Pathologic causes of wear					
Bruxism	2-body	Saliva	Tooth/restoration	Tooth/restoration	. . .
Xerostomia	2-body	. . .	Tooth/restoration	Tooth/restoration	. . .
Erosion	. . .	Saliva	Tooth/restoration	. . .	. . .

Unusual habits	2-body	Saliva	Tooth/restoration	Foreign body	. . .
Prophylactic causes of wear					
Toothbrush and dentifrice	3-body	Water	Tooth/restoration	Toothbrush	Dentifrice
Prophylactic pastes	3-body	Water	Tooth/restoration	Polishing cup	Pumice
Scaling and cleaning instruments	2-body	Saliva	Tooth/restoration	Instruments	. . .
Cutting, finishing, polishing					
Cutting burs/diamonds	2-body	Water	Tooth/restoration	Bur	. . .
Finishing burs	2-body	Water	Tooth/restoration	Bur	. . .
Polishing pastes	3-body	Water	Tooth/restoration	Polishing cup	Abrasive slurry

Physiologic Wear

Physiologic wear, or attrition (Ref 5), is caused by processes involving sliding contact wear, contact wear (impact without sliding), and noncontact wear from food abrasion alone. Sliding contact wear produces the most prominent effects during masticatory function. An example of severe attrition is shown in Fig. 1. Attrition occurs because of function (Ref 6) and occurs only where the opposing teeth come into contact (Ref 7), so it can be distinguished from erosion (see the discussion of "Pathologic Wear" given below).

Fig. 1 Severe occlusal wear resulting from dental attrition. Source: Ref 4

Attrition in primitive man was often severe (with pupal exposure) owing to the nature of the aboriginal diet of tough meat and sandy, fibrous plants, as studies on both skeletal and living representatives of aboriginal populations have attested (Ref 8, 9, 10).

Fundamental research on the degree and types of attrition found in the teeth of ancient, primitive, and modern populations has dealt mainly with the wear planes produced on molars surfaces (Ref 11, 12, 13) and with the effects of attrition on facial height (Ref 14, 15, 16, 17) and on the position of the temporomandibular joint (Ref 16, 18). It is apparent that not all people wear on their teeth the same way. The patterns produced are frequently characteristic of ethnic variations.

Improved tooth care and dietary habits have lessened considerably the occurrence of attrition in modern populations. For additional information on the effects of food, degree of function, and age on attrition, see Ref 19, 20, 21, 22, 23, 24, 25.

Pathologic Wear

This cause of wear can be particularly destructive to individual teeth or the entire dentition. Xerostomia and bruxism are the most frequently reported pathologic causes of wear.

Xerostomia. This condition results in dryness of the oral cavity and causes brittleness of the teeth. It has been observed in women during and after menopause (Ref 26). Investigation of causes of abnormal tooth wear must take salivary factors into consideration (Ref 27, 28). Mucin-based saliva substitutes lubricate with values comparable to whole human saliva, whereas substitutes based on carboxymethylcellulose do not appear to lubricate well (Ref 29).

Bruxism. This condition is a nonfunctional mandibular movement that is manifested by occasional or habitual grinding or clenching of the teeth (Ref 30). The major effects of severe bruxism can be tooth wear and accelerated alveolar bone loss. An example of occlusal wear resulting from bruxism is shown in Fig. 2. This abnormal wear rapidly removes the cusps of teeth. Wear takes place mainly on incisal edges of upper and lower anterior teeth. With time, edges become highly polished and flattened. In the posterior teeth, wear appears as small saucer-like excavations.

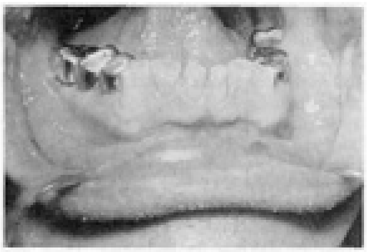

Fig. 2 Occlusal wear resulting from bruxism. Source: Ref 4

Erosion. This condition is the chemical weakening of human enamel resulting from acid decalcification. The pH affects the rate of decalcification for cleaned, and mechanically abraded enamel (Ref 31). Chemical decalcification may be caused by environmental pollutants contaminating air and/or saliva of patients. Accelerated wear is observed in people employed in occupations (for example, mining, or sulfuric acid production) where an unusual or severe atmospheric environment exists (Ref 32).

Unusual Habits. People who grasp needles or nails with their teeth or smoke pipes may also exhibit localized pathologic wear.

Prophylactic Wear

Toothbrush and Dentifrice. Oral hygiene is necessary for maintaining a healthy mouth and for social acceptance. The emphasis in the study of wear of the dentition by toothbrush and dentifrice has been the elimination of overly abrasive dentifrice components. Cervical abrasion resulting from improper and excessive toothbrush and dentifrice use is shown in Fig. 3.

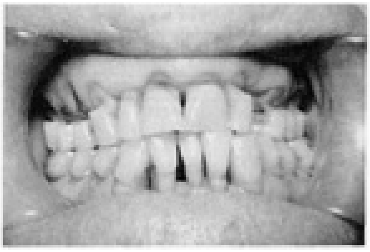

Fig. 3 Cervical abrasion resulting from excessive toothbrush and dentifrice use. Source: Ref 4

The primary function of a dentifrice is to clean and polish the surfaces of the teeth accessible with a toothbrush. During cleaning, extraneous debris and deposits need to be removed from the tooth surface. These deposits listed in order of increasing difficulty of removal are (Ref 33): food debris, plaque (a soft, mainly bacterial film), acquired pellicle (a proteinaceous film of salivary origin), and calculus.

The ideal abrasive should exhibit a maximum cleaning efficiency with minimum tooth abrasion. In addition, a dentifrice should polish the teeth. Highly polished teeth are not only aesthetically desirable, but they may also be less receptive to the retention of deposits (Ref 34).

Typical dentifrice abrasives include: calcium carbonate, dibasic calcium phosphate dihydrate, anhydrous dibasic calcium phosphate, tricalcium phosphate, calcium sulfate, calcium pyrophosphate, insoluble sodium metaphosphate, and hydrated alumina (Ref 35).

Selection of a dentifrice by a dentist for a patient should be based on: (1) degree of staining, (2) force exerted on the brush, (3) method of brushing, and (4) amount of exposed dentin and cementum. The Council on Dental Therapeutics of the American Dental Association published information on the abrasivity of dentifrices in 1970 (Ref 36).

Prophylactic Paste. A dental prophylactic paste should be sufficiently abrasive to remove effectively exogenous stains, pellicle, *materia alba,* and oral debris from the tooth surface without causing undue abrasion to the enamel, dentin, or cementum. Polymeric materials, such as denture base and artificial tooth resins, composite restorations, and pit and fissure sealants, are particularly susceptible to abrasion because of their low hardness. The undesirable results of wear can be a reduction in anatomic contours and increased surface roughness.

Abrasives in commercial prophylactic pastes include: recrystallized kaolinite, silicon dioxide, calcined magnesium silicate, diatomaceous silicon dioxide, pumice, sodium-potassium-aluminum silicate, and zirconium silicate (Ref 37).

Cutting, Finishing, and Polishing Wear

Tooth structure and restorative dental materials are routinely reshaped and smoothened using special instruments for cutting and finishing. A highly polished surface is then produced by treatment with polishing pastes containing alumina or diamond abrasive particles less than 1 μm in size.

Wear Studies

Traditional wear theory divides observed wear into categories of adhesive, abrasive, corrosive, and fatigue wear; however, predictions of these wear models depend on the materials behaving in a relatively brittle fashion. Most dental materials under intraoral circumstances do not behave in this way; therefore, it is difficult to rank dental materials performance. Most wear tests have not faithfully predicted clinical performance.

Wear information on dental materials has been collected from fundamental studies with simple laboratory tests, simulation studies with customized machines, and clinical studies. Unfortunately, the fundamental laboratory tests and the simulation studies have not had much success in correlating with observed clinical wear.

Fundamental Laboratory Studies

In a single-pass sliding technique, fluorapatite single crystals served as a simple model system for human enamel, which is composed of hydroxyapatite. The wear and friction of fluorapatite single crystals under conditions of single- and multiple-pass sliding with a diamond hemisphere (360 μm in diameter) can be evaluated by interpretation of tangential force, track width, and surface failure classification data (Ref 38, 39, 40). A failure classification scale (Fig. 4) includes:

- *Class 1:* entirely ductile
- *Class 2:* mostly ductile with some tensile cracking
- *Class 3:* essentially tensile cracking
- *Class 4:* mostly tensile cracking with chevrons (chipping)
- *Class 5:* chevrons

Examples of Classes 1, 3, and 5 are shown in Fig. 5.

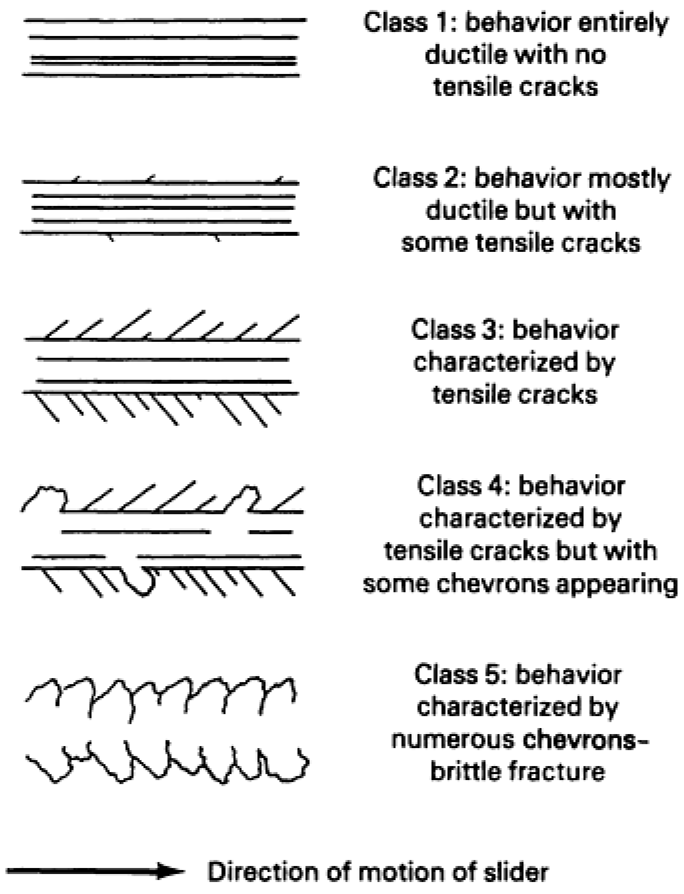

Fig. 4 Failure classification scale. Source: Ref 40

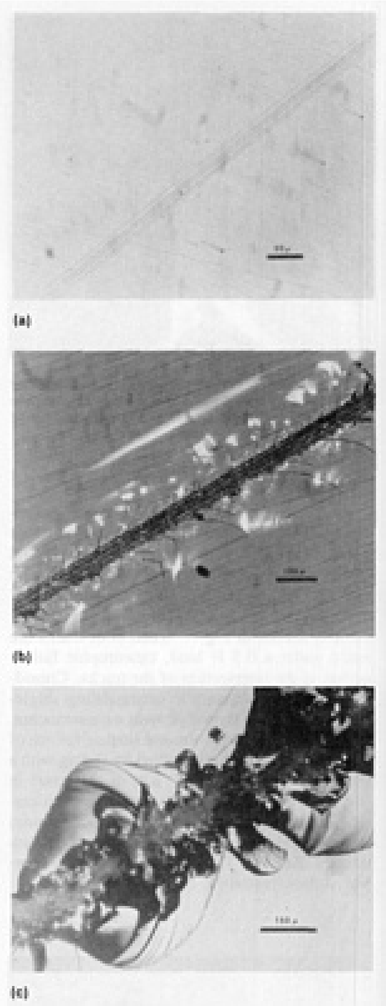

Fig. 5 Examples of surface failure of fluorapatite single crystals. (a) Class 1. (b) Class 3. (c) Class 5. Source: Ref 40

The failure of fluorapatite at a 0.1 N load for single-pass sliding in the <2110> direction is essentially ductile and progresses toward brittle failure as the load is increased (Ref 41). At 0.5 N loads and higher, failure is characterized by chevron formation. Track width follows an exponential function, whereas the tangential force (friction) increases linearly with normal load (Ref 41). The coefficient of friction is not a perfect indicator of wear. The track width data indicate that the principal mechanisms for the accommodation of strain are elastic deformation and cracking. Sliding in the <0110> direction results in slightly lower friction but substantially increased surface damage (Table 4).

Table 4 Influence of sliding direction and environment on friction and wear properties of fluorapatite single crystals for single-pass sliding on the basal plane

Condition	Coefficient of friction (β)	Ductile-to-brittle transition load, N
<2110> direction in air	0.22	0.75
<0110> direction in air	0.19	0.15
<2110> direction in water	0.24	0.18
<2110> direction in dimethylformamide	0.24	0.62

Source: Ref 41, 42

The ductile-to-brittle transition for sliding of diamond on fluorapatite occurs at higher normal loads in air and dimethylformamide than in water (Table 4) (Ref 42). The lowering of the transition in water is explained on the basis of

surface hardening as a result of the interaction of polar water molecules or their dissociation products and charged near-surface species. The interaction results in pinning of dislocations and a reduction in the ability of the lattice to accommodate strain by slip and thus effectively lowers the stress required to cause fracture.

Single-pass sliding by itself cannot completely describe the wear of fluorapatite single crystals (Ref 43). Wear tracks for a single and double pass on the same track in the opposite direction under a 0.7 N load are shown in Fig. 6. The effect of sliding a second pass across a wear track is shown in Fig. 7. When both tracks are made under a 0.5 N load, catastrophic failure occurs at the intersection of the tracks. Considerable care is necessary in extrapolating single-pass wear data to repetitive wear measurements.

The frictional behavior and surface failure of human enamel has been studied by sliding with a diamond hemisphere (360 μm in diameter) in water (Ref 44, 45). Similar tests have been carried out on a sintered hydroxyapatite ceramic, which approximates the properties of human enamel (Ref 46). Table 5 compares the properties of these materials.

Table 5 Properties of a sintered hydroxyapatite ceramic compared with human enamel

Property	HAP-60K-1200C	Human enamel
Compressive strength, MPa (ksi)	380 (55)	400 (58)
Young's modulus, GPa (psi × 10^6)	120 (17.4)	80 (11.6)
Knoop hardness, kg/mm^2	450	340
Density, g/cm^3	3.1	2.96

Simulation Studies

Chewing Machines. An early attempt to study attrition used a machine capable of simulating the actions of the human mandible during chewing to produce a variety of wear patterns (Ref 47). Much more sophisticated chewing machines have been developed to examine dental composite wear and are discussed later.

Brushing Machines (Dentifrices). Three main methods used to determine the loss of hard tooth tissue from brushing are: (1) measuring the amount of tooth tissue abraded from an irradiated tooth by the concentration of radioactive phosphorus in the wear debris (Ref 36, 48, 49, 50, 51), (2) determining the change in profile of samples (Ref 52), and (3) measuring the change in reflectance of the surface of tooth structure (Ref 53).

Dentifrices used in 1942 were compared to a calcium carbonate standard (Ref 54, 55). Abrasion was found to occur 25 times faster on dentin and 35 times faster on cementum than on the enamel tips of cusps. Abrasive power (percent abrasion of a calcium carbonate control) increases linearly with particle size (Ref 56, 57). On the other hand, the polishing ratio of zirconium silicate increases with decreasing particle size, and particle size distribution is important (Ref 53). Increasing the load on the brush also increases enamel and dentin abrasion scores (Ref 50, 58).

The radiotracer method can measure wear rates of dental tissues by as few as one or two strokes of a brush on dentin with commercial dentifrices. Use of this method has led to the observation that wear of dental tissues is proportional to penetration hardness if hard abrasives are used (Ref 49).

Brushing Machines (Toothbrush). A number of studies have attempted to determine the influence of the toothbrush and its variables on the wear of dental tissues. Plastic toothbrush bristles have little abrasive or polishing power (Ref 59, 60, 61, 62). Other studies have compared automatic versus hand toothbrushes (Ref 63, 64, 65). In general, the mechanical toothbrushes produce less abrasion of hard tooth tissue than simulated manual brushing, but the forces associated with manual brushing are usually larger.

Many variables of toothbrushes and dentifrices have been examined with brushing machines. (These include (Ref 4):

- *Dentifrice properties:* hardness, particle size, and particle distribution of the abrasive, and composition and concentration of remaining components
- *Toothbrush properties:* geometry, hardness, stiffness, and number of bristles
- *Substrate properties:* orientation, hardness, surface preparation
- *Testing conditions:* brush load, stroke length, stroke rate, number of strokes, and presence of saliva

Machines for Prophylaxis. Products containing quartz and pumice show higher cleansing values but generally result in greater abrasion to enamel and dentin (Ref 66). Abrasion of dentin by a pumice slurry is about 20 times greater than abrasion of enamel under standardized conditions (Ref 67). Increases in treatment time, load and cup speed cause linear increases in abrasion of irradiated human enamel and dentin (Ref 68). Commercial products containing calcined magnesium silicate and sodium-potassium-aluminum silicate show best polishing with low abrasivity (Ref 37). No clinical study has yet correlated the degree of abrasivity with any destructive effect on hard and soft tissues. American Dental Association Specification No. 37 includes a suggested abrasivity test that uses a radiotracer technique (Ref 69).

Cutting Machines. Cutting of human enamel by a high-speed diamond stone is enhanced by use of a solution of glycerol, ethanol, and water (2:1:2) when compared to cutting with water alone (Ref 70). Such a chemomechanical effect is also observed in the cutting of amalgam with diamonds and carbide burs and the cutting of composites with carbide burs. Cutting of hydroxyapatite blocks with autoclaved tungsten carbide burs is enhanced if the burs are dipped in sodium nitrate or commercial anticorrosive dips before autoclaving (Ref 71).

Clinical Studies

Clinical studies collect physiologic wear data produced by: (1) sliding contacts or direct contact alone (occlusal-contact-area wear) and (2) noncontact wear (contact-free wear), which is related to food abrasion. To effectively examine these

events, pathologic and prophylactic wear must be absent or controlled. In addition to the restorative treatment variables in clinical studies, there are also intraoral variables and patient factors that complicate clinical results and interpretations.

Occlusal-contact-area wear of human enamel has been measured with a computerized three-dimensional measuring technique on tooth replicas over a period of four years (Ref 72). The steady-state wear rates at enamel occlusal contact areas are about 29 μm/year for molars and about 15 μm/year for premolars. These data agree with earlier reports of 33 μm/year (Ref 73) and 41 μm/year (Ref 74).

Observations of orthodontic patients with arrested carious lesions indicate that functional wear and toothbrushing are responsible for the arrestment by disturbance and removal of bacterial deposits (Ref 75). Changes in surface enamel morphology after acid etching are also the result of abrasion rather than the precipitation of mineral from saliva (Ref 62).

Enamel undergoes physiologic wear but is routinely redeposited by nucleation and growth of new hydroxyapatite from the calcium phosphate present in saliva. This process helps to compensate for losses that occur during physiologic, prophylactic, and polishing wear. Dentifrice abrasivity of enamel as measured *in vivo* by a cellulose acetate replication technique is much lower than abrasion caused by pumice or zirconium silicate (Ref 76).

Dental Amalgam

Dental amalgam is an alloy that results when mercury is mixed with an alloy containing silver, tin, copper, and sometimes zinc (Table 1). Before it hardens, the freshly mixed mass of amalgam can be packed into a cavity prepared in a tooth. Amalgams are usually limited to replacement of tooth issue in the posterior teeth and often function in stress-bearing areas susceptible to occlusal wear. Some properties of dental amalgams are listed in Table 2.

Fundamental Laboratory Studies

Abrasion Tests. Two-body abrasion of dental amalgam has been measured using a Taber abrader (Ref 77), a silicon carbide two-body abrasion test (Ref 78), and a pin-on-disk test (Ref 79). With the Taber abrader, smearing of amalgam and clogging of the abrader wheel cause inconsistent ranking with clinical observations; clogging of the abrasive surface is avoided by abrading at a low load over a fresh abrasive surface on each pass. Ranking of amalgam and composite restorative materials with two-body abrasion tests is in better agreement with clinical observations than that done with three-body abrasion tests. Two-body abrasion test result on some typical dental amalgam alloys are given in Table 6. As indicated by these results, a dispersed high-copper amalgam (Dispersalloy) exhibited better resistance to silicon carbide two-body abrasion than spherical low-copper amalgams.

Table 6 Material loss on abrasion of dental amalgams

Material	Material loss, 10^{-4} mm^3/mm of travel(a)	
	24 h	**1 month**
Spher-a-Caps	7.0	7.0
New True Dentalloy	6.5	6.3
Dispersalloy	5.6	4.9

(a) Load: 0.17 MPa.

The pin-on-disk test (Ref 79) utilizes a cylindrical sample of enamel to rub on a rotating disk of amalgam. Measurements of wear rate are possible, but transfer of material from the disk to the pin confuses interpretation of the results.

Single-Pass Sliding. The wear of dental amalgam also has been studied by single- and double-pass sliding with a diamond hemisphere (360 μm in diameter) (Ref 80). The dispersed high-copper amalgam has the lowest values of tangential force and track width. The mode of surface failure under single- and double-pass sliding is ductile with no evidence of subsurface failure. Smearing of phases for both spherical and dispersed amalgams during sliding does occur, but the dispersed amalgam is more resistant to smearing. Cracks that occur at higher loads propagate around the stronger

phases. Wear is determined by resistance to penetration and by a ductile mode of surface failure over the load range tested.

Friction of dental amalgam is altered when any transfer of material from one member of the pair to the other member occurs (Ref 81). For example, when gold or dental composite slide against amalgam, amalgam material is transferred to the gold or composite surface and the friction then becomes that of amalgam on amalgam.

Fracture toughness, critical strain energy release rate, and critical stress intensity factor have been determined for several types of dental amalgams (Ref 82). Data are consistent with surface failure observed in single-pass wear studies.

An equation developed from single-pass studies (Ref 83) has been derived that relates the sliding frictional force (F) to normal load (N), fracture toughness, modulus of elasticity, yield strength, and slider diameter in the form of $F = KN^n$ (Table 7). The observed friction is caused primarily by plowing or deformation during single-pass sliding.

Table 7 Friction of dental materials as described by various properties including fracture toughness

Material	Modulus of elasticity		Yield strength		Fracture toughness, J/m^2	*n*	*K*

Simulation Studies

Amalgam abrasion from dentifrices in brushing machines has been studied by profilometry and laser reflection techniques, which both indicate that amalgam wears about 10 times more rapidly than gold alloys under the same conditions of simulated brushing with normal dentifrices (Ref 84).

Clinical Studies

The physiologic wear rates of amalgam are 6 to 15 μm/year in contact-free areas and 28 to 58 μm/year in occlusal contact areas (Ref 85). This wear may be compensated by continual amalgam expansion that produces occlusal extrusion. Therefore, the rate of attrition of amalgam is usually not considered to be a clinical problem.

Amalgam degrades at the tooth-restoration interface by a process called marginal fracture, which is the result of electrochemical corrosion in the presence of direct-contact stresses (Ref 86). Direct-contact areas on amalgams that are not stabilized by contacts on enamel may also produce noticeable facets.

Composite Restorative Materials

Composite restorative materials consist of a cross-linked polymer matrix that is chemically bonded by coupling agents to the surfaces of dispersed silica-based filler particles (Table 1). Composite restorations have the appearance of natural tooth tissue and can be placed directly into a cavity preparation for *in situ* hardening. They are recommended for restorations where occlusal stress is minimal and appearance is crucial. Composites are also available for limited posterior use in areas of occlusal stress, but they are less durable than amalgam (Ref 87). Some properties are listed in Table 2.

Wear resistance of composite restorations is important for clinical longevity, esthetics, and resistance to dental plaque. The need for markedly improved wear resistance has been emphasized by recent literature reviews (Ref 88, 89, 90, 91). The reason that wear-resistant composites have not been developed is primarily because of the lack of understanding of the mechanisms of clinical wear. This problem is confounded by the lack of reliable and consistent clinical wear data.

Fundamental Laboratory Studies

The problem with all wear theories has been the lack of correlation of clinical wear results with laboratory properties. Mechanical properties do correlate with filler types and loading levels (Ref 92, 93, 94, 95, 96, 97), but they do not predict clinical performance. To bridge the gap, a wide range of tests have been performed. Some of these are described below.

Abrasion Tests. Taber abrasion (Ref 81), single-pass sliding on abrasive papers (Ref 98), pin and plate (Ref 99), pin and disk (Ref 100), metallographic polishing (Ref 101), toothbrushing (Ref 102), and oscillating wear (Ref 103) tests have shown very little or on success in explaining intraoral wear. With the Taber abrader, smearing of resin and clogging of the abrader wheel produced apparently better resistance for unfilled resins than for composites; these results are inconsistent in ranking with clinical observations.

A silicon carbide two-body abrasion test was developed to avoid clogging effects (Ref 78). This test provided some agreement with early clinical studies, but its primary usefulness was to examine the relative effects of different formulation variables.

Improvements in the durability of composites depend on a thorough understanding of the wear bahavior of the resin matrix (Ref 104). The resin with the lowest value of two-body abrasion also showed the lowest coefficient of friction and the most ductile behavior during single-pass sliding. (Table 8). Abrasion resistance was improved by finishing the cured surface before testing (Ref 105). Reduced wear of large-particle composites was related to the increased size (relative to the abrasive), increased hardness, and increased volume fraction of the filler particles (Ref 106, 107).

Table 8 Material loss on abrasion and single-pass wear characteristics of dimethacrylate resins

Material	Material loss, 10^{-4} mm^3/mm of travel[(a)]	Coefficient of friction (β)	Ductile-to-brittle transition load, N
Tetraethylene glycoldimeth-acrylate	22.0	0.45	7.0

Bisphenol A-bis (2-hydroxypropyl)methacrylate + ethylene glycol-dimethacrylate (1:1)	15.5	0.35	>10
Bisphenol A-bis ethylmeth-acrylate + octafluoro-1-pentyl-methacrylate (9:3)	19.1	0.61	4.0
Bisphenol A-bis ethylmeth-acrylate + octafluoro-1-pentyl-methacrylate (3:9)	32.2	1.48	3.0

Source: Ref 104

(a) Load: 0.18 MPa.

Pin-on-disk testers were popular at least in part become subsurface damage detected during microdefect analysis of a few composites recovered from *in vivo* service was apparently the same as the structure observed in composites subjected to pin-on-disk wear using stainless steel sliders (Ref 108).

Two-body pin-on-disk abrasion of composite veneering resins was shown to be much higher for rubbing contact against porcelain versus enamel, gold, or the same veneering resin (Ref 109). Combinations of composite with composite, silver-reinforced glass ionomer, or porcelain wore excessively (Ref 110).

The enthusiasm for abrasion testing produced a large amount of data, but actual clinical wear mechanisms often proved to be quite different.

Single-Pass Sliding. The wear of composites also has been studied by single- and double-pass sliding with a diamond hemisphere (360 μm in diameter) (Ref 111, 112). The surface failure for unfilled diacrylate resins was more severe than that observed for an unfilled acrylic resin. Addition of nonsilanated filler to the diacrylate resin increased resistance to penetration but did not dramatically change the mode of failure (Fig. 8). Diacrylate resins that contained silanated filler (commercial composites) were ductile in failure during sliding and showed the higher resistance to penetration. Damage was more severe for double-pass than for single-pass sliding. Single-pass data did not, however, provide an estimate of volume lost on repetitive wear of composites.

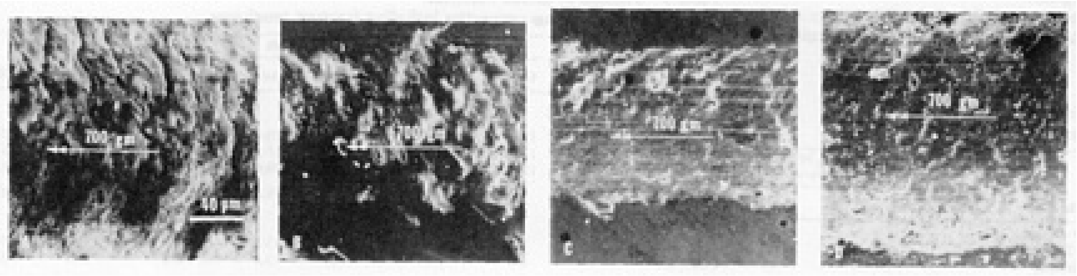

Fig. 8 Scanning electron micrographs of double-pass wear scars made under a normal load of 7 N of (A) unfilled diacrylate resin, (B) unfilled acrylic, (C) diacrylate resin with silanated filler, (D) diacrylate resin with nonsilanated filler. Source: Ref 112

Aging and Chemical Softening. The surface degradation of composites caused by accelerated aging in a weathering chamber was characterized by erosion of the resin matrices and exposure of filler particles (Ref 113). Differences in surface roughness and profile indicated that the aged composites were eroded at different rates. Surface crazing (Fig. 9) was observed for some aged composites. Surface degradation also resulted in color changes, particularly for large-particle composites but much less so for microfilled composites (Ref 114).

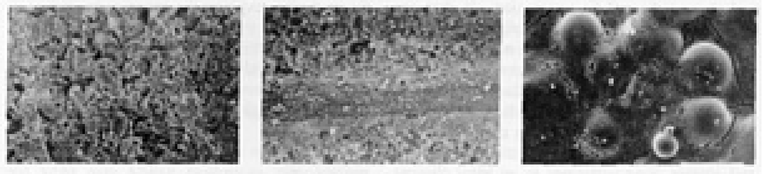

Fig. 9 Scanning electron micrographs of composites aged for 900 h showing surface crazing. Source: Ref 113

Single-pass sliding wear of aged, chemically cured, large-particle composites resulted in smaller track widths, lower tangential forces, easier dislodging of material, and more severe surface failure at lower normal loads than that of unaged composites (Ref 115). Ductile-to-brittle transitions occurred at lower normal loads (Table 9), and changes in morphology became more severe (Fig. 10) with increased aging (Ref 116).

Table 9 Influence of increased aging on single-pass wear transitions of composites under conditions of accelerated aging

Material	Ductile-to-brittle transition load, N

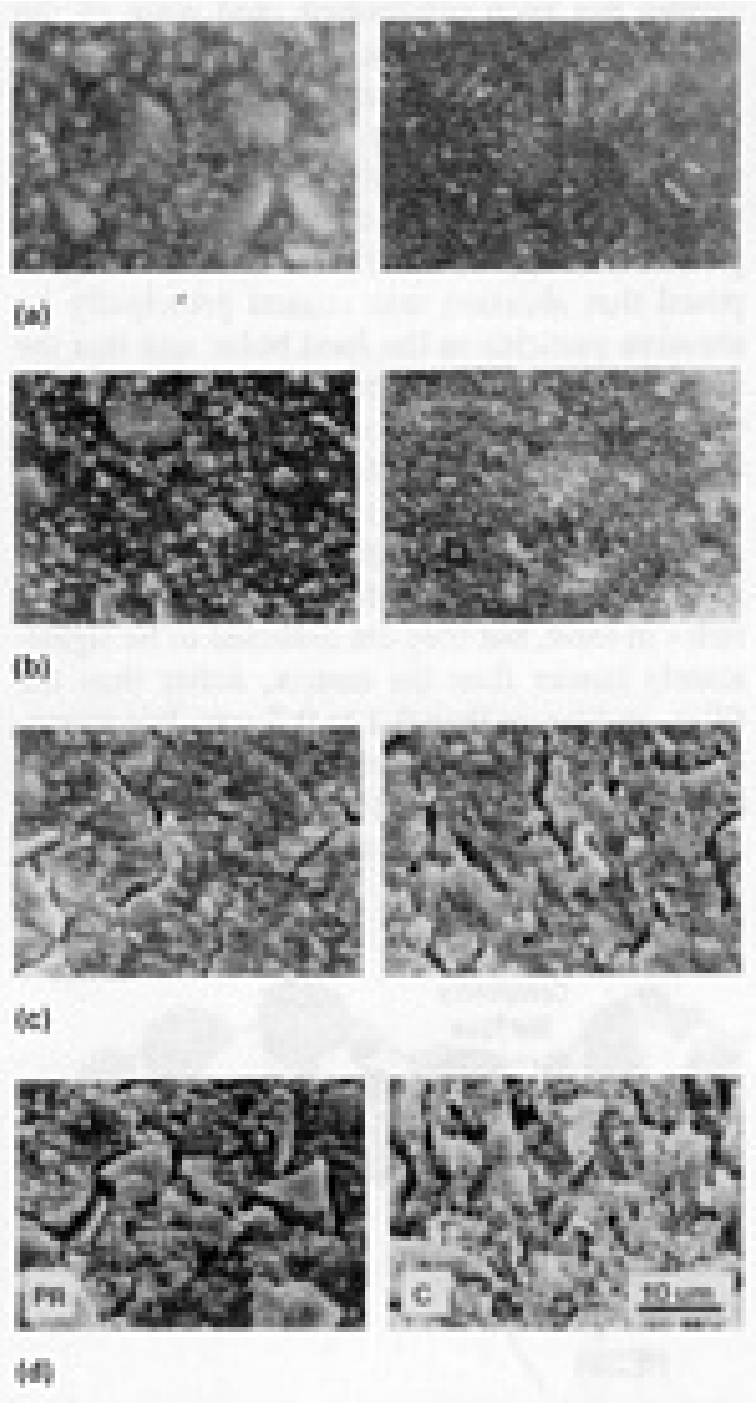

Fig. 10 Scanning electron micrographs of surface morphology of two large-particle composites at (a) 0, (b) 300, (c) 600, and (d) 900 h. Source: Ref 116

Preconditioning composites in food-simulating liquids (heptane and several ethanol/water solutions) has been shown to decrease the hardness with a corresponding increase in pin-on-disk wear (Ref 117). Swelling of the polymer matrix and surface damage occurs during preconditioning. Increasing the degree of cure of the matrix polymer may inhibit diffusion of penetrants, and additional cross-linking may reduce swelling and damage by solvents. Evidence of erosion has also been observed under *in vivo* conditions (Ref 118).

Fracture toughness, critical strain energy release rate (G_{Ic}), and critical stress intensity factor (K_{Ic}) have been determined for experimental and commercial composites (Ref 119). The commercial composite was less resistant to crack initiation and had a higher K_{Ic} than its unfilled diacrylate resin. Data were consistent with surface failure observed in single-pass wear studies of these resins.

Correlating Abrasion with Hardness and Tensile Data. Hardness and tensile strength of large-particle composites were not related to measured *in vitro* abrasion rates (Ref 120). However, clinical abrasion of microfilled composites and unfilled resins appeared related to indentation hardness (Ref 121).

Simulation Studies

Most simulation studies evaluate physiological wear. Few studies have dealt with prophylactic wear. Microfilled composites subjected to brushing abrasion with a dentifrice wore 5 to 10 times faster than large-particle composites (Ref 122). Abrasion slowed once the resin-rich layer of a composite was lost or when the composite was postcured by heat.

A limited study was reported in which composites were abraded by an artificial food bolus (Ref 123). Composites were placed along the edge of a rotating disk immersed in a millet seed suspension and ground against a stainless steel wheel. Although not perfect, the ranking of composites agreed with clinical studies.

Chewing machines have been developed to simulate the full range of intraoral wear events (Ref 124). To date, the results have only shown a limited agreement with clinical studies.

Clinical Studies

Many direct clinical evaluations of wear rely on the United States Public Health Service (USPHS) criteria for classifying the loss of anatomical form of posterior restorations (Ref 125). Unfortunately, the USPHS criteria alone are not sufficient to detect early loss of material in posterior composites (Ref 126, 127, 128, 129, 130, 131). Because of the crudeness of the USPHS scale, there was considerable impetus in the early 1980s to develop more precise indirect measurement techniques.

The first indirect method to become popular was designated the Leinfelder technique. It measured the loss of material using a stone cast poured from a clinical impression of the restoration to compare it to a series of calibrated stone casts (Ref 126, 130, 132). Other similar indirect cast methods have tired to refine the Leinfelder approach (Ref 133, 134, 135). Unfortunately, because of operational differences, these scales have been shown to underestimate actual wear by 50%.

The major advantage of indirect methods employing stone casts and evaluators is their inexpensive nature. All other methods, particularly computer digitization, are remarkably costly and thus impractical for even small clinical studies.

Electroplated or epoxy resin replicas of restorations have been prepared from impressions and studied by optical, scanning electron, or reflex microscopy; by Moiré techniques; or with computer digitization (Ref 86, 136). Wear has also been measured by monitoring the recession of resin on the surfaces of prominent filler particles by scanning electron microscopy of sequences of impressions of a restoration (Ref 137).

A less-complicated method of clinically evaluating restorations is to place them into denture teeth in a removable denture (Ref 138, 139, 140, 141, 142). The dentures permit direct measurements of the samples by profilometry or three-dimensional computerized surface digitization.

Because of the large number of uncontrollable clinical variables involved in these studies, there is a broad distribution of results at each recall. The results are different for molars and premolars. Differences in operators and techniques among clinical studies are often so great that the results are not comparable at all. The reported results are often misrepresented as wear rates rather than total wear. Wear does not occur in a linear fashion.

Published wear rates for composites are 12 to 79 μm/year in contact-free areas and 39 to 135 μm/year in occlusal contact areas (Ref 85). For autocured (Ref 143) and ultraviolet light-polymerized (Ref 144, 145) composites, wear has been shown to occur at decreasing rates during the first three years (Fig. 11). This same pattern of decreasing wear has now been reported for several newer visible light cured composites (Ref 146, 147, 148). For one composite, about 74% of the total wear over a three-year period occurred during the first year, followed by 19% in the second year, and 6% in the third year. This pattern is less obvious if the first six months of data are excluded. The wear rate for the next few years may appear almost constant (Ref 149). The rate reported for a few microfilled composites appeared to be nearly linear (Ref 85, 150), but early wear may have been hidden by beveling of the restoration margins. Recently, wear rates for posterior composites have been reported to drop to very low values after 5 to 8 years (Ref 145, 147, 148). Because of this overall decreasing rate of wear, it is hazardous to project long-term wear rates from any short period of time.

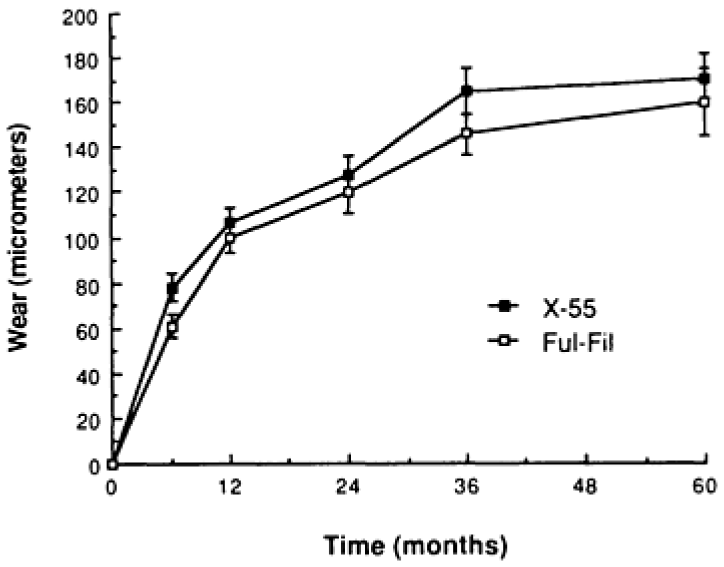

Fig. 11 Decreasing clinical wear rate with time. Source: Ref 148

Wear of posterior conventional composites involves exfoliation of the filler particles as the resin matrix is continually worn away (Ref 147, 151). This process gives the appearance of a restoration submerging below the surface (Fig. 12). The wear is reduced in the hybrid composites by reducing the mean filler particle size from a range of 30 to 50 μm to a range of 3 to 5 μm and by increasing the amount of filler from 75 to 86 wt% (Ref 128). The use of softer barium glass (HK 400) to replace quartz filler (HK 600) in the particle size range of 10 to 20 μm also results in better wear resistance, although the glass particles themselves show evidence of wear.

Fig. 12 Scanning electron micrograph of a composite restoration (Concise) with severe occlusal wear after a seven-year period. 10×. Source: Ref 188

Other factors leading to breakdown include the degradation of the silane coupling agent, which can cause microcracking of the resin (Ref 152) and the large mismatch in coefficient of thermal expansion between filler and resin (Ref 86, 118). Maximizing filler particle-to-particle contacts does not improve wear resistance (Ref 153). Resistance to wear is higher for unfinished composites than for those finished conventionally with a finishing bur and white stone, suggesting that finishing at least initially mechanically weakens the surface (Ref 154).

Another problem for clinical research is that different evaluation systems record different wear events. For the most part, the indirect method relies on relief occurring at margins to create contrasts that can be compared to standards. This method does not measure wear elsewhere on the occlusal surface. It is not clear where on the restoration direct clinical

evaluation measures wear, but it seems most likely to be at the marginal areas. Profiling methods measure the general occlusal surface very well but are least accurate at the margins (Ref 155, 156).

A further complication of clinical research studies is that there has always been the wide distribution of wear values for individual restorations at any recall period. After three years, the wear ratings for composites vary from 0 to 350 μm (Ref 148).

In an attempt to understand this variation, the factors contributing to intraoral wear have been collected into categories for statistical analysis (Ref 157). The categories include factors involving cavity preparation, restoration, manipulation, intraoral location, and the patient. Although not all of these factors are yet well known, it has been possible to identify the major ones.

Intraoral location is the most important factor. First molars wear more than second molars, second premolars, and first premolars, in that order. Restoration width is also important. There are minor effects from arch, gender, and complexity of the restoration. Differences in formulations of materials have secondary effects (Ref 158). Understanding these effects, it is possible to normalize differences among clinical studies to pool the clinical data for posterior composites and correct these variations to an ideal clinical population using Weibull analysis (Ref 159).

Numerous theories of wear have been proposed for dental composites based on their microstructures and resistance to microstructure. The analysis typically is presented in terms of the filler, coupling agent, or resin matrix being the weakest link (Fig. 13). The percent conversion of monomer to polymer during curing (Ref 160, 161, 162, 163, 164, 165, 166, 167), the depth of curing (Ref 168, 169, 170, 171, 172, 173, 174), the glass transition temperature of the polymer (Ref 175, 176), and the strength of the polymer (Ref 177, 178, 179, 180, 181, 182) have all been proposed as reasons that the matrix might be most susceptible to microfracturing and thus wear. Problems with coupling agent effectiveness and hydrolysis have been proposed as possible weak links (Ref 152). It has been hypothesized that the surfaces of composites absorb chemicals from food and become predisposed to microfracture, thus permitting wear (Ref 108, 117). Different wear mechanisms have been theorized for different composite types (Ref 149). None of these mechanisms has been established, and none of the explanations is predictive.

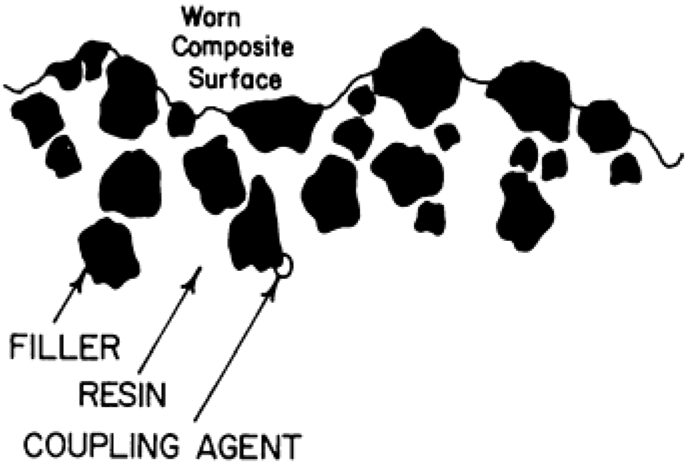

Fig. 13 Schematic of worn composite restoration indicating possible weak links

A key observation was made by examination of local patterns of wear on composite surfaces (Ref 121, 138). Wear of resin seemed to occur only when separation of filler particles was greater than approximately 0.1 μm. It was proposed that abrasion was caused principally by abrasive particles in the food bolus and that the smallest effective particles were larger than 0.1 to 0.2 μm. Therefore, composites with interparticle spacings less than that dimension were microscopically protected against wear. No information has been available about the size, amount, or abrasivity of the wear-producing particles in food, but they are assumed to be significantly harder than the matrix, softer than the filler, and larger than 0.1 to 0.2 μm. For microfills and many hybrids containing ≥20 vol% of 0.4 μm microfiller particles, the computed average filler particle separation is <0.2 μm. This theory readily explains the apparent resistance to wear of

those composites *in vivo.* Theoretical calculations of microfiller levels required for microprotection indicate that only a few percent are required. However, assuming that microfiller tends to be agglomerated, levels of 45 to 50% are necessary.

An extension of this argument has been that macroscopic protection would also exist for small cavity preparations. Increased exposure of the preparation walls shelters the adjacent composite and causes a decrease in the clinical wear rate. Most of the observed wear patterns and decreasing wear rates appear to be explainable on the basis of these two protection mechanisms alone (Fig. 14).

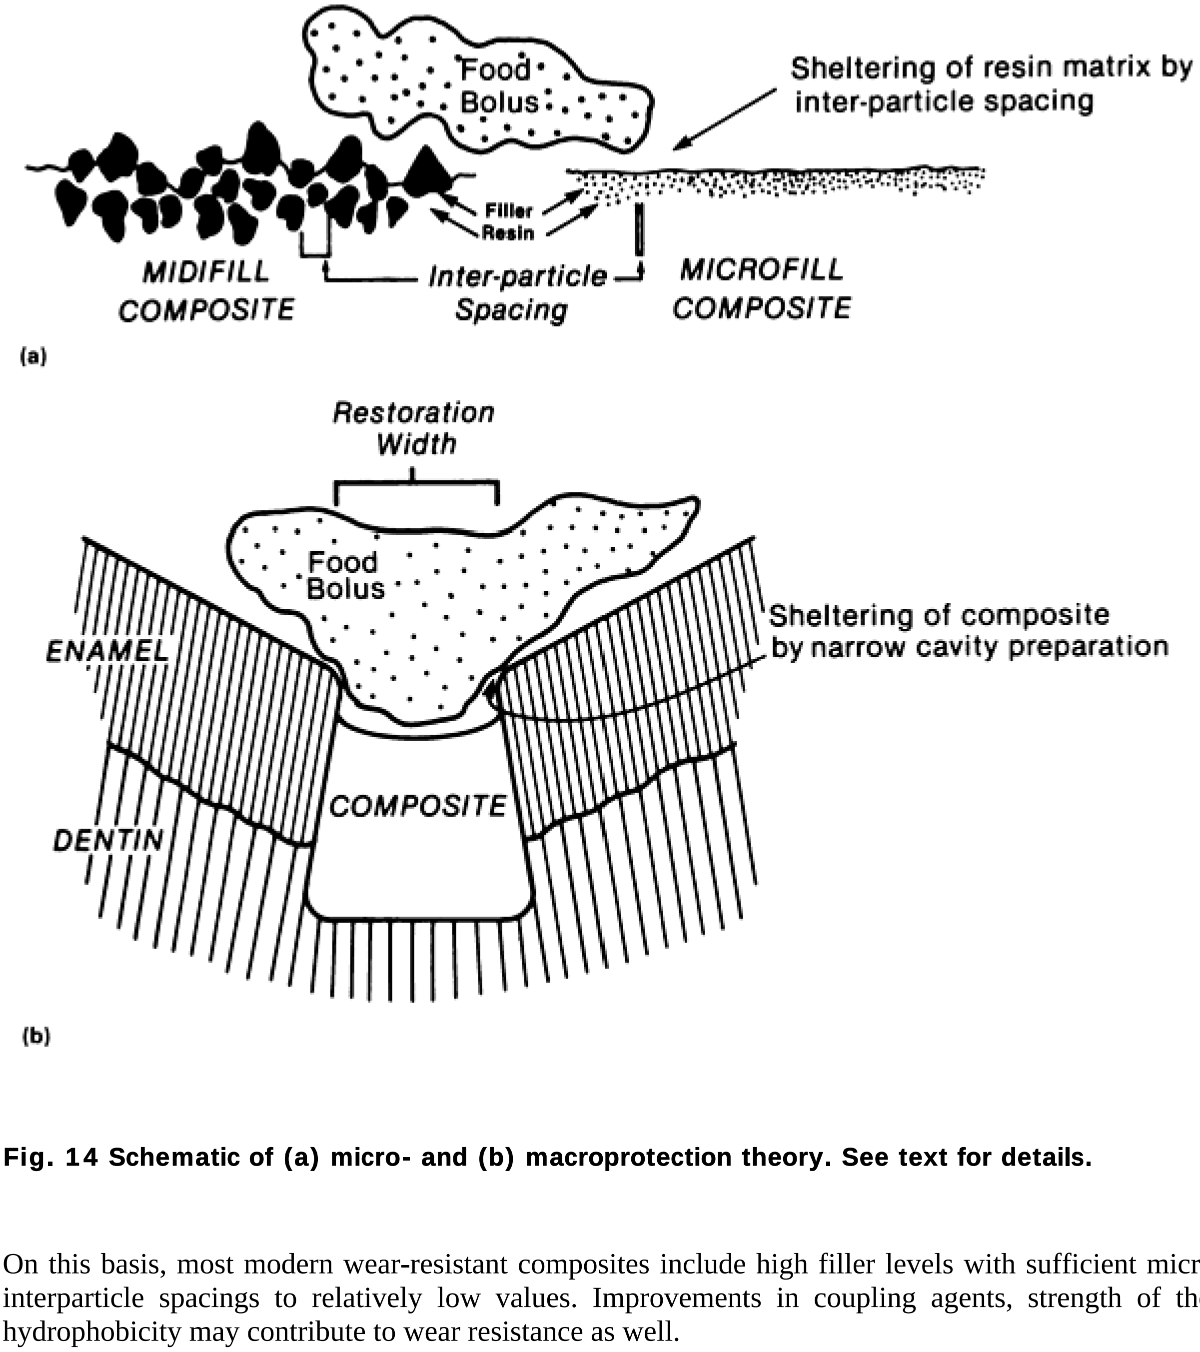

Fig. 14 Schematic of (a) micro- and (b) macroprotection theory. See text for details.

On this basis, most modern wear-resistant composites include high filler levels with sufficient microfiller to reduce the interparticle spacings to relatively low values. Improvements in coupling agents, strength of the resin matrix, and hydrophobicity may contribute to wear resistance as well.

Pit and Fissure Sealants

Pit and fissure sealant consist mainly of a polymer matrix with minor amounts of dispersed filler particles, primarily for coloration (Table 1). Sealants are designed to be more fluid than composites so they will penetrate the pits, fissures, and etched areas of enamel to produce macroscopic and microscopic mechanical retention. The purpose of sealants is to penetrate all cracks, pits, and fissures on the occlusal surfaces of deciduous or permanent teeth at risk to dental caries, to seal these areas, and to provide effective protection against caries-producing bacteria. Some properties of sealants are listed in Table 2.

Fundamental Laboratory Studies

Two-body abrasion of sealants has been measured using a silicon carbide two-body abrasion test (Ref 183). Weight-loss data range from 22×10^{-4} to 24×10^{-4} mm^3/mm of travel, which is characteristic of wear of diacrylate resins with little or no filler. The addition of 40 wt% quartz to a sealer did not affect its resistance to two-body abrasion.

The wear of sealants also has been studied by single-pass sliding with a diamond hemisphere (360 μm in diameter) (Ref 183). The sealant with 40 wt% quartz was more resistant to penetration and showed less surface damage from single-pass sliding than two unfilled diacrylate sealants.

Clinical Studies

Direct clinical observations of 205 restorations after 4 years has shown that physiologic wear of sealants in the non-stress bearing areas of pits and fissures is only slight (7%) (Ref 184). Wear on other occlusal surface areas where sealant may be applied inadvertently is apparently irrelevant, because these areas are naturally self-cleansing by abrasion from food. Therefore, the wear of sealants in that regard is clinically unimportant.

Dental Cements

Various modified zinc oxide-eugenol and zinc polyacrylate dental cements are used for temporary fillings (Table 1). Glass ionomers and silver-reinforced glass ionomers may be used for certain permanent resolutions not subject to high occlusal forces. Representative mechanical properties of cements are listed in Table 2.

Table 10 Material loss on abrasion of dental cements used as temporary filling materials

Material	Material loss, 10^{-4} mm^3/mm of travel[(a)]
Zinc oxide-eugenol cements

EBAC	15.8
Zinc polyacrylate cements	
PCA Cement	5.0
Durelon	4.9

Source: Ref 185

(a) Load: 0.036 MPa.

Fundamental Laboratory Studies

Two-body abrasion of temporary filling materials has been measured using a silicon carbide two-body abrasion test (Ref 185). The materials are ranked in an order that agrees with clinical observations. Two zinc polyacrylate cements (base consistency) had rates of abrasion much lower than modified zinc oxide-eugenol cements (Table 10).

The two-body abrasion of early glass ionomer cements used for Class V restorations is similar to that of modified composites (Table 11) (Ref 186). Pin-on-disk wear of silver-reinforced glass ionomer restorative materials is less than that for conventional glass ionomers (Ref 187). Incorporation of silver appears to provide lubrication; however, the incidence of catastrophic failure during sliding is only reduced slightly.

Composites	
Cervident	14.7
Enamelite 500	19.5

Source: Ref 186

(a) Load: 0.18 MPa.

Clinical Studies

Clinical investigations of glass ionomer restorations show increasing surface roughness and volume loss (Ref 188). In the absence of occlusal forces, glass ionomers demonstrate some erosion, but a good internal bond is still maintained between the glass particles and the gel matrix (Ref 118).

Noble and Base Metal Alloys

Numerous alloys based on gold-silver-copper, gold-palladium, or nickel-chromium are commercially available to make crowns to restore part or all of the coronal portion of a tooth. These alloys are used primarily in the posterior portion of the mouth where high strength is required and cosmetic appearance is secondary. They are presumed to be resistant to wear and have always been assumed to produce little or no wear of opponent teeth. Thus, very little research has been conducted. Crowns of porcelain fused to metal are often used to combine the aesthetics of porcelain with the strength and fit of a cast crown. In these situations, the abrasion characteristics of the metal alloy are supplanted by the properties of the porcelain.

Clinical Studies

From the limited data available, it appears that wear rates of gold alloys and porcelain are the same when opposing porcelain-fused-to-metal crowns, as shown in three patients with known bruxing and wear problems (Ref 189).

Porcelain and Plastic Denture Teeth

Porcelain or plastic denture teeth are fabricated at factories rather than in the dental office or dental laboratory. Their representative composition is reported in Table 1. Controversy continues among dentists as to the greater benefits of porcelain versus plastic teeth for prosthetic appliances (complete dentures, partial dentures). Shortly after plastic teeth were introduced (*circa* 1940), research reports condemning the choice of acrylic teeth for dentures also started appearing (Ref 190, 191). Since that time, acrylic teeth have been substantially improved and are now the prosthetic tooth material of choice for many dentists.

Fundamental Laboratory Studies

Two-body abrasion of acrylic teeth against sandblasted glass or with a Taber abrader has demonstrated that acrylic wears much faster than 22 carat gold, porcelain, and enamel, but only about 5% more rapidly than dentin (Ref 81, 192, 193). Under intermittent sliding, the rougher the porcelain, the more rapid was the wear of opposing gold and enamel (Ref 194).

The frictional behavior and surface failure of acrylic and porcelain denture teeth have been studied by single- and double-pass sliding with a diamond hemisphere (360 μm in diameter) in water and saliva (Ref 195, 196). Coefficients of friction are higher for acrylic teeth than for porcelain teeth (Table 12). Acrylic teeth show ductile behavior under sliding with ductile-to-brittle transitions occurring about 5 N. Porcelain teeth show brittle behavior under sliding with ductile-to-brittle transitions occurring between 1.5 and 2.5 N. Differences in wear from sliding in water or saliva are not significant. Acrylic teeth show greater deviations from a Hertzian model.

Table 12 Friction and wear properties of acrylic and porcelain denture teeth for single-pass sliding

Material	Coefficient of friction (β)	Ductile-to-brittle transition load, N
Acrylic teeth		
Dentsply		
Dentin	0.62	. . .
Enamel	0.62	4.8
Myerson		
Dentin	0.55	. . .
Enamel	0.54	5.6
Porcelain teeth		
Dentsply		
Dentin	0.24	. . .
Enamel	0.24	2.6
Myerson		
Dentin	0.26	. . .
Enamel	0.26	2.4

Source: Ref 195, 196

The friction of various prosthetic tooth materials varies from wet to dry conditions (Ref 81, 197). When the materials in the two-body pair both involve polar bonding, the presence of water or other polar liquids increases the friction. However, when one of the solids involves nonpolar bonding, water either has no effect or acts as a mild lubricant. Lower loads on acrylic surfaces produce lower friction as a result of the ductile behavior of acrylic. The friction coefficient of acrylic/porcelain combinations (β = 0.30) is less than acrylic/acrylic (β = 0.37) and porcelain/porcelain (β = 0.51) combinations.

Simulation Studies

Chewing machines have traditionally been employed to evaluate abrasion resistance of prosthetic teeth. An articulator attached to a grinding machine was used as an early abrasion test (Ref 198). Dentures with full sets of acrylic teeth, porcelain teeth, or gold restorations were abraded against a denture with porcelain teeth in water, with and without an abrasive. Wear was measured as changes in vertical dimension of occlusion. Acrylic teeth showed heavy wear. Porcelain teeth withstood abrasion but were friable. Teeth with gold restorations wore severely when an abrasive was present. Similar tests with an instrument using a hemispherical pin on an elliptical disk (similar to a stomatognathic system) showed that acrylic/acrylic and porcelain/acrylic combinations had less wear than porcelain/porcelain combinations (Ref 199).

The results of different pairs of wearing surfaces have not been consistent for all wear machines. Results from several chewing machines showed that acrylic/acrylic combinations produced less wear than acrylic/porcelain (Ref 200) and that wear decreased as contacting surface area of the acrylic teeth increased (Ref 201). In other wear machine tests, less wear was observed for porcelain/acrylic combinations than with acrylic/acrylic or porcelain/porcelain combinations (Ref 202, 203).

Recent occlusal wear studies using an artificial mouth and computerized profilometry to measure wear have shown that denture teeth made from a highly cross-linked copolymer with an interpenetrating polymer network (IPN) were more wear resistant than traditional acrylic resin teeth (Ref 204). The IPN denture teeth do not appear to produce measurable wear in contact with human teeth.

Clinical Studies

Acrylic teeth, when studied as a means of obtaining balanced functional occlusion in partial dentures, showed no tendency to wear over a period of 6 to 24 months (Ref 205). Abrasion of acrylic teeth has been observed clinically in dentures of 9 of 12 patients (Ref 206). A five-year clinical appraisal of 114 denture patients with acrylic teeth showed a loss of occlusion in centric relation as a result of wear of acrylic posterior teeth (Ref 207). Porcelain teeth and variables

such as bone loss or varying occlusal concepts were not evaluated. The results of a survey of 77 dentists were that porcelain/acrylic combinations appear to wear less than acrylic on acrylic (Ref 208).

Techniques involving removable sections of a fixed prosthesis along with replicas have been used to study wear in a male patient with extreme bruxing habits (Ref 209). Light-cured composite, gold alloy, porcelain, and heat-cured acrylic restorations generally wore more when opposed by porcelain or acrylic denture teeth (Table 13). Wear mechanisms observed included: combined tribochemical wear and fatigue for heat-cured acrylic, fatigue wear for light-cured composite and porcelain, and abrasion and fatigue wear for gold alloys. Wear of both porcelain and cross-linked resin teeth was mainly via fatigue. Abrasive wear occurred in the presence of hard particles (Ref 210). Microfilled composite resin teeth appeared to wear by fatigue and tribochemical wear (Ref 189).

Table 13 Loss of materials (mm^3/month) caused by acrylic or porcelain denture teeth on opposing restoration

Restorations	Opposing denture teeth	
	Acrylic	**Porcelain**
Heat-cured acrylic	3.9	8.3
Light-cured composite	1.9	5.4
Porcelain	1.0	1.1
Type III/IV gold alloy	0.6	1.2

The average vertical loss of denture teeth appears to be 0.1 mm or less per year for acrylic resin teeth (Ref 211, 212) and less for porcelain teeth (Ref 211). Clinical wear of a single acrylic tooth for one year has been measured from computer-generated data obtained from a reflex microscope and is 7.2 mm^3 (Ref 213).

Denture Acrylics

Dentures are made primarily from poly(methyl methacrylate), vinyl-acrylic, or rubber-reinforced acrylic polymers (Table 1). Their main use is to support plastic or porcelain artificial teeth. Some typical properties are listed in Table 2.

Fundamental Laboratory Studies

Two-body abrasion of heat-cured and self-cured acrylic denture resins correlates with scratch measurements and values of flexural modulus of elasticity (Ref 214). The abrasive wear rate of denture resins was much higher than that of composites, alloys, or teeth (Ref 215).

Dental Feldspathic Porcelain and Ceramics

Dental porcelain is primarily a glass with either some dispersed leucite or alumina crystals, or fluoride-mica crystals (Table 1). Porcelain has excellent aesthetic properties and resists wear extremely well. Some representative properties are reported in Table 2.

Fundamental Laboratory Studies

The frictional behavior and surface failure of dental feldspathic porcelain has been studied by single-pass sliding tests using a diamond hemisphere (360 μm in diameter) in air and water (Ref 216). The friction of as-glazed porcelain is higher and the surface damage is more extensive in water than in air (Table 14). Crack initiation within porcelain occurs at flaws such as scratches or residual pores, and these are propagated by elastic stresses associated with normal intraoral loads. The higher friction in bulk water is attributed to increased cracking and reduced amounts of recoverable elastic strain energy. Coating the porcelain with gold or chromium makes the friction independent of environment. Gold coating reduces the friction, but chromium coating does not. Chromium coating reduces the extent of damage from sliding compared to the as-glazed porcelain.

Table 14 Friction and wear properties of dental feldspathic porcelain for single-pass sliding

Condition	Coefficient of friction (β)	Ductile-to-brittle transition load, N
As-glazed		
Air	0.18	5.9
Water	0.23	4.9
Gold coated		
Air	0.14	5.9
Water	0.14	4.9
Chromium coated		
Air	0.22	5.9
Water	0.22	5.9

Source: Ref 216

Simulation Studies

Simulated occlusal wear studies in an artificial mouth using enamel occluding on porcelain has demonstrated a high coefficient of wear for dental porcelain and suggests that an abrasive wear mechanism is involved (Ref 217).

Die Materials (Stone, Resin, and Metal)

The most common die material is calcium sulfate dihydrate (gypsum), but dies may be fabricated from epoxy resin or electroplated with silver or copper (Table 1). A dental die is a replica of the hard or soft tissues, or both, and must be strong and resistant to abrasion because it is subjected to the stresses of carving and finishing a restoration. Some representative properties are listed in Table 2.

Fundamental Studies

Two-body abrasion of stone, resin, and metal-plated dies is shown in Table 15. The metal-plated dies have the highest hardness and lowest loss in two-body abrasion. Although the dental stone is harder than the resins, the surface morphology of the stone (Fig. 15) makes it less abrasion resistant.

Table 15 Material loss on abrasion and surface hardness of dental die materials

Material	Material loss, 10^{-4} mm^3/ mm of travel	Knoop surface hardness, kg/mm^2
Dental stone		
Duroc	14.8	54
Duroc with hardener	16.3	62
Resin		
Die-Met	2.8	25
Epoxydent	4.8	25
Metal		
Copper-plated	1.5	134
Silver-plated	0.9	128

Source: Ref 218

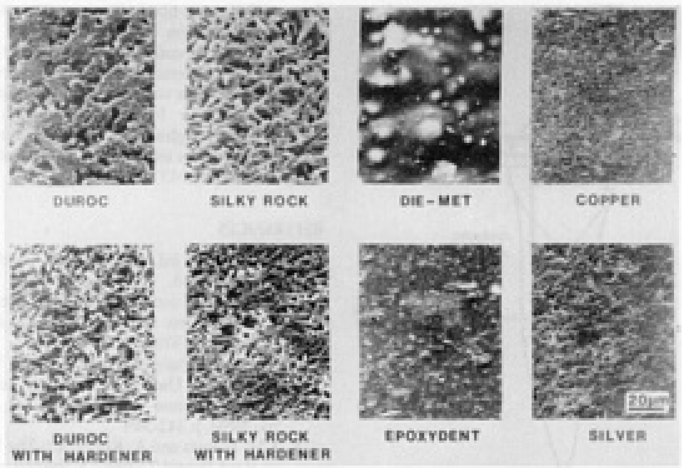

Fig. 15 Scanning electron micrographs of stone, resin, and metal-plated dies. Source: Ref 218

The surface failure of stone, resin, and metal-plated dies has been studied by single-pass sliding with a diamond hemisphere (360 μm in diameter) (Ref 218). The metal-plated dies are ductile up to a normal load of 10 N, whereas the resin and stone dies shown brittle failure above 1 to 2 N.

Endodontic Instruments

Endodontic instruments such as files and reamers are manufactured from stainless steel or carbon steel wires by various combinations of machining and twisting (Table 1). These instruments are used to clean and shape the root canal before it is sealed.

Simulation Studies

The cutting mechanism of a reamer on dentin involves compression and chipping (Ref 219). Triangular reamers cut deeper than rectangular ones. The smaller the angle of the cutting edge, the greater the cutting ability (Ref 220).

Cutting in bovine bone as measured by a drill press apparatus is more efficient with triangular than square reamers (Ref 221). Instruments appear to lose sharpness because of deformation or fracture of the blade.

Cutting in bovine bone or acrylic with a push-pull stroke in a linear motion also can be measured for various instruments (Ref 222, 223). Chips of acrylic appear to impair cutting efficiency. Reduced cutting efficiency has been observed with bovine bone.

Cutting ability of K-type stainless steel files was measured by depths of cut in poly(methyl methacrylate) on an instrument that controls the force on the files and the length and number of pull strokes (Ref 224). Variations in cutting are observed around the circumference of individual files and among files of the same size and brand (Ref 224, 225). Dry heat and salt sterilization has no effect on cutting ability of stainless steel files, but autoclave sterilization causes a reduction in their cutting ability (Ref 226). Sodium hypochlorite, hydrogen peroxide, and ethylene-diaminetetraacetic (EDTA) acid-urea peroxide irrigants cause a decrease in cutting ability, but a saline irrigant has no effect. Wear of K-type files under these conditions was not observed.

Cross-sectional design and flute design are more important variables in cutting than rake angle, wear resistance, capabilities for chip removal, and mode of use (Ref 227). Cutting efficiency of the tip of a file is better than the flute portion (Ref 228). In constricted canals (0.33 mm, or 0.013 in., in diameter), tip angles of files of 60 to 90° are most effective; whereas in larger canals (0.40 mm, or 0.016 in., in diameter), tip angles of files of 40 to 49° are most effective. The tip geometry, however, exerts a greater influence over cutting efficiency than tip length or angle. The pyramidal design is most efficient, whereas the conical tip is least efficient.

Periodontal Instruments

High-quality cutting edges of periodontal instruments are essential for effective subgingival scaling and root planning in periodontal therapy. Cuttability is affected primarily by cutting forces, chip thickness ratios, chip form, and tool wear (Ref 229, 230, 231). Edge quality may be evaluated by the angle between the two edge-forming contiguous surfaces, the smoothness of the edge, edge sharpness or dullness, and the presence or absence of metallic projections (Ref 232).

A sharp curette is the most proficient means for removing calculus and for achieving an acceptable, smooth root surface in periodontal therapy (Ref 233). A dull instrument leaves behind smeared deposits on the root surface, and a damaged curette causes heavy scratches.

Fundamental Laboratory Studies

Laboratory cutting tests of whale bone indicate that high-speed steel results in more-balanced chip formation than cemented carbide, better cutting forces than stainless steel and cemented carbide, less tool wear than stainless steel, and more ideal chip form than cemented carbide (Ref 231).

Simulation Studies

Root planning of extracted single-rooted teeth mounted in mannikin jaws indicates that stainless steel curettes show edge deformation after only 15 strokes (Ref 234). High-carbon steel curettes are more resistant to wear than stainless steel curettes (Ref 232).

Orthodontic Wires

Space closure and canine retraction in continuous arch wire techniques require sufficient force to overcome frictional forces between the bracket attached to the tooth and the arch wire (Fig. 16). Excessive wire/bracket friction may result in loss of anchorage or binding accompanied by little tooth movement. Factors that may influence friction are engagement of the arch wire in brackets that are out of alignment, ligatures pressing the arch wire against the base of the slot, active torque in rectangular wires, and bodily tooth movement in which the tipping tendency is resisted by two-point contact between the bracket and arch wire (Ref 235).

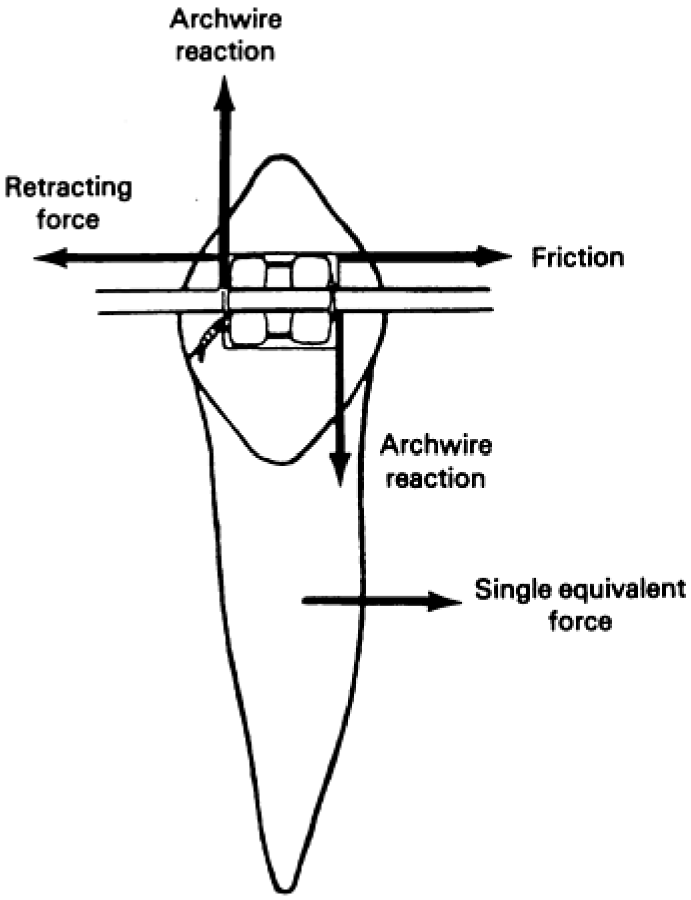

Fig. 16 Forces acting on a tooth/bracket system during translation. Source: Ref 235

Simulation Studies

Arch wire/bracket friction is affected by wire size, angulation, ligation force, bracket size, and wire type (Ref 236, 237, 238). Kinetic coefficients of friction of stainless steel, beta-titanium, nickel-titanium, and cobalt-chromium arch wires sliding on stainless steel or Teflon polymer increase with normal load (Table 16) and increase in the presence of artificial saliva as compared to dry conditions (Ref 239). Stainless steel and beta-titanium wires show wear tracks after sliding under low normal loads (40 to 80 N).

Table 16 Coefficient of friction of orthodontic wire/material combinations for a normal load of 40 and 80 N under wet conditions

Material	Coefficient of friction, 40 N	Coefficient of friction, 80 N
Stainless steel/stainless steel	0.035	0.085
Beta-titanium/stainless steel	0.025	0.122
Cobalt-chromium/stainless steel	0.041	0.122
Nickel-titanium/stainless steel	0.044	0.115
Stainless steel/Teflon	0.003	0.013

Source: Ref 239

There appears to be agreement that nickel-titanium wires have higher wire/bracket friction than stainless steel wires in zero torque/zero angulated brackets (Ref 240). At bracket angulations >3°, nickel-titanium wires have lower wire/bracket friction than stainless steel (Ref 238, 241). Under conditions of two-point contact, friction is inversely proportional to bracket width and is less for stainless steel wires than for nickel-titanium or beta-titanium wires (Ref 235). Surface roughness of nickel-titanium or beta-titanium wires may explain their relatively high friction (Ref 242).

Friction and Wear of Electrical Contacts

Ralph A. Burton, Burton Technologies Inc.

Introduction

ELECTRICAL BRUSHES running on metallic slip rings or commutators represent one of the oldest applications of dry sliding contacts. Brush performance is influenced by parameters such as current, sliding speed, load, contact dynamics, and ambient atmosphere. Although a carbon brush gliding over a copper current collector (slip ring or commutator) was successfully employed in electrical power machinery over 100 years ago, research actively continues on:

- Improved composite materials for higher conductivity and lower wear
- Low electrical noise in instrumentation
- Materials resistant to arcing
- Substitute materials to replace compositions that are hazardous in manufacture or use

A separate field of development has focused on the use of static contacts for applications such as communications and computer systems where noise, development of contaminant films, fretting under vibration, and resistance to attack by atmospheric components are concerns.

Research contributions have come from many disciplines, and the literature published annually is extensive. A continuing source of timely literature is the annual Institute of Electrical and Electronics Engineers (IEEE) Holm Conference on Electrical Contacts, sponsored by the Components, Hybrids, and Manufacturing Technology Society of the Institute of Electrical Engineers, Inc.*

The classic textbook in the field of electrical contacts was written by Holm (Ref 1). It is now out of print but is must reading if it can be located.

A later textbook, also out of print, is by Shobert (Ref 2). A relatively recent summary on carbon materials, which includes glassy carbon, is given by Kinoshita (Ref 3).

A 1982 issue of *Wear* (Ref 4) contains 25 papers that collectively provide a summary of the electrical contact field from the viewpoint of tribology. This publication includes papers on fiber brushes and very high performance brushes.

Seventy-five papers are featured in a publication edited by Ji-Gao Zhang (Ref 5). It includes a concise yet very informative summary, written by Morton Antler, of the tribology of contact finishes for electronic connectors.

Note

* *Copies of the proceedings may be obtained through the IEEE Service Center, 445 Hoes Lane, P.O. Box 1331, Piscataway, N.J. 08855-1331. Many of the papers ultimately appear in the IEEE Proceedings. A cumulative index through 1989 has been prepared (W.L. Brodsky, Task Group Chairman) and is available as IEEE Catalog Number JH 9412-H.

Contact Resistance

The passage of current through a sliding contact of solids is accompanied by a contact potential drop (voltage), in addition to the drop through the bodies themselves. This drop is exacerbated by the fact that solids only contact one another at the peaks of roughness asperities. The actual contact area is determined by the hardness, P_H, of the softer material of the contact pair. Because normal stress on brushes and sliders tends to be low in order to minimize frictional dissipation, the actual area of contact, A_c, may be as small as 10^{-5} A_N, where A_N is the nominal contact area (area of the brush face).

For an isolated circular contact spot, Holm (Ref 1) has derived contact resistance as:

$$R = r/2a \qquad \textbf{(Eq 1)}$$

where R is the resistance in Ω, r is the resistivity in $\Omega \cdot$ cm, and a is the radius of the contact spot.

For n independent contact spots conducting in parallel, the combined resistance, R_N, is given by:

$$R_N = r/2an \qquad \textbf{(Eq 2)}$$

If, however, the spots are clustered over a patch of radius, α, Greenwood (Ref 6) has shown:

$$R_N = (r/2)\,(1/na + 1/\alpha) \qquad \textbf{(Eq 3)}$$

This can be written as (Ref 7):

$$R_N = (r/2\alpha)\,[1 + (A_N/nA_C)^{1/2}] \qquad \textbf{(Eq 4)}$$

Williamson and Hunt (Ref 8) have shown that for high contact loads (for example, between two spherical surfaces), the ratio A_N/A_c is $\sim$0.5 even when the nominal normal stress on the contact patch, P_N, exceeds the Brinell pressure, P_H, under which the surfaces take a permanent indentation. In that case, for any reasonable n (for example, n = 200), the second term in brackets of Eq 4 becomes 0.1, and is therefore small relative to the first term. The resistance, then, is that of the patch of radius α as if it were in full contact.

This observation explains why the smaller asperities, or subasperities, on larger asperities need not affect conduction. It also explains why resistance measurements (both thermal and electric) indicate a few relatively large contact patches on a sliding brush rather than large numbers of microscopic ones.

Effect of Insulating Films (Fritting). The above concepts can provide a guide to estimate the contact resistance of untarnished noble metals in contact. However, even the simplest system (that is, carbon on copper) develops an insulating film when operating in air. Early experiments showed this film to have an amorphous structure and to be composed of copper oxide and carbon. Similar to oxide films in other applications, such a film is prone to breakdown when the potential gradient at asperity junctions exceeds a limiting value. When a breakdown at one location leads to formation of a conductive junction, this reduces the potential difference between the carbon and the copper. This phenomenon is known as fritting.

When a carbon-copper contact is placed in series with resistances, and potential across the assembly is increased, contact potential rises to a characteristic magnitude and remains at this magnitude as current is increased. This happens because an increase of potential across nonfritted junctions results when increased current passes through those junctions that have been fritted. Increased potential leads to increased numbers of fritted junctions.

Figure 1 shows data compiled by Shobert (Ref 2) for composite brushes that contained a varied metal content. The fritting potential is dependent upon the polarity of the brush and is typically lower for the cathodic contacts. In terms of diffusion mechanics, it has been theorized that the cathodic potential encourages copper ions to diffuse from the substrate into the film, thus reducing its resistance and encouraging breakdown of the film. This mechanism is aided by local defects in the insulating film. The initial breakdown and formation of a metallic pipe through the film is called A-fritting; the growth of conductivity with increased current, known as B-fritting, is hypothesized to proceed by a different mechanism that involves resistance heating of the conductive pipes.

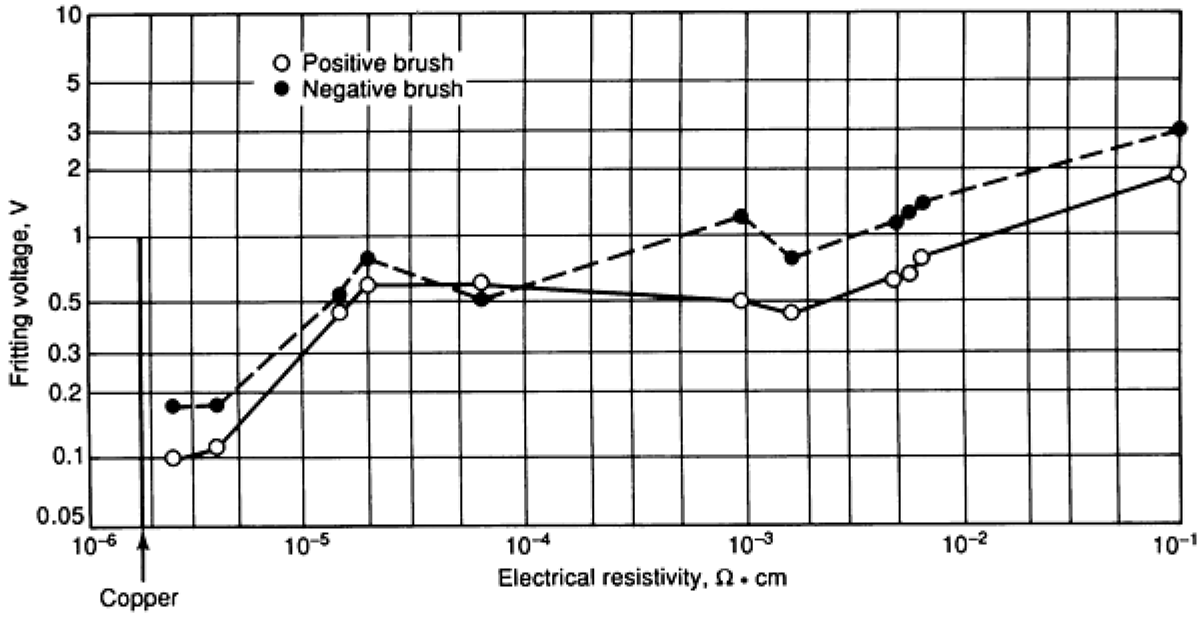

Fig. 1 Plot of fritting voltage versus electrical resistivity showing polarity dependence of composite brushes. Voltage was generated by the contact potential drop between a copper collector and a carbon/copper composite brush separated by an insulating film that was produced by rubbing action of the collector and the brush components.

Resistivity of the film is not as important a factor in thermal conduction as it is in electrical conduction because the ratio of thermal resistivities for the insulator and the metal is several orders of magnitude smaller than the ratio of electrical resistivities.

Tunneling. When thin insulating films are used between two conductors, electrons can freely move across the films thicknesses of $\leq$2 nm ($\leq$20 Å). In Fig. 2, Shobert shows how tunneling resistance varies with film thickness and work function, Φ, of the conductors. The shaded region represents the domain of a typical brush (for example, carbon on copper) where the work function, Φ, is between expected values of 2 and 4 V. In the sliding brush, the fritted spots may oxidize between contacts. However, if film growth is kept to <1 nm (<10 Å) because of wear, tunneling will occur with very little resistance.

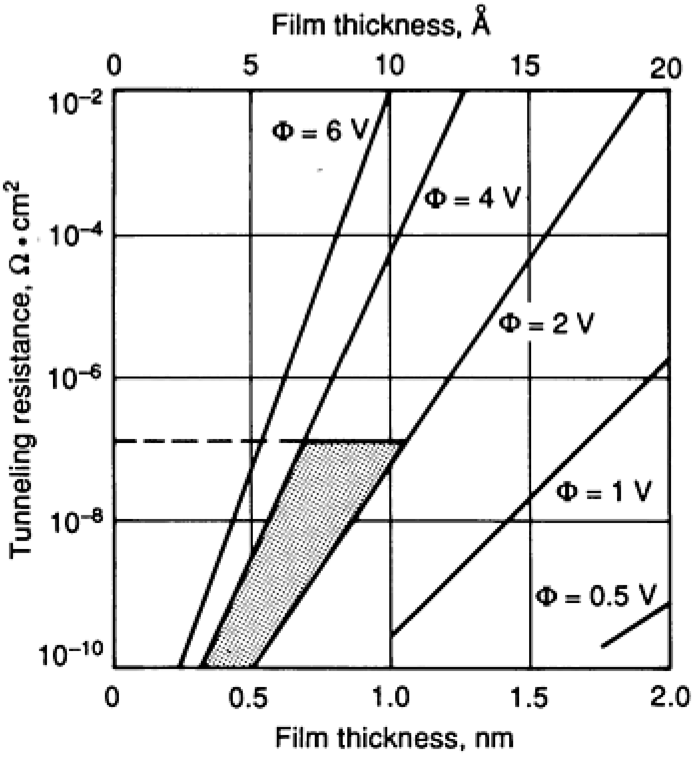

Fig. 2 Plot of tunneling resistance versus film thickness at selected work function, Φ, values. Shaded region represents typical operating range for carbon-on-copper brush components.

Mechanical Factors. Reichner (Ref 9) has presented an overview of the effects of geometric errors in a current collector. In steady operation, the brush wears in to conform to the radius of the current collector. However, both angular and radial runout tend to cause the brush face to develop a relative rounding as though part of a toroidal surface. The contact patch eventually becomes elliptical.

For simple spherical contact, the radius α of the contact patch is approximately:

$$\alpha = 0.880(F_N\Gamma/E)^{1/3} \qquad \textbf{(Eq 5)}$$

where E is Young's modulus for the carbon (E value for the metal is typically high and can be neglected). Poisson's ratio has been taken as 0.3, and $1/\Gamma$ is a composite of the principal relative curvatures of the contacting bodies:

$$1/\Gamma = (1/\Gamma_1 + 1/\Gamma_2) \qquad \textbf{(Eq 6)}$$

Thermoelastic Mounding. A brush and a collector that conform to one another in the static condition may be subject to thermoelastic deformation, which leads to a quasispherical mounding and a quasi-Hertzian contact patch formation. In contrast to the simple elastic spherical deformation discussed in the section "Mechanical Factors" of this article, thermoelastic mounding does not necessarily respond to an increase in load with an increase in the α value.

Frictional Heating. When frictional heating predominates, an increase in the load results in an increase in the thermal deformation component, which causes a corresponding decrease in Γ. The net effect is to make α almost independent of load. In that case, α would be primarily dependent upon sliding speed.

Electrical Heating. When electrical heating is the dominant effect, an increase in load will reduce contact resistance and, upon consequent heating, will result in an increase in Γ.

Heat Transfer onto Slip Ring. For typical slip ring geometry, both the frictional heat and electrical heat generated are transferred with negligible heat loss into the metallic ring, which subsequently develops a mound that is nearly stationary in space at the contact spot. Because of the low value of Young's modulus for typical carbon brushes, mounding of the brush is not a major factor. Experiments (Ref 10) indicate that this phenomenon can occur at modest sliding speed, leading to $\alpha \leq 1$ mm (0.04 in.).

Burnout. Williamson (Ref 11) has analyzed the thermal problem of resistive heating of a stationary contact spot in which the electrical resistivity rises with temperature. An instability exists at which point the rising resistance leads to runaway heating. Similar to the fuse-wire burnout phenomenon that occurs at a critical current level, a fuse wire will begin an accelerated rise in temperature until it burns out. It is also a process that is exploited in the spot welding of metallic sheets or plates. This phenomenon could possibly be involved in A-fritting. Bryant (Ref 12) recently published an analysis of thermal, stress, and electrical behavior of a three-dimensional model of this phenomenon.

Circuit Breaking

Circuit breaking under current flow is a primary wear phenomenon in switches and is an important factor in direct current (dc) vehicular electric systems. Although electrical motors are designed to minimize current flow at the moment of breaking in commutation, residual effects are always present. Inadvertent breaking occurs when runout, which is coupled with inadequate brush-holder design, leads to bouncing against a current collector.

In a gaseous atmosphere, the breaker points may be paralleled by a capacitance that accepts the displaced current and provides a controlled potential rise between the breaker points. If the rate of separation is rapid enough, the potential gradient in the gas between the points can be kept from exceeding the breakdown potential of the gas. Should a brief plasma discharge occur, refractory metal points or hard carbons can resist the heat-flash with minimal damage.

The mechanical components of circuit breakers for energy distribution systems are designed to allow the points to acquire a relative velocity before parting. In such systems, acceleration from a stationary contact occurs in sliding, and breaking occurs when one point reaches the edge of the other.

Dow and Kannel (Ref 13) have carried out experiments with a gravity-loaded brush in which bouncing took place to show the effects of coupled thermoelastic wear and electrical discharge.

Bryant's model (Ref 12) accounts for some of the surface damage. For brushes that have normal oscillations relative to the current collector, the Williamson effect (Ref 11) causes disintegration of a packet of solid material as the conduction is funneled through spots of decreasing size or diminishing quantity.

Takagi (Ref 14) has written a summary of his own work and that of others on the process of contact breaking. The effect of material migration on contact breaking is shown in Fig. 3.

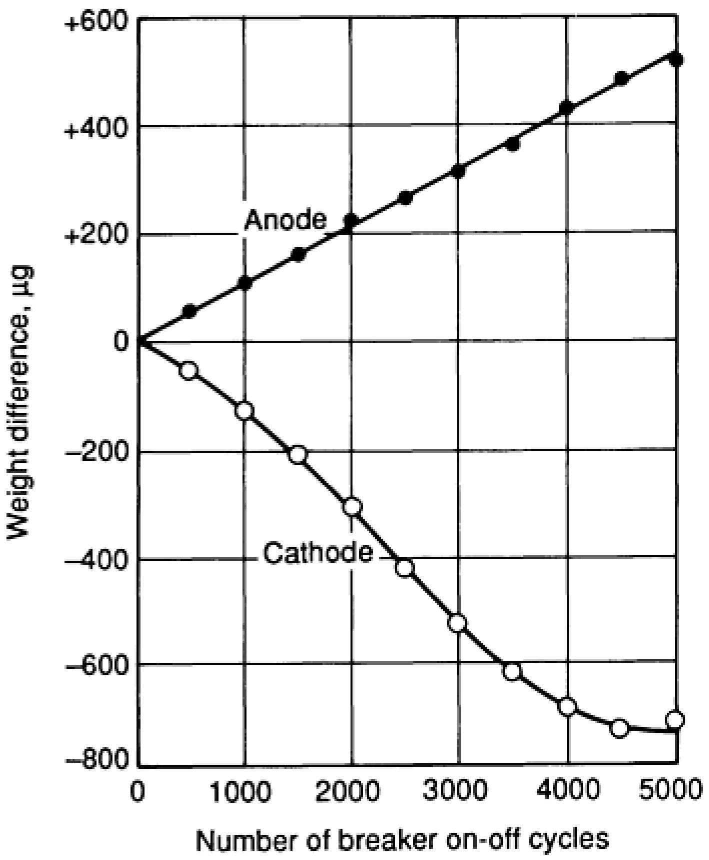

Fig. 3 Metal transfer (weight gain or loss) between silver contact breaker points at a current of 3 A

Atmospheric Effects

Graphitic carbons, in particular, depend upon atmospheric components such as water to weaken the bond between layers, to promote sliding, and to provide a bond between graphite particles and the metallic oxide substrate. In dry (dew point, <10 °C, or 50 °F) or inert gas environments, the phenomenon of dusting, whereby rapid wear of the sliding brush produces copious amounts of carbon dust, is encountered.

Dusting can be controlled with the addition of molybdenum disulfide, barium fluoride, or lithium carbonate into the brush microstructure (Ref 2). In addition, alcohols or even aliphatic hydrocarbons in the atmosphere can minimize the dusting problem. Air is the atmosphere of choice due to its availability; however, moist hydrogen is preferred when available because it will cause one-tenth of the wear rate that is generated in air. This is also true of other inert atmospheres such as ammonia and carbon dioxide (Ref 15). Recent studies of glassy carbon indicate that this form of carbon is immune to dusting even without additives in dry nitrogen (Ref 16).

Greatly accelerated wear can be caused by silicone vapor (Ref 17) as low as 10 ppm in ambient air. This is moderated by the addition of cadmium fluoride, which converts silica to a gaseous material. Solvents and paint thinners may also accelerate wear.

Brush Materials

Traditional carbon brushes are produced with the aid of organic binders, which are used to blend and form powders of lampblack, synthetic or natural graphites, amorphous carbons, dusting inhibitors, and metallic powders. These compositions are then fired slowly at temperatures >1000 °C (>1830 °F). A tremendous range of hardness and resistivity results from the propriety compositions of materials used in brushes. Determine the materials used for various applications is arrived at through experience with similar applications. Brush "reading," or damage inspection, can lead to recommended changes in hardness, transfer film reaction, or metallic content.

Initial evaluation of composites formed by massive electrical discharges (Ref 18) and composites formed from glassy carbon (Ref 16) indicates that these carbon-based materials have potential uses as brush materials.

Friction and Wear of Semiconductors

Steven Danyluk and Soo-Wohn Lee, University of Illinois at Chicago

Introduction

SEMICONDUCTOR CIRCUITS are produced using a variety of mechanical deformation processes. Single-crystal semiconductors, such as silicon and gallium arsenide, are grown from the melt into solid cylinders (ingots) that must be shaped, polished, and cut into geometries suitable for handling and processing (Ref 1). Figure 1 illustrates the typical processing sequence for the production of waters that serve as substrates for large-scale integrated (LSI) circuits. The diameter of the as-grown ingot is usually not uniform. Therefore, after the ends are cropped, the outside surface is abrasively ground to produce a precise diameter. In addition, an orientation flat is ground along the length of the cylinder to indicate the dopant type and the crystallographic orientation. The ingot is etched to remove the gross grinding damage. Then sliced by diamond-impregnated blades into wafers approximately 1 mm (0.04 in.) thick. The wafer circumference is made uniform by grinding along the perimeter, and the faces are lapped with an abrasive slurry. The lapped wafers are etched and then polished on one side.

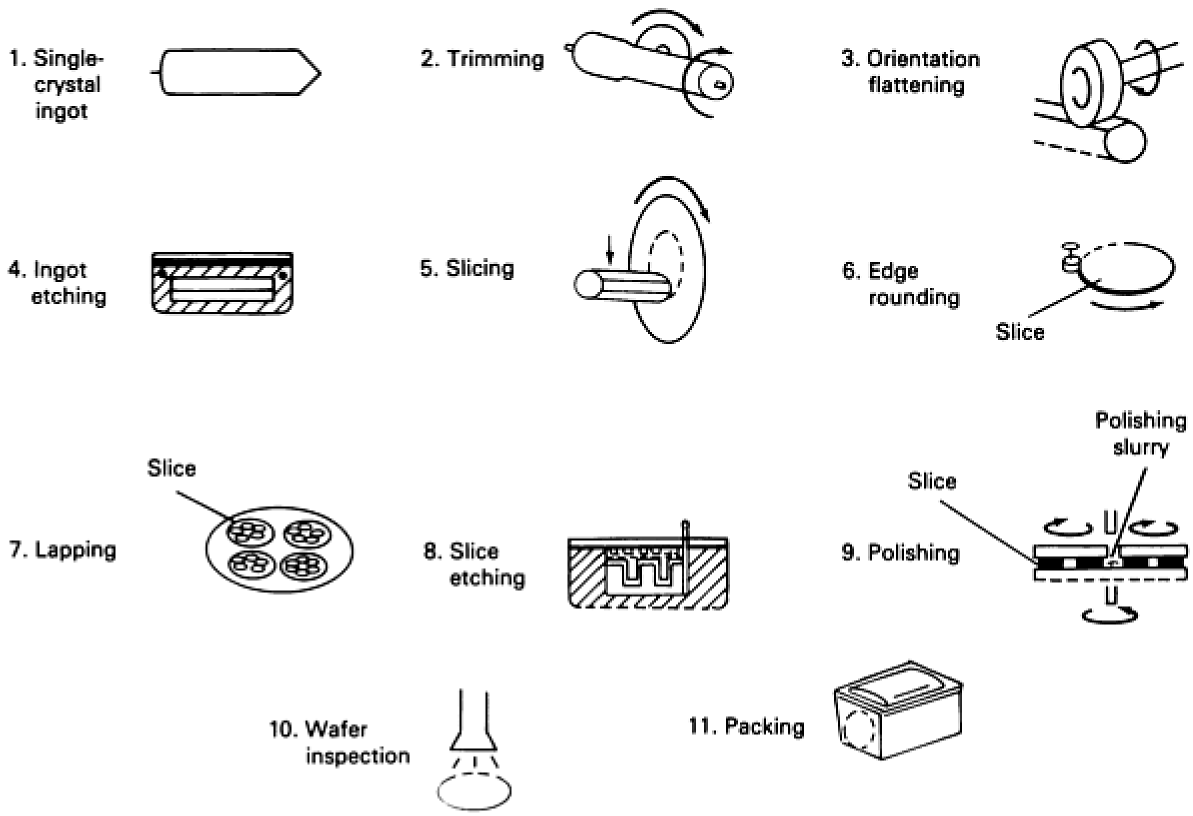

Fig. 1 Typical processing sequence required to produce wafers that serve as substrates for LSI circuits

LSI circuits are fabricated on the polished side of a wafer by a variety of diffusion, deposition, and heat treatment steps. The complexity of a particular device, or die, determines the number of steps needed to complete the circuit, as well as the physical dimensions of the circuit. The dies are removed by dicing the wafer with diamond-impregnated blades. They are then mounted on a substrate and electrical leads are attached by the physical positioning of metal wires onto thin-film metal pads.

Sawing, grinding, lapping, polishing, and dicing involve frictional contact between abrasive particles and the semiconductor surfaces, resulting in surface microcracks and dislocations. The depth to which these defects propagate beneath the surface depends on the contact stresses, temperatures, and lubricants used in the processing, and on the doping level and orientation of the semiconductor. Microcracks are particularly insidious in single-crystal semiconductors because of the brittle nature and anisotropic mechanical properties of these materials (Ref 2).

Microcracks propagate on cleavage planes at very low stresses (Ref 3), and dislocations can glide on slip planes over large distances beyond the immediate contact zone of the abrasive particles (Ref 4). Thus, precise control of the size of the damage zone produced by grinding or dicing, and elimination of cracking by polishing or etching are impossible unless the cutting variables are controlled and the deformation mechanisms are known. Failure to remove microcracks

may result in unexpected catastrophic failure of wafers or dies, and failure to remove dislocations may degrade the electrical properties of the dies (Ref 5). In either case, the yield of usable devices will be decreased.

Because friction and wear are important in the processing of semiconductor devices, much effort has gone into determination of the mechanisms of the surface deformation caused by frictional contact. Research hsa focused on the friction of abrasive particles in contact with semiconductor surfaces, the chemical interaction with lubricants, and the influence of dopants and crystallographic orientation. This article describes the result of several of these studies.

Mechanical Damage at Silicon Surfaces Caused by Wafering

Wafering of ingots is accomplished by string, reciprocating blade, or inner diameter (ID) sawing (Fig. 2). These three methods (Ref 6) rely on the abrasive action or hard particles for comminution of the semiconductor in the vicinity of the contact of the abrasive particles. For example, string and blade saws work by carrying an abrasive slurry over the surface of the ingot. The abrasive particles contact the surface and rotate and tumble as the string or blade moves in either a straight-through or a reciprocating motion (Fig. 2a). The fluid carries the abrasive and removes and the frictional heat generated in the process.

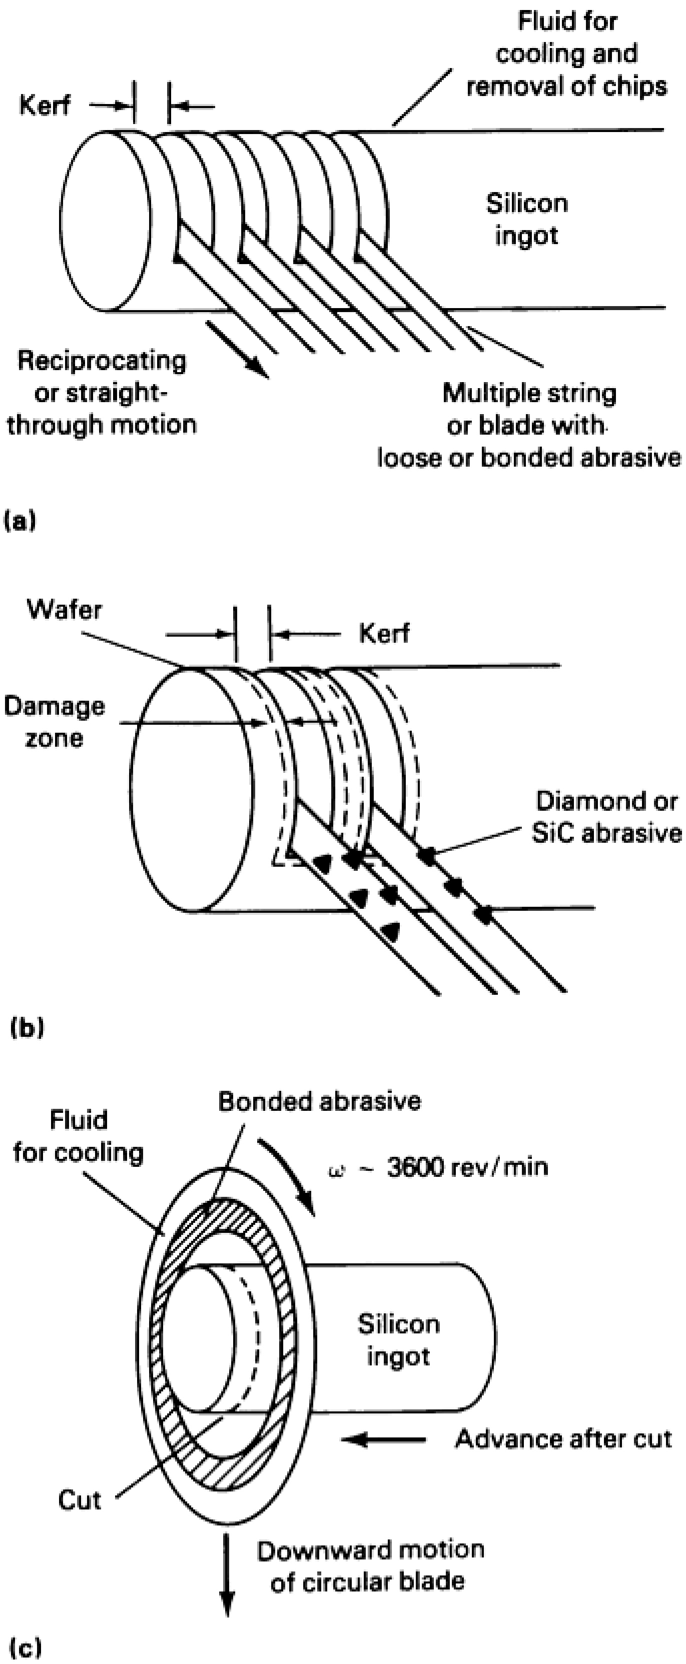

Fig. 2 Processing of ingots into wafers using two types of cutting techniques. (a) Typical multiple string or reciprocating blade sawing setup for wafering. (b) Closeup of damage zone generated by string or blade kerf. (c) Inner diameter sawing

ID sawing is a special type of blade sawing in which the abrasive is bonded to a circular wheel that rotates at high speed (Fig. 2b). Because of the slice-to-slice thickness uniformity and quality, approximately 80% of wafers are produced by ID

sawing (Ref 6). In this process, a thin steel blade (0.3 to 0.4 mm, or 0.01 to 0.02 in., thick) with a 0.10 to 0.15 mm (0.004 to 0.006 in.) diam hole in the center is tensioned in a fixture. The ingot is inserted in the central hole as the lubricant-cooled blade is rotated at 3600 rev/min. The inner surface of the hole is coated with an electrodeposited nickel film that contains a 0.5 μm diamond grit. The contact of the diamond with the silicon creates cracks and dislocations. If the cracks intersect the surface, conchoidal fracture will produce comminution of the silicon. The width of the cut, called the kerf, depends on the blade parameters (thickness, vibration, and so on), dopant type and crystallographic orientation of the ingot, and lubricant properties. A typical as-cut wafer thickness is 1.0 mm (0.04 in.). Other requirements include parallelism within 0.03 mm (0.0012 in.), flatness within +0.03 mm (0.0012 in.), and surface damage (depth) of less than 0.025 mm (0.0010) in.).

Much research has focused on the damage caused by cropping (removal of unusable sections of the ingot), centerless grinding (mill grinding to produce uniform shapes), and exit chipping (fracture of wafers and ingots as the blade exits the cut) (Ref 7), the influence of lubricants on the dislocation density at surfaces produced by ID sawing (Ref 8), and the stresses generated in wafering (Ref 9). For example, Dyer (Ref 7) has found that fracture caused by cropping, centerless grinding, exit chipping (bending), and deep saw damage results from excessive feed rates, saw blade eccentricity, and vibration. Figure 3 shows examples of a cropping chip, a crack produced by centerless grinding, a chip produced during wafering, and exit (bending) chips in a (100) silicon ingot. Data indicate that such cracks are either due to bending or Hertzian stress generation and are generally produced at the edges of the ingot or wafer. A fracture mechanics analysis (Ref 9) of the ID wafering geometry in which the ingot is rotated during the cut and the center 25 mm ($\frac{1}{4}$ in.) is pulled away has shown that the minimum wafer thickness depends on the surface damage (cracks) and the stresses imposed by the blade. The minimum wafer thickness is given by:

$$t^2 = \sqrt{\pi a_c P_A \beta / K_{Ic}} \quad \textbf{(Eq 1)}$$

where t is the water thickness, a_c is the minimum surface damage (crack), K_{Ic} is the fracture toughness, P_A is the applied force, and β is a parameter related to the ingot geometry. Equation 1 predicts that the minimum wafer thickness under this condition may be controlled to 200 μm for an ingot diameter of 100 mm (4 in.) when the minimum flaw size is less than 8 μm. The minimum flaw size is related to the subsurface damage when the diamond grit contacts the silicon.

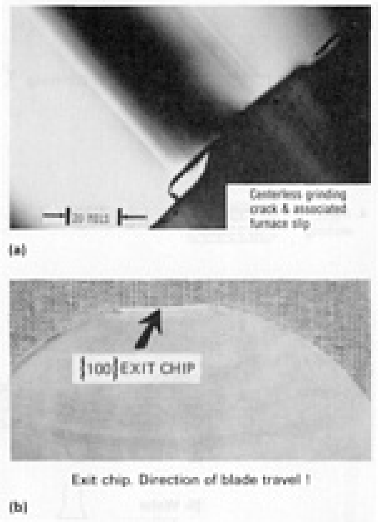

Fig. 3 Cracks induced by Hertzian stresses at the edges of an ingot or water. (a) Cracks and cavities associated with slip lines. (b) Exit chip

The interaction of the lubricant with the wafer surfaces has also been studied in relation to blade parameters (Ref 10). It was found that dielectric oil produced a greater density of dislocations compared with deionized water or methyl silane, and that these effects could be linked to blade vibration.

Mechanical Damage at Silicon Surfaces Caused by Dicing

Dicing refers to the sawing of a wafer to remove completed electronic circuits (dies) prior to packaging. The wafer is mounted on a vacuum chuck that is part of a movable stage. A rotating circular blade impregnated with diamond grit on the outside edge is brought into contact with the wafer surface while being sprayed with a lubricant. Typically, a linear cut is made along the paths separating the devices. Figure 4 shows scanning electron micrographs (SEMs) of the damage produced at the perimeter of a silicon die from a typical circuit. This die was diced by a diamond-impregnated blade using water as the lubricant. Figures 4(a) and 4(b), at higher magnification, show damage, evident as conchoidal fracture, as well as plastic smearing of the cut surface just beneath the top surface of the die.

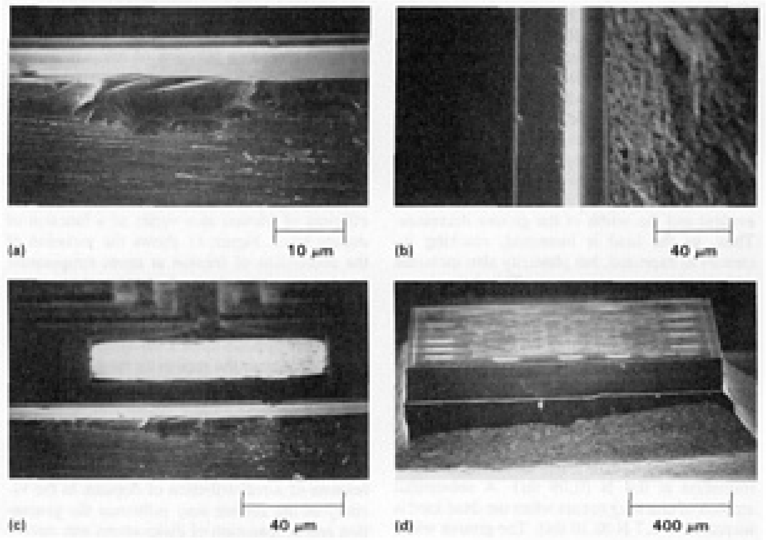

Fig. 4 Scanning electron micrographs showing typical dicing damage at the perimeter of a silicon die from an LSI circuit

Dicing damage has been studied in laboratory experiments, where blade speed, silicon temperature, and lubricant environment could be controlled (Ref 11). Figure 5 shows SEMs of a typical groove formed in a (100) silicon surface by a blade rotating at 1000 rev/min. Deionized water was used as the lubricant, and the depth of the groove and the silicon temperature were controlled. Figure 5(a) shows that the surface of the groove is streaked with even finer grooves. The higher-magnification insets (Fig. 5b to d) show that the morphology of these small grooves varies with the silicon temperature. As the temperature is increased, these miniature grooves become broader, and each can be associated with an individual diamond grid particle that contacted the surface.

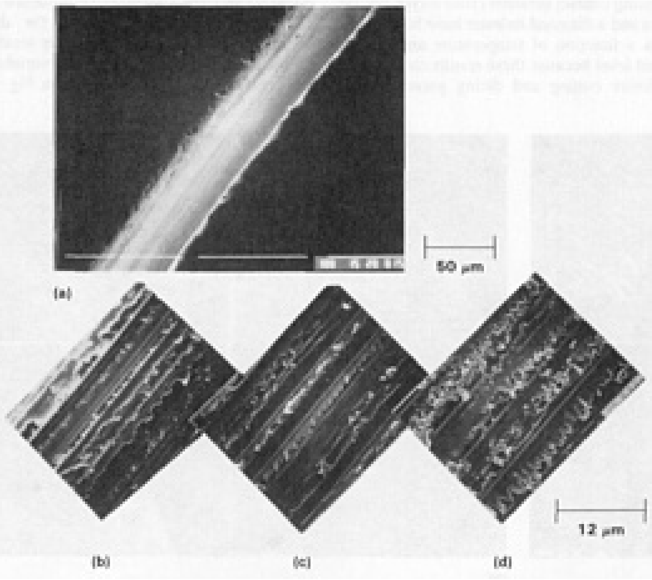

Fig. 5 Effect of temperature on groove surface morphology of (100) *p*-type silicon. (a) Typical groove produced by blade rotating at 1000 rev/min using deionized water as lubricant. (b) Room temperature. (c) 150 °C (300 °F). (d) 200 °C (390 °F)

Cracks also propagate beneath the surface. An example of such crack propagation associated with the laboratory-simulated dicing groove is presented in Fig. 6, which shows that median cracks have propagated in the [110] cleavage direction, perpendicular to the orientation of the dicing groove.

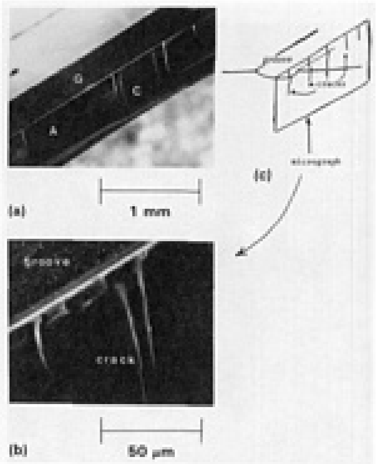

Fig. 6 Cross section of dicing groove in *p*-type silicon. (a) Scanning electron micrograph of groove (G) and subsurface cracks. (C). (b) Close-up view. (c) Schematic showing location of subsurface damage beneath groove

Simulation of Dicing Damage by Single-Point Diamond Scratching of Silicon

Laboratory simulation experiments of dicing damage in silicon have shown that the subsurface damage results from the contact of individual diamond grit particles. As a result, studies have been carried out by simulating single-point contact of silicon surfaces using diamond indenters (Ref 12, 13). One example of this type of study is shown schematically in Fig. 7. An instrumented Vickers pyramidal diamond is dead-weight loaded and then traversed across the polished silicon surface in a specific crystallographic direction. The diamond generates a groove by either single, multiple, or reciprocating motion, and the silicon can be heated or immersed in a lubricant during the test. The groove contains cracks

(Fig. 7a) within an orientation that depends on wafer crystallography and scratching direction. Expected crack geometries for gallium arsenide and silicon are indicated in (Fig. 7(b).

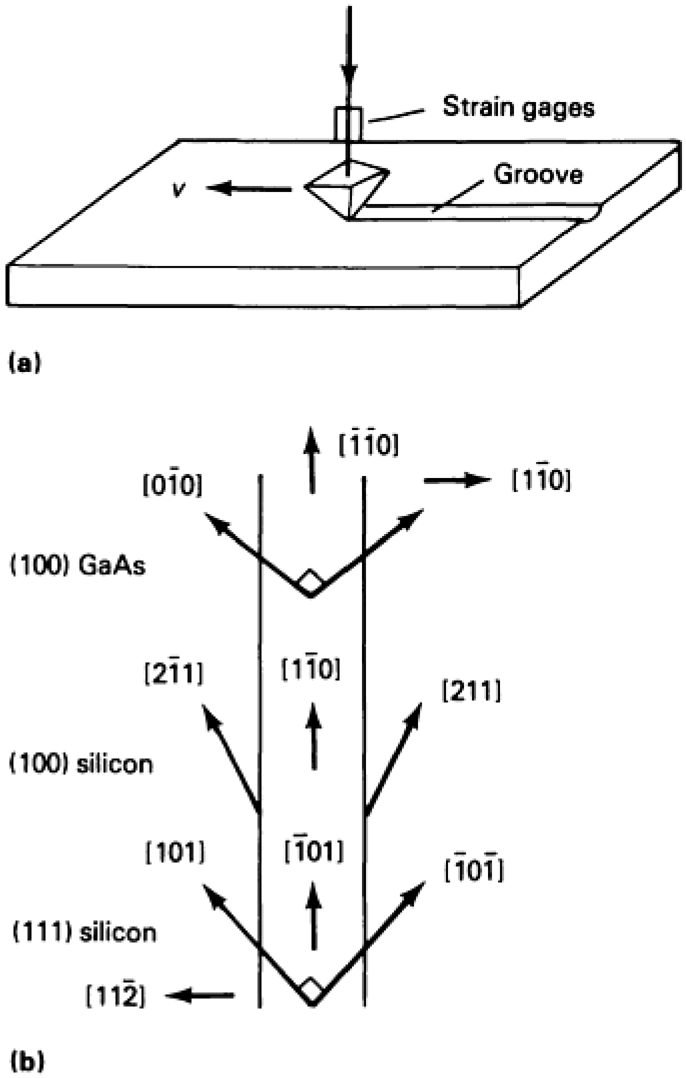

Fig. 7 Effect of crystallography on scratch testing with an instrumented Vickers pyramidal diamond indenter. (a) Schematic of test apparatus. (b) Cracking geometries generated in (100) and (111) silicon and (100) gallium arsenide

Figure 8 shows scanning electron micrographs of the scratch morphology and the subsurface damage as a function of temperature and the dead-weight load on the diamond. When the load was 0.4 N (0.09 lbf), the room-temperature scratch indicates long, lateral cracks that generate large chips near the surface. The cross-sectional view shows long, branched median cracks that propagate in the [110] direction. The extent of this damage is increased when the load is increased to 0.7 N (0.16 lbf). The surface morphology changes when the temperature is increased. For example, the scratch made at 100 °C (212 °F) shows evidence of plastic deformation in the groove region and a reduction of subsurface cracking. As the temperature is increased to 300 °C (570 °F), the plasticity is more evident and the width of the groove decreases. Thus, as the load is increased, cracking increases as expected, but plasticity also increases with increasing temperature. This behavior is indicative of a brittle-to-ductile transition.

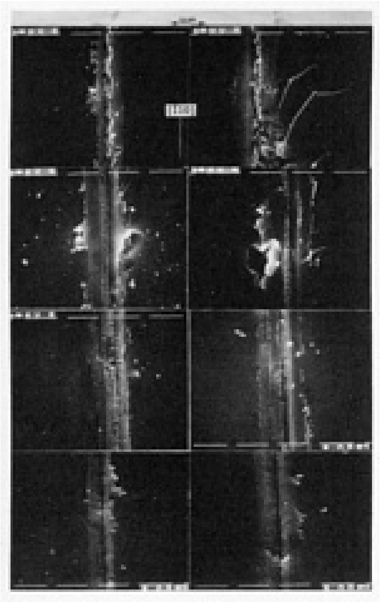

Fig. 8 Scanning electron micrographs of single scratches in (100) *n*-type silicon as a function of scratching temperature and load on the diamond. (Right side) Vickers pyramidal diamond at 0.4 N (0.09 lbf). (Left side) Vickers pyramidal diamond at 0.7 N (0.16 lbf). Under both load conditions, silicon temperature was at room temperature, 100 °C (212 °F), 200 °C (390 °F), and 300 °C (570 °F), respectively (top to bottom).

Similar experiments have been carried out on gallium arsenide surfaces. Figure 9 compares the scratch morphology at (100) *n*-type silicon and (100) *p*-type gallium arsenide surfaces scratched at 200 °C (390 °F) by a dead-weight loaded Vickers diamond using loads of 0.4 and 0.7 N (0.09 and 0.16 lbf). It is evident that the gallium arsenide surface also exhibits plastic deformation at 0.4 N (0.09 lbf). A substantial amount of cracking occurs when the dead load is increased to 0.7 N (0.16 lbf). The groove width is at least three times larger for the gallium arsenide surface compared with the silicon surface.

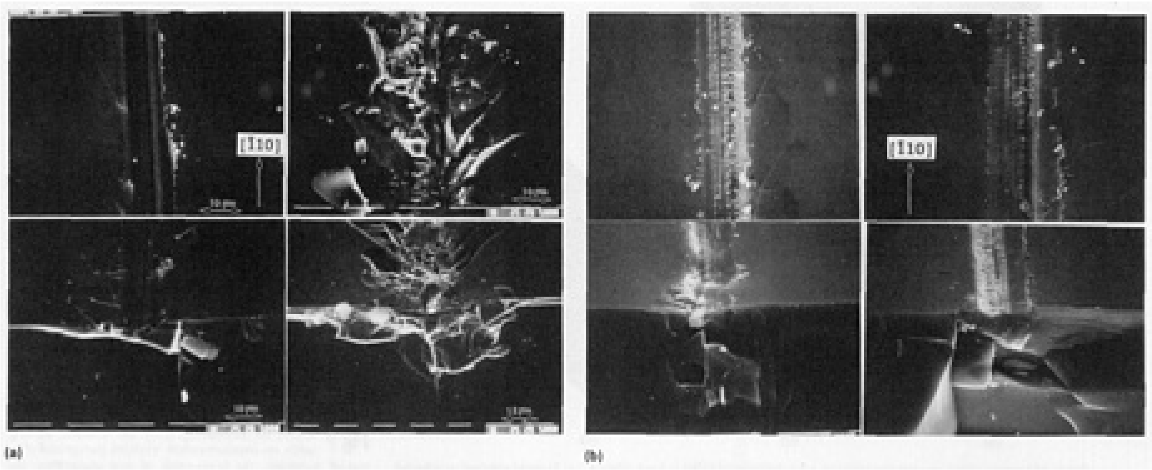

Fig. 9 Scanning electron micrographs of single scratches made by a Vickers pyramidal diamond at 200 °C (390 °F) as a function of material and load on the diamond. (a) *p*-type gallium arsenide. (b) *n*-type silicon. For both materials, load was 0.4 N (0.09 lbf) (left side) and 0.7 N (0.16 lbf) (right side).

Dynamic Friction Coefficient in Silicon and Gallium Arsenide as a Function of Temperature and Doping

The dynamic friction coefficients associated with sliding contact between (100) *n*-type silicon surfaces and a diamond indenter have been measured as a function of temperature and dopant type and level because these results can be used to optimize cutting and dicing parameters of these semiconductors. Figure 10 shows the friction coefficients obtained with a Vickers pyramid diamond as a function of temperature for (100) *n*-type silicon with a resistivity of 3.3 $\Omega \cdot$ cm. The dead-weight load on the diamond was varied from 0.4 to 0.7 N (0.09 to 0.16 lbf). The friction coefficient exhibits a maximum with temperature at approximately 200 °C (390 °F). As the load is increased, the variation in the coefficient of friction is also increased. The coefficient of friction also varies as a function of dopant level. Figure 11 shows the variation of the coefficient of friction at room temperature versus resistivity obtained at room temperature by sliding a Vickers diamond in the [110] direction; the load on the diamond was 0.5 N (0.11 lbf). There appears to be a variation of approximately 15% over the resistivity range of 10^{-2} to 10 $\Omega \cdot$ cm.

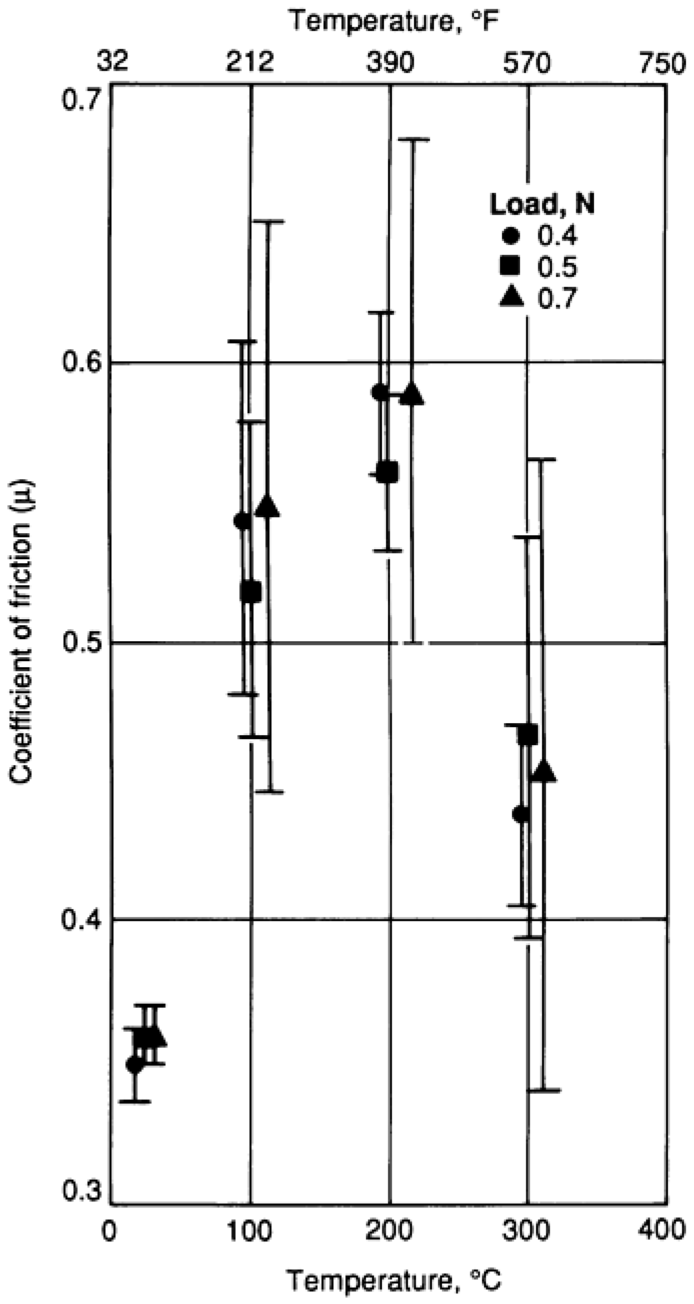

Fig. 10 Plot of the dynamic coefficient of friction versus temperature for (100) *n*-type silicon (electrical resistivity, ρ, of 3.3 $\Omega \cdot$ cm) abraded by a Vickers pyramidal diamond at selected loads.

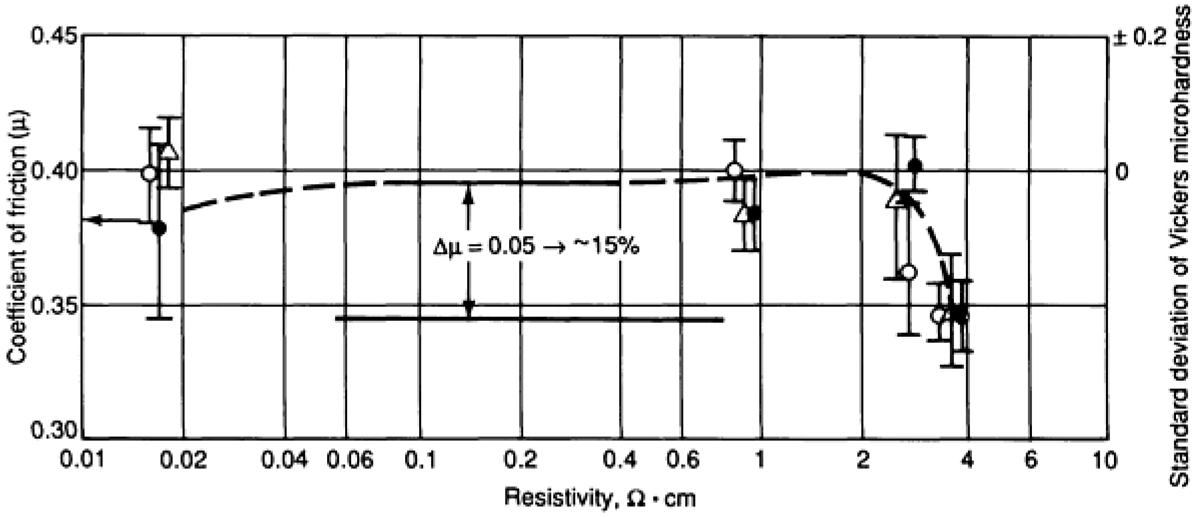

Fig. 11 Plot of the coefficient of friction versus electrical resistivity for (100) *n*-type silicon abraded at room temperature by a Vickers pyramidal diamond with a 0.5 N (0.11 lbf) load

The variability of the coefficient of friction with dopant concentration is not completely understood, but there has been some suggestion (Ref 14) that surface space charges that form because of a redistribution of dopants in the vicinity of the surface may influence the generation and propagation of dislocations and microcracks. This model can be described as follows: Semiconductor surfaces have electrical fields that physically extend into the bulk. The depth of these electrical fields is described by a Debye length that is related to dopant concentration, temperature, and other surface effects such as surface states. When the dynamic coefficient of friction is measured, compressive and tensile stresses are generated ahead and behind the sliding diamond. If the physical extent of the stresses is of the order of the space charges, then dopants can have a measurable influence on the coefficient of friction because the damage caused by sliding will be retarded or accelerated by the surface space charges. The variability of the coefficient of friction shown in Fig. 11 implies that the surface becomes harder, damage is reduced, and electrical fields are stronger as the doping is increased.

Introduction to Materials for Friction and Wear Applications

W.A. Glaeser, Battelle Columbus Laboratories

Introduction

WEAR OF TOOLS AND WEAPONS dates back to the dawn of human history. Beginning with stone and wood, materials at hand were adapted for increasingly complex uses. The search then began for harder, more wear-resistant rocks and materials (such as flint and obsidian) that could be shaped to a sharp edge and that would hold an edge. This approach to materials selection has not changed much right up to today. Very few materials have been developed for specific tribological applications; instead, available materials have been adapted. The development of bronze and then cast iron and steel quickly led to their use in applications involving sliding and rolling contact. Perhaps the first attempt to design a wear-resistant tool involved embedding stones in wooden plows. Examples of this advance in agriculture have been found that date from the sixteenth century. This practice continued on into the nineteenth century; examples of such plows have been found in remote regions of the American Southwest, where they were used in place of iron plows because of the difficulty of obtaining processed iron.

With the industrial revolution came the need for low-friction bearings and pistons for steam engines and water-powered machines. The use of lubricants became more sophisticated, and the need for effective journal bearings demanded the use of soft bearing materials such as lead and tin. The babbitt alloys that were developed for this need might be considered *bona fide* tribological materials. Still, however, most materials used for the new machinery were adapted--as were, for example, cast iron, bronze, and wood.

Selection Guidelines

The following sections on materials for friction and wear applications provide information on a wide variety of materials that have potential tribological use. However, as mentioned earlier, very few engineering materials have been uniquely developed for tribologists. How then does one go about selecting the proper material for a given application? Following are some general guidelines that might be used to reduce time in the selection process.

For wear and abrasion resistance, the general rule is, the harder the better. Thus, for the most economical approach, one would select heat-treated carbon or alloy steels. Other hard materials, such as cemented carbides, tool steels, and hardfacing alloys, are expensive and should be reserved for severe abrasion conditions or special environmental requirements.

For conditions of marginal lubrication, the cast irons are an economical choice. Gray cast iron has been used in many applications requiring resistance to adhesive wear (for example, piston rings, cylinder liners, wheels, slideways, and thrust bearings). Cast iron also provides good damping properties for the control of machine vibrations.

For prevention of galling and seizure, microstructure is as important as hardness. Materials containing large carbides, such as hardfacing alloys and alloy cast irons, can be considered for applications where this is a factor.

Bearing Applications. Rolling-contact bearings use special-grade steels designated as "bearing steels." For high-temperature applications, stainless steels, tool steels, cemented carbides, superalloys, and ceramics are useful in sliding or rolling contacts. If corrosion resistance is required, stainless steels, hardfacing alloys, superalloys, titanium-base alloys, ceramics, carbon-graphite, and polymers should be considered.

Journal bearing materials, which require conformability, embeddibility, softening under frictional heating, and fail-safe properties, are discussed in the article "Friction and Wear of Sliding Bearing Materials." These materials include babbitts, bearing bronzes, zinc-base alloys, and aluminum-base alloys; some polymers also fall under this classification. For sliding bearings operating in water, carbon-graphite is an excellent selection; some polymers are appropriate for these

applications as well. Self-lubricating materials for use under dry sliding conditions include various polymers, carbon-graphite materials, and metal-matrix composites.

Material State

Hardness often is a necessary property for wear resistance. Similarly, material physical properties such as thermal conductivity, thermal expansion, density, and heat capacity are important parameters in the selection of materials. However, the state in which one finds materials when they are to be assembled into a machine is equally important. This means the microstructure, the surface finish, the residual stresses, and the porosity and depth of hard coating or soft coating can be significant factors in the final performance of a bearing, gear, or seal. Thus, just changing from one material to another will not necessarily solve an excessive wear or surface damage problem.

For example, a roller bearing with races heat treated and finish ground with a condition of residual tensile stresses in the race surfaces will have a propensity to spalling failure. Thus, when this bearing experiences contact stresses above its normal operating limits (as sometimes happens in machinery), it is likely to fail. A bearing with compressive residual stresses in the races has added insurance against failure when unplanned excursions of load occur.

Cast irons that have the same hardness but different graphite structures will behave differently in wear. The preferred graphite structure in cast irons is a well-distributed flakelike morphology. The size and distribution of flakes is a significant factor in the wear resistance of the cast iron.

Steels for rolling-contact bearings must be exceptionally clean (that is, free of inclusions). Hard silicates are the most damaging to performance. Special vacuum melting processes are used to produce high-quality bearing steels. Thus, in this class of materials, hardness alone is not the deciding parameter for optimum performance.

Other material properties that have nothing to do with the particular tribological problem should also be considered. For example, a shaft may have to withstand bending fatigue conditions or stress-corrosion as well as wear of the contacting bearing material. It may turn out that tensile strength is as important as hardness for a given application.

Tribological problems such as excessive wear are not always solved by searching for a better material. Sometimes appropriate design may be the more economical and lasting solution. Designs that provide a lubricant film support to a contacting system may mitigate the need for a super wear-resistant material.

Surface finish is also of great importance in tribological applications. Smooth surfaces are generally required. This is especially important in journal bearings and rolling-contact bearings, where very thin lubricant films are needed for the performance of the bearings. If the surfaces are too rough, the high points penetrate the thin oil film and initiate wear or failure.

Great savings in manufacturing cost can be achieved by applying coatings or surface treatments to economical structural steels in order to provide wear resistance at selected areas in machine components. The Section "Surface Treatments and Coatings for Friction and Wear Control" in this Volume discusses the selection of wear-resistant coatings and surface treatments.

The following articles on materials for friction and wear applications have been written by experts in each class of materials. Because of the individual style and experience of each author, you will not find a constant format running through each article. This is to be expected, however, because each class of material has a different history and significance in its application to tribology.

Friction and Wear of Cast Irons

T.S. Eyre, Eyre Associates (U.K.)

Introduction

CAST IRON is a general term applied to a family of engineering materials that includes gray iron, white or chilled iron, malleable iron, and nodular iron. These irons have very different compositions, casting characteristics, and heat treatments, which result in physical, chemical, and mechanical properties of wide variation.

Cast irons are unique tribological materials that can be used in a range of applications, particularly those in which wear resistance is important. The matrix of these materials can be varied from pearlite to martensite, in order to support graphite, which is a solid lubricant. Hard phases can be varied to resist abrasion. The primary characteristics of gray and nodular irons are described below, in terms of very general selection guidelines, as well as later in this article, in greater detail.

Gray Iron. All of the excess carbon in gray iron is present in the form of flakes of graphite in a matrix that varies from all-ferrite to pearlite, with or without phosphide eutectic or carbides. Gray irons are brittle and have relatively low strength and hardness properties. Graphite provides good damping capacity, and its thermal conductivity value is higher than that for steel. Graphite cavities provide chip-breaking qualities, which allow free machining with short chips. A fractured surface will appear gray and dull, because of the presence of graphite.

Because graphite is an excellent solid lubricant, it confers good sliding wear resistance with a relatively low coefficient of friction. This class of cast iron is widely used for internal combustion engine components, including engine blocks, cylinder liners, and piston rings, as well as machine tool slideways.

White or Chilled Iron. Carbon can be retained as a primary carbide in a pearlitic or martensitic network by suitable alloying or heat treatment, or by the use of chilling. In this condition, the iron is very hard (up to 700 HV), unmachinable, and quite brittle. A fractured surface will appear white and crystalline. By varying the manufacturing route (for example, by chilling), it is possible to produce components that are gray, or graphitic, in some areas and white, or carbidic, in the chilled areas. These materials are used for abrasive wear applications in mining, grinding, mineral handling equipment, and camshafts in the internal combustion engine.

Malleable Iron. Castings initially produced as white iron can be suitably heat treated to produce a more ductile structure. Upon fracture, this structure produces either a white facet (whiteheart), which is due to the presence of pearlite, or a black facet (blackheart), which is due to the presence of graphite. These treatments impart a significant change to the otherwise brittle characteristic of a white iron. Ductility and impact properties improve considerably for stress-bearing components for which gray iron would be unsuitable.

Nodular or Spheroidal Graphite Iron. By converting graphite from the flake to a nodular form, the brittleness of flake (gray) irons is immediately diminished and, with suitable heat treatment, a steel-like structure can be produced. Because pure materials and rather special melting procedures are required, cost is increased significantly, but the improvement in mechanical properties allows these irons to compete with heat-treated steels for applications such as crankshafts and gears. Significant developments in recent years have extended the properties of specific alloys, such as austempered ductile iron, which competes favorably with surface-hardened steel in applications such as cast gears.

Constitution of Cast Iron

Cast iron is essentially an iron-carbon alloy that contains from 2.5 to 4.0% carbon and other essential alloying elements, the most important of which are silicon and phosphorus. Pure iron melts at 1535 °C (2795 °F); the eutectic of iron and carbon occurs with a carbon content between 4.2 and 4.3% and a melting point of 1153 °C (2107 °F). The eutectic melting temperature for cast iron varies slightly with silicon content, and usually falls between 1135 and 1150 °C (2075 and 2102 °F). Cast irons therefore have a melting range that is approximately 400 °C (720 °F) lower than that for steel.

Additions of silicon lower the percentage of carbon in the eutectic by about 0.33% for each 1% of silicon added, so that with 1% of silicon, the eutectic will occur at approximately 3.97% of carbon. Additions of phosphorus affect the eutectic carbon value to about the same amount as silicon, so that for an iron containing 1% silicon and 1% phosphorus, the eutectic will occur with approximately 3.6% carbon. Other elements, in the amounts that are normally present, have a much smaller effect on eutectic carbon value, but they do have other significant effects that are referred to later in this article.

A cast iron can have a composition that makes it hypoeutectic, eutectic, or hypereutectic with regard to carbon. Its position in this respect is important, because not only does the initial solidification point (liquidus) depend on it, but also the manner of solidification and, thereby, the structure.

The carbon content of most commercial irons is within the range noted above (from 2.5 to 4.0%). The iron-carbon diagram in Fig. 1 shows only the iron carbide/austenite (ledeburite) system in the high-carbon region. Such irons, when commercially produced, are known as white, or chilled, irons and are hard, brittle, and unmachinable. Gray irons, however, solidify with the formation of graphite instead of iron carbide, and are reasonably strong and machinable. An intermediate material, known as mottled iron, in which both graphite and iron carbide are formed during solidification, also exists. Such irons are harder and less readily machinable than the gray irons.

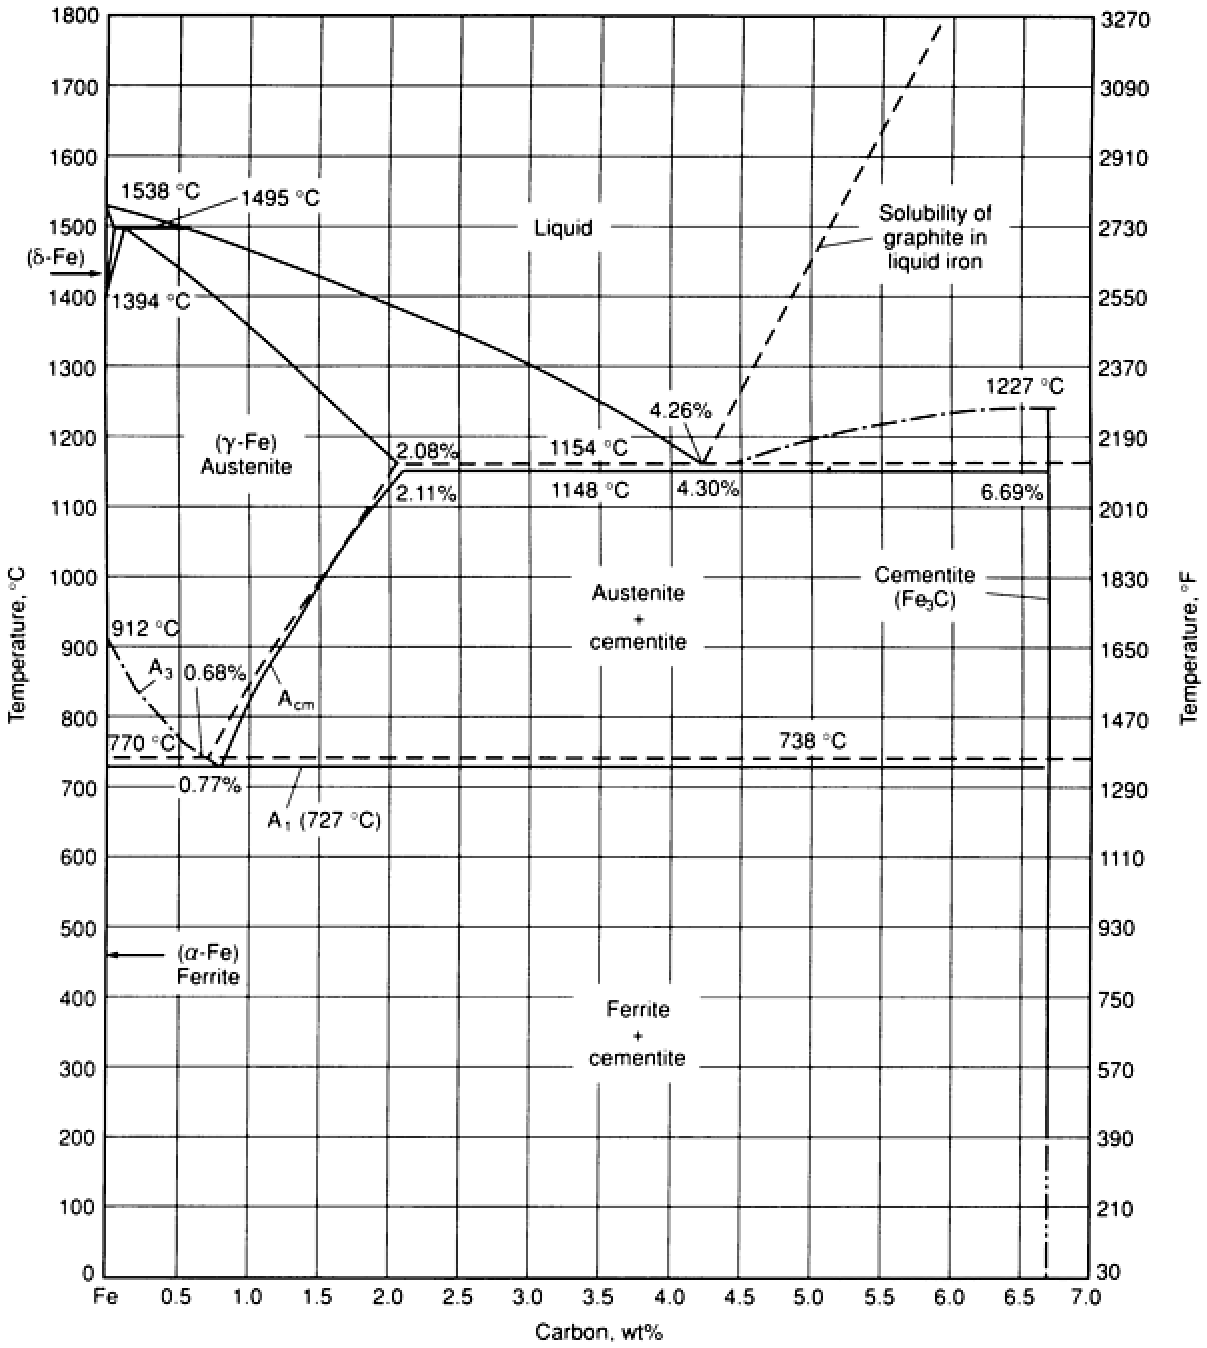

Fig. 1 Iron-carbon diagram, where solid curves represent metastable system Fe-Fe_3C, and dashed curves, the stable system Fe-graphite

Whether an iron solidifies as gray, white, or mottled primarily depends on the eutectic value and the rate of cooling. However, before attempting to evaluate the effect of cooling rate, the effect of composition must be simplified. The two most important factors in understanding the mechanical properties and, thus, their efficiency in engineering applications, are:

- Composition, or carbon equivalent value
- Cooling rate, or section sensitivity

Both factors act independently and have a significant effect on the microstructure, which itself controls the properties produced. Different microstructures can be produced at different positions in the same casting.

Composition, or carbon equivalent (CE) value, is the most common simplification used, in which

$$CE = \text{Total carbon \%} + \frac{\text{Silicon\%} + \text{Phosphorus\%}}{3} \quad \textbf{(Eq 1)}$$

It is this value, rather than the actual total carbon content, that applies to commercial irons when the iron-carbon diagram in Fig. 1 is used.

The CE value immediately indicates whether an iron is hypoeutectic or hypereutectic, and by how much. Thus, an iron with 3.2% carbon, 2% silicon, and 0.4% phosphorus has a CE value of 4.0 and is hypoeutectic. An iron with 3.2% carbon, 2% silicon, and 1.3% phosphorus has a CE value of 4.3 and is eutectic. An iron with 3.2% carbon, 2.9% silicon, and 1.3% phosphorus has a CE value of 4.6 and is hypereutectic.

In general, the lower the CE value, the greater is the tendency for an iron to solidify as either white or mottled. The solidification period determines whether a given iron becomes gray, mottled, or white; the form of the graphite is altered very little by the subsequent cooling period.

Cooling Rate, or Section Sensitivity. The tensile test can be regarded as the standard test by which cast iron is specified, the exception being white iron, for which hardness only is specified. Tensile strength is the stress required to pull apart a testpiece by an axially applied load. The test is almost always performed on a round, machined testpiece, in which the middle section of the length is reduced in diameter. The testpiece is machined from either independently cast bars or broken transverse test bars. Specifications normally give details of casting sizes appropriate to each size of cast bar. Because the strength of cast iron is particularly dependent on the section size into which it is cast, the strength of gray iron is defined in relation to the diameter of as-cast bars from which standard tensile specimens can be machined.

For gray flake iron, each of the eight grades is designated by the tensile strength required on the 30 mm (1.2 in.) diameter bar (Table 1). The specification for each grade, however, requires a higher tensile strength for bars of smaller diameter, and a lower tensile strength for bars of larger diameter. However, the variation in strength given in the specification according to size of the test bar is less than has been found in practice, and merely indicates in an arbitrary manner the commercial difficulty of producing a given tensile strength in a given bar.

Table 1 Expected tensile strengths of testpieces machined from cast-on test samples and from the castings

Tensile Properties

All of the principal countries specify cast iron on the basis of standard-diameter test bars. However, it is common knowledge in the foundry industry that test bar results cannot be used to give the strength of the casting itself, because section thicknesses and cooling rates can vary appreciably. This can be summarized as follows:

- For all foundry alloys, the separately cast test bar is essentially a check on metal quality only
- Strength relationships between the test bar and the casting vary with the nature of the alloy being cast
- The control of castings, especially for vital services, demands the use of the separately cast test bar as a check on metal quality, but must be supported with check tests on the castings themselves. For repetition castings, such tests can be conducted on a proportion of the castings produced. Otherwise, some suitable form of nondestructive testing must be applied

It is important to realize that national specifications merely define the metal in the ladle and do not give a direct indication of the strength of the casting itself. As explained earlier, the strength of the material in the casting is a function of the cooling rate of the particular portion under consideration. However, when the strength of the metal cast under standard conditions is known, it becomes possible to estimate, with some degree of accuracy, the probable tensile strength to be found in a gray iron casting of a given thickness. If the test bar were cast onto the casting itself, then it would be impossible to relate the results obtained from such a test bar with those obtained from another test bar under standard conditions. Such a test would be almost valueless, because the test bar would not be representative of the casting itself, nor could it be related to other standards.

In past practice, it was quite common to specify cast-on test bars, on the assumption that such a test bar must necessarily be representative of the casting itself. However, this practice did not provide the necessary information. Except in certain cases, the use of the independently cast test bar has now almost entirely superseded the use of the cast-on test bar.

Effect of Section on Strength. To interpret the results obtained from the standard test bar in terms of the strength of the casting itself, some relationship must be established between various section sizes and the bar. This is best exemplified by discussing the properties of gray iron.

A statistical survey of a large number of industrially cast gray iron test bars of different sizes has been made, the results of which are shown in Fig. 2. The curve shows the falling off in strength with increasing test bar size for the main grades of unalloyed gray cast iron. The line for each grade is really the center of a zone of uncertainty amounting to 5 to 10 Pa (0.00075 to 0.0015 psi), because there is a possible variation in each grade that is due to differences in composition, pouring technique, and other factors. A version of this curve is usually included in the relevant national or international specifications.

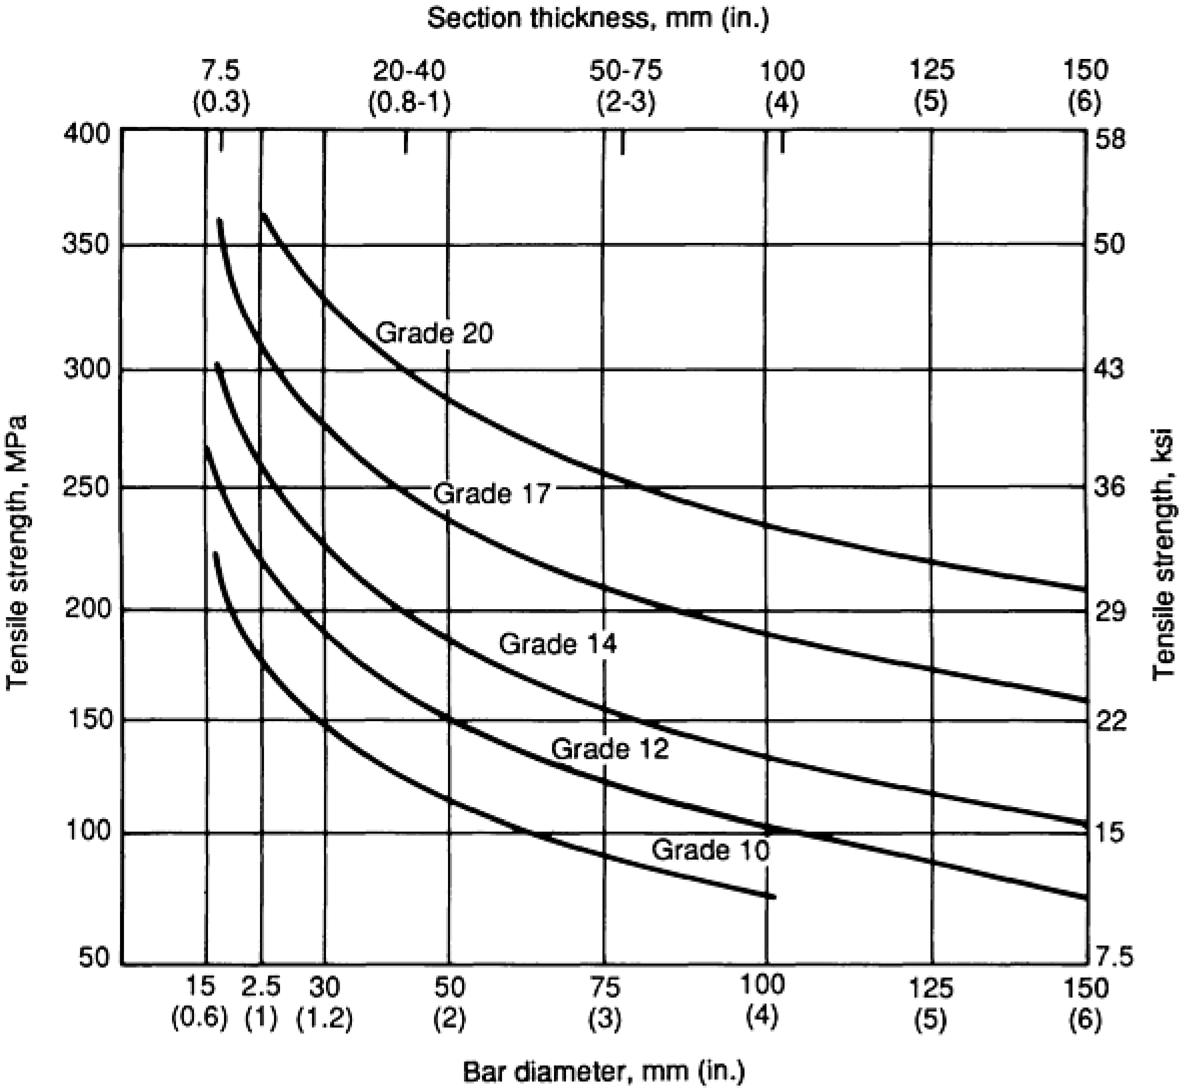

Fig. 2 Relationship between tensile strength and section thickness for different grades of flake gray iron. Source: ISO R185. 1961; British Standard (BS) 1452: 1990

The total strain (recoverable and nonrecoverable) of gray iron tensile testpieces at fracture usually varies between 0.5% for high-tensile iron and 0.75% for low-tensile iron. The non-elastic strain varies between 0.2% for high-tensile iron and 0.6% for low-tensile iron.

White Irons

If the iron is sufficiently below the eutectic value, has a very low silicon content, and contains appreciable quantities of carbide or stabilizing elements, or if the cooling rate is sufficiently rapid, then the formation of graphite does not occur. Under these conditions, solidification takes place first by the formation of austenite dendrites. The remaining liquid in the interdendritic spaces then becomes enriched in carbon and solidifies as a eutectic of iron carbide and austenite, known as ledeburite. As the solid casting cools down, at a temperature ranging from 720 to 750 °C (1330 to 1380 °F), the austenite, which is γ iron with carbon in solution, transforms to α iron, in which carbon is substantially insoluble. Carbon is then

rejected as iron carbide in the form of lamellae alternating with lamellae of α-iron to form a matrix of pearlite. The initially formed iron carbide, however, remains unchanged.

The structure of a white iron at room temperature, therefore, consists of primary dendrites of pearlite with interdendritic areas of transformed ledeburite, which is a eutectic structure of iron carbide and pearlite. The pearlite areas are formed from the original austenite. In some cases, the austenite produced during the final eutectic solidification of iron carbide and austenite is deposited on the already existing austenite dendrites, and the interdendritic area is predominantly carbide. The final structure will then consist of dendrites of pearlite surrounded by cementite that contains very little transformed eutectic pearlite (Fig. 3).

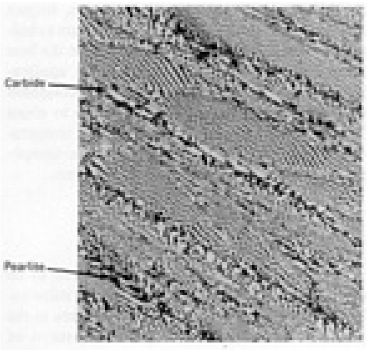

Fig. 3 Pearlitic white iron showing the original austenite dendrites that transformed to pearlite and the interdendritic eutectic structure of cementite and austenite, where the austenite transformed to pearlite. White phase, carbide; dark phase, pearlite. 80×

These irons are characterized by a completely white fracture and a high hardness (400 to 600 HV), which is an average of the carbide (900 to 1200 HV) and pearlite (200 to 300 HV). Various grades of white iron are available, depending on composition and heat treatment. The cheapest white irons are either unalloyed or low-alloy grades containing between 2.4 and 3.4% carbon and up to 2.0% chromium. A hardness of 350 HV is achieved in the cast condition. By increasing the chromium content (up to 10%), it is also possible to increase the carbon content to produce increased amounts of carbides. By including nickel, it is also possible to carry out heat treatment to produce a martensitic, rather than pearlitic, matrix.

These changes have the overall effect of increasing the hardness to 600 HV and reducing the effect of section sensitivity. When increased corrosion resistance and maximal abrasion resistance are required, irons containing up to 28% chromium can be used, but as the percentage of carbides (or carbon content) increases, impact resistance decreases. Thus, it is important to balance the composition carefully to obtain the best combination of properties for specific applications. These irons in the heat-treated condition develop the maximum hardness of up to about 700 HV, and are the least affected by temperature in service. Table 2 summarizes the composition and hardness of various white irons.

Table 2 Composition and hardness values for white irons

Composition, %									Hardness, HV
C	**Si**	**Mn**	**Cr**	**P**	**Mo**	**Ni**	**Cu**	**S**

Gray Irons

In hypoeutectic irons, the first phase to be deposited from the melt is austenite, a solid solution of carbon in γ iron that crystallizes in the form of dendrites, the length and pattern of which depend on the temperature gradients. The austenite dendrites continue to grow, and the remaining liquid increases in carbon content until the eutectic temperature and concentration are attained. Solidification begins from a number of centers, each with an approximately spherical crystallization front, and simultaneous deposition of graphite and austenite occurs. Ultimately, these eutectic cells meet and consume the remaining liquid. The austenite of the dendrites and that of the eutectic becomes continuous, and the structure appears as a dispersion of graphite flakes in a matrix of austenite.

After solidification, the eutectic cell structure and the random orientation of the primary austenite dendrites throughout the structure are essentially complete. They cannot be subsequently modified either by cooling or subsequent treatment. Only in strongly hypoeutectic iron is the austenite dendrite pattern clearly visible.

Hypereutectic irons solidify by the direct formation of graphite from the metal in the form of coarse flakes that are called kish. Because of its low relative density, kish tends to rise to the surface of the melt. However, when entrapped by the metal, kish generally appears in the microstructure as characteristic long straight flakes, or, in rapidly cooled sections, as lumpy flakes. This phase is deposited over a range of temperatures, starting at the liquidus surface, until the carbon content of the remaining melt is at the eutectic concentration when a simultaneous crystallization of graphite and austenite occurs. Generally, this eutectic graphite in hypereutectic irons occurs in flake form on a finer scale than does the primary kish.

The austenite, upon cooling through the critical temperature range (from about 720 to 830 °C, or 1330 to 1525 °F), transforms to pearlite. The products of this transformation depend on the rate of cooling and composition of the material. Under normal conditions, the products will consist of pearlite, or graphite and ferrite, or mixtures of all three. Where the eutectoid transformation produces graphite and ferrite, the graphite is deposited on the already existing eutectic graphite flakes. The formation of ferrite is most likely to occur with slow rates of cooling and high silicon contents that reduce the stability of iron carbide, or with high CE values, or with fine undercooled graphite. The formation of a fully pearlitic structure is more likely to occur with moderately rapid cooling rates or low CE values.

If the iron is very rapidly cooled through the critical temperature, for example, by oil quenching, then the transformation of austenite to pearlite or ferrite can be suppressed, and a hard matrix of martensite formed. This treatment can be given deliberately when increased hardness is desired.

Graphite

The form and distribution in which graphite is deposited depends on numerous factors, such as melting temperature, nucleation, cooling speed, and others. The basic forms are flake graphite, aggregate or temper carbon, and nodules or spheroids.

A convenient standard for graphite (ASTM A247-47 and 67) defines shape, size, and distribution, and has been extended by the International Organization for Standardization (ISO Recommendation 945) to cover additional forms. The basic nomenclature and grading for flake graphite follows the generally accepted ASTM pattern.

Flake graphite can form as one of four types:

- Kish, which occurs in hypereutectic irons and can be present as straight and undistorted flakes (ASTM Type C; ISO Form I, distribution C) or very thick lumpy flakes
- Normal flakes (ASTM Type A; ISO Form I, distribution A)
- Rosette (ASTM Type B; ISO Form I, distribution B)
- Undercooled (ASTM Type D; ISO Form I, distribution D)

The undercooled, or type D graphite, is normally associated with rapid rates of cooling and is particularly common in thin sections, but can be produced by other means (such as addition of titanium). The rosette pattern is typical of slightly less rapid cooling and is not uncommon in the more rapidly cooled surfaces of castings with sections of 9.6 mm ($\frac{3}{8}$ in.) or more. Both undercooled and rosette graphite are frequently associated with ferrite, rather than pearlite, because the larger available surface area of graphite reduces the distance required for carbon diffusion during transformation from γ to α

iron in the critical temperature range. When ferrite is associated with random or coarse flake graphite, the iron is usually hypereutectic or the rate of cooling in the mold has been very slow.

Widmanstätten and mesh-form graphite can occur when lead or tellurium are present. These structures profoundly weaken the iron. When gray iron passes through the γ to α critical transformation range, graphite may be rejected from the γ phase onto existing graphite flakes and form spiky irregularities on the graphite surface.

When minimum friction and maximum wear resistance are required under dry, marginally lubricated or fully lubricated conditions, it is very important to precisely specify the microstructural requirements. These properties can be met by a requirement for Type A graphite in the size range from 3 to 5, with a pearlitic matrix, free from primary ferrite (Fig. 4). Phosphorus is desirable at a level of up to approximately 0.75%, which produces a hard, dispersed interdendritic phase that improves abrasion resistance at the expense of machinability.

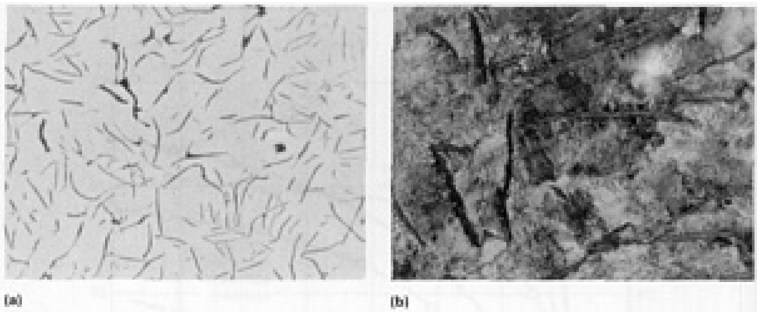

Fig. 4 (a) Gray flake iron with random graphite in an unetched matrix 75×. (b) Etching showing pearlitic matrix. 300×

Although each flake appears to be separated from adjacent ones in a two-dimensional microstructural view, it must be recognized that in each colony, as viewed in three dimensions, the flakes are connected at the nucleation source to produce a lettuce leaf-like structure. This can only be observed by deep etching the matrix and by selective dissolution, so that the graphite structure can be seen to stand above the matrix. The sharpness of the graphite cavities acts as an internal stress raiser and produces the brittleness that characterizes gray iron. However, the material is immune from the effects of external stress raisers.

Nodular Graphite. The shape of the graphite precipitated on solidification can be modified to the nodular or spheroidal form (ISO Form VI) by additions of magnesium and/or cerium. Intermediate or degenerate forms can also be produced. The ISO Form II crab type is a degenerate form of flake graphite occasionally found in magnesium-treated irons containing lead, bismuth, arsenic, or titanium, and can be suppressed by additions of cerium. Unless pure melt charge materials can be guaranteed, it is the recommended practice to use a combined addition of magnesium and cerium. Quasiflake graphite (ISO Form III) is usually the result of insufficient magnesium additions to produce the fully spheroidal form. Irregular open, or "exploded," type spheroids (ISO Form V) may occur with very pure raw materials treated with magnesium and cerium. Misshapen spheroids tend to occur in heavy sections.

Irons that contain graphite nodules (Fig. 5) that are either primarily or totally spheroidal in the as-cast condition have properties that are fundamentally different from those of gray iron with flake graphite. They possess greater tensile strength and have a considerable degree of ductility, as well as greater impact resistance and enhanced fatigue resistance. Their properties are much closer to those of steel than to gray iron (Fig. 6).

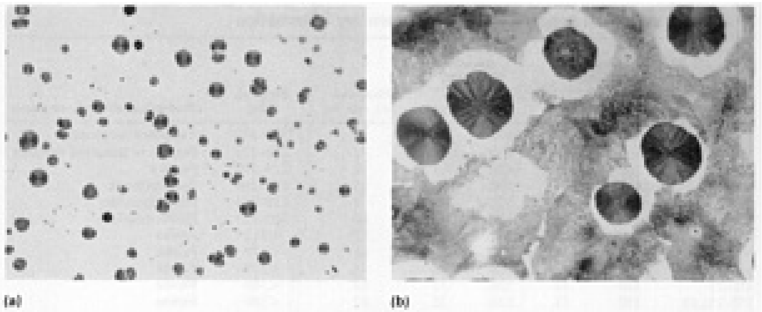

Fig. 5 (a) Nodular graphite in unetched matrix. 75×. (b) Etching shows that matrix consists of ferritic envelope around the nodules surrounded by a pearlitic matrix. 300×

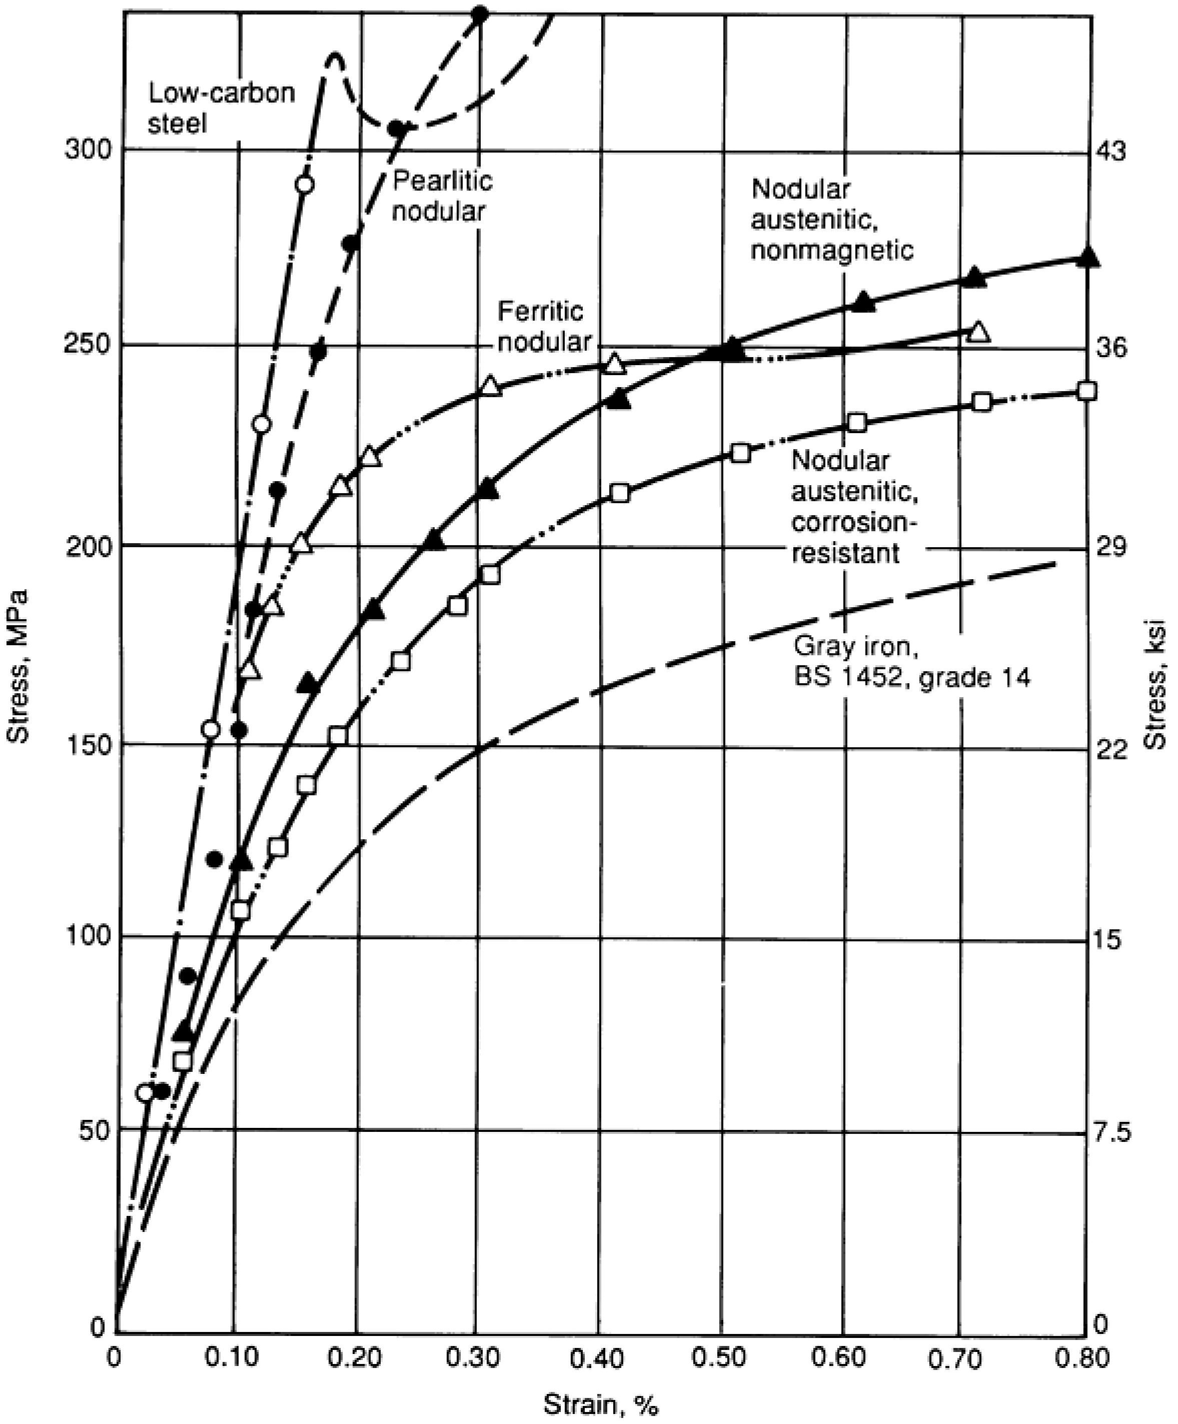

Fig. 6 Typical stress-strain curves in tension for various cast irons and steels. Source: British Standard (BS) 2789:1985

The properties to be expected in the nine different grades of nodular iron currently available are summarized in Table 3. It is also possible to heat treat these materials using techniques similar to those used for steel. In this way, a nodular graphite in a martensitic matrix can be produced.

(a) Verification of the 0.2% proof stress ($R_{p0.2}$), is optional.

(b) Verification of hardness values is optional.

In the as-cast state, the microstructure of nodular iron can range from a completely white structure where thin sections are involved, to that of nodular graphite in a completely ferritic matrix. By virtue of the fact that nodular irons have their own "carbon bank" available, like gray irons do, heat treatments can be applied to produce a wide range of matrix structures. Thus, by heating to a temperature above the critical temperature, graphitic carbon will dissolve in the austenite until equilibrium conditions are attained. By air-cooling from this temperature, the austenite undergoes the pearlitic transformation, thus maintaining an amount of carbon dispersed in the matrix.

On the other hand, a very slow cooling through the temperature range will deplete the carbon from the matrix, and, instead, secondary graphite is deposited around the graphite nodules. The heat treatments normally applied on a commercial scale can be summarized as follows:

- Heat to a temperature between 850 and 900 °C (1560 and 1650 °F). The length of soaking time depends on the amount of free carbide present. Air-cooling from this temperature provides a predominantly pearlitic matrix, except in heavy sections
- Remove carbides and austenitize as described above. Oil quench at a temperature between 850 and 900 °C (1560 and 1650 °F) to produce a martensitic matrix that can then be tempered to produce the required range of mechanical properties. This treatment is limited to castings of relatively thin section, unless alloying elements to improve hardenability are present
- Remove carbides and austenitize as described in the first bullet. Cool to a temperature between 680 and 700 °C (1255 and 1290 °F). It is common to hold at this temperature for a period of time in order to effect complete graphitization with the production of a ferritic matrix. The need for holding and the time involved will vary with basic composition and section size, but is usually of the order of from 8 to 12 h. The material is finally cooled to about 600 °C (1255 °F) before removal from the furnace
- The air-cooled material from the process described in the first bullet, which possesses a pearlitic matrix, can be annealed at a subcritical temperature (700 to 720 °C, or 1290 to 1330 °F), giving a completely ferritic matrix, as in the third bullet. The holding time at the subcritical temperature depends on composition and section size, but from 8 to 12 h should be adequate
- Any castings that are complex and likely to contain residual stresses, either in the as-cast condition or after normalizing, can be stress-relieved by heating to a temperature from 450 to 550 °C (840 to 1020 °F). Although no marked structural change occurs during this treatment, there is a tendency for softening to occur when the higher temperatures are used
- Nodular irons can also be transformed to a bainitic structure through the use of austempering carried out by cooling from 850 to 950 °C (1560 to 1740 °F) into a bath at a temperature between 230 and 425 °C (445 and 795 °F). Heat-treatment stresses and distortion are minimized and their overall properties

vastly improved. For example, a tensile strength ranging from 1200 to 1600 MPa (175 to 230 ksi) can be achieved with significant ductility, toughness, and fatigue strength. In this condition, austempered ductile iron is now being used for gears and other highly stressed parts

Nodular irons are used in such applications as crankshafts and gears, where they compete against through-hardened and surface-hardened steels. Their near-net-shape forming characteristics, coupled with the presence of graphite (which confers sliding wear resistance), offer a unique combination of properties for more hostile tribological applications.

Typical Microstructures

For all critical wear applications, it is recommended that both microstructure and hardness values at and close to the surface (where wear is likely to occur) be checked and actually become part of the manufacturing specification. The reasons behind this recommendation are the importance of microstructure in terms of control of engineering properties, as well as the variability that is due to section sensitivity.

Described below are the different microstructures that can be produced in engineering castings. The matrix structure of cast irons usually contains one or more of these constituents: ferrite, pearlite, cementite, phosphide eutectic, martensite, bainitic transformation structures, austenite, and graphite, the latter of which was already been discussed.

Ferrite in cast iron is essentially a single-phase solid solution of silicon in amounts that vary with graphite structure, cooling rate, and silicon content. The amount tends to increase as the cooling rate decreases and the silicon content increases, and the graphite approaches the undercooled form. Fully ferritic structures are normally only obtained by annealing. Ferrite should be avoided in all wear parts.

Pearlite consists of alternate lamellae of ferrite and cementite. The degree of fineness depends on cooling rate. The finer the pearlite, the stronger (harder) is the iron. At low magnification, pearlite appears as a half-tone color. This structure is formed by the transformation of austenite during normal cooling in the mold or in the air through the critical temperature range from 720 to 900 °C (1330 to 1650 °F). This is a highly desirable matrix for sliding wear resistance.

Cementite (Fe_3C) in the massive eutectic form is a hard white constituent formed during solidification, as in mottled or white irons, and in the lamellar form in pearlite, where it is formed by the transformation of austenite through the critical temperature. Eutectic carbides can increase hardness for wear resistance. Harder carbides can be obtained by alloying with Cr and Mo.

Phosphide eutectic (melting point of about 930 °C, or 1706 °F) occurs in two distinct forms in cast irons with more than 0.06% phosphorus. The normal form is pseudobinary, which consists of ferrite and iron phosphide (Fe_3P). The true eutectic forms from the liquidus as austenite plus iron phosphide. Upon cooling, the austenite transforms to ferrite and pearlite, and, with iron phosphide, gives a bulk hardness between 420 and 600 HV.

In mottled irons and in apparently gray irons, this structure can occur in ternary form, where it solidifies as austenite, iron carbide, and iron phosphide. At room temperature after transformation of the austenite, it appears as a eutectic of ferrite, free carbide, and iron phosphide. This form is likely to occur if chromium or vanadium are present in amounts over 0.1% and has a bulk hardness of about 780 to 800 HV, because of the high hardness of the free carbide (800 to 1015 HV). Although it is desirable to improve the sliding wear resistance of gray irons, it markedly increases tool wear in machining operations.

Martensite is a fine acicular, slow-etching structure, normally produced either by very rapid cooling (quenching) of austenite through the critical temperature range or by alloying. The presence of martensite achieves maximum hardness in parts that require abrasion resistance.

Acicular or bainitic transformation structures are produced by either isothermal quenching or alloying. They are often referred to as acicular ferrite and are softer and tougher than martensite, but harder and stronger than pearlite. These acicular structures range from the upper bainites, or acicular ferrites, to martensite, depending on the transformation time, composition, and other factors. Austempered parts provide resistance to the more hostile stress conditions encountered in gear trains, for example.

Austenite can be made stable at room temperature by the addition of alloys, such as nickel and manganese, which depress the critical temperature at which the γ to α change occurs. Although the transformation may have been suppressed at room temperature, it can still occur at a lower temperature, depending on the amount of alloy present. These irons are not normally used for wear resistance.

Applications

Cast irons have been widely used by engineers in applications that require low cost, excellent castability, good damping capacity, ease of machining, and wear resistance. These general terms do not describe precisely the requirements for specific applications, and it is not possible to obtain all of those desirable characteristics in any single alloy.

Cast irons are traditional materials that have an extensive use history and a considerable property database. For tribological purposes, they are the most widely used of all materials. This family of materials sets the standard by which other materials, including composites and ceramics, are compared.

Although there have been many attempts to supersede the use of cast irons in extremely hostile environments, such as in the internal combustion engine, successes are still few in number. The reasons are quite simple and are due to the versatile properties of excellent sliding and abrasive wear resistance, coupled with low cost, casting versatility, dimensional stability over a broad temperature range, and, for certain alloys, ease of machining. Typical wear applications for a variety of cast iron grades are identified in Table 4.

Table 4 Guidelines for industrial applications of selected cast irons for wear parts

Cast iron type	Applications[(a)]
Gray (flake) iron	Piston rings and cylinder bores for compressors and internal combustion engines; machine tool beds and slideways; brake blocks; low-stress gears
Nodular iron	Crankshafts; gears; highly-stressed piston rings
Chilled iron	Cams and tappets where the Hertzian stress is high and lubrication is borderline
White iron (cast and heat treated)	Grinding balls; chute and mill plates and tiles; cone, feeder, deflector, and breaker liner plates; grizzlies
White iron (by hardfacing)	Dragline buckets, shrouds, pick holders, and side plate protection; hardfacing of steel digger teeth for shovels

(a) In all of these applications, there is a wide range of compositions, cooling rates, and heat-treatment variations that control the microstructure and thus the level of wear resistance which can be obtained. A balance also has to be obtained between wear resistance, corrosion resistance, and impact resistance (particularly for mineral handling applications). Great care is therefore required when choosing the optimum material for a specific wear application.

Suppliers and users of cast irons continually update and extend applications into more hostile conditions by improving surface engineering in terms of treatment coatings and machining. A sound engineering understanding of the relationship between composition, manufacture, microstructure, and engineering properties will ensure that these materials continue to be used extensively in tribological applications decades from now.

Friction and Wear of Carbon and Alloy Steels

W.A. Glaeser, Battelle Memorial Institute

Introduction

CARBON STEELS are those steels whose major hardening agent is carbon. Alloying elements such as chromium, vanadium, and molybdenum for improving hardenability are not found in these steels in any significant amount. Carbon steels containing <0.4% C are not hardenable by heat treatment and are not used very much for sliding or rolling contact applications.

Carbon steels have wide and diversified use in tribological applications. Application, rather than specific composition, has determined the need for this class of materials. A few steels have been modified in composition and heat treatment methods for use in bearings. AISI 52100 steel (high-carbon steel), used for ball and roller bearings, is subjected to special vacuum melting practices for inclusion control and is given a special heat treatment to minimize residual austenite content and to ensure dimensional stability. This grade of steel is discussed in the article "Friction and Wear of Bearing Steels" in this Volume.

Austenitic manganese steel (Hadfield manganese steel) is used in the mining, earth moving, and railroad industries where high toughness, impact resistance, and abrasive wear resistance are needed. This alloy contains 1% C and 11 to 14% Mn. It is an austenitic steel that transforms to martensite when abraded heavily. This results in a tough core with a hard skin that continually renews itself as it is worn off. Therefore, this alloy is capable of extensive work hardening under abrasive impact conditions.

Steel is used in machinery for load bearing components such as shafting, gearing, housings, cable, thrust surfaces, and so on. For efficiency, steel surfaces are being coated with wear-resistant materials. In this way, the structural strength of the steel can be used for large components, and a small amount of expensive wear-resistant material is applied to specific areas where it is needed.

Steel Metallurgy

Two abundant elements, iron and carbon, are the basis for the steel industry. Carbon is soluble in iron in small amounts, and steels cover a range of carbon-iron alloys from 0.005 to 2.00 wt% C. The iron-carbon equilibrium diagram, well established from years of research, provides a map of possible phases based on temperature and carbon content. An iron-carbon equilibrium diagram for $\leq$6.67 wt% C is shown in Fig. 1. The portion of the diagram from 0 to 2.0% C covers steels. Higher carbon contents are typical for cast irons.

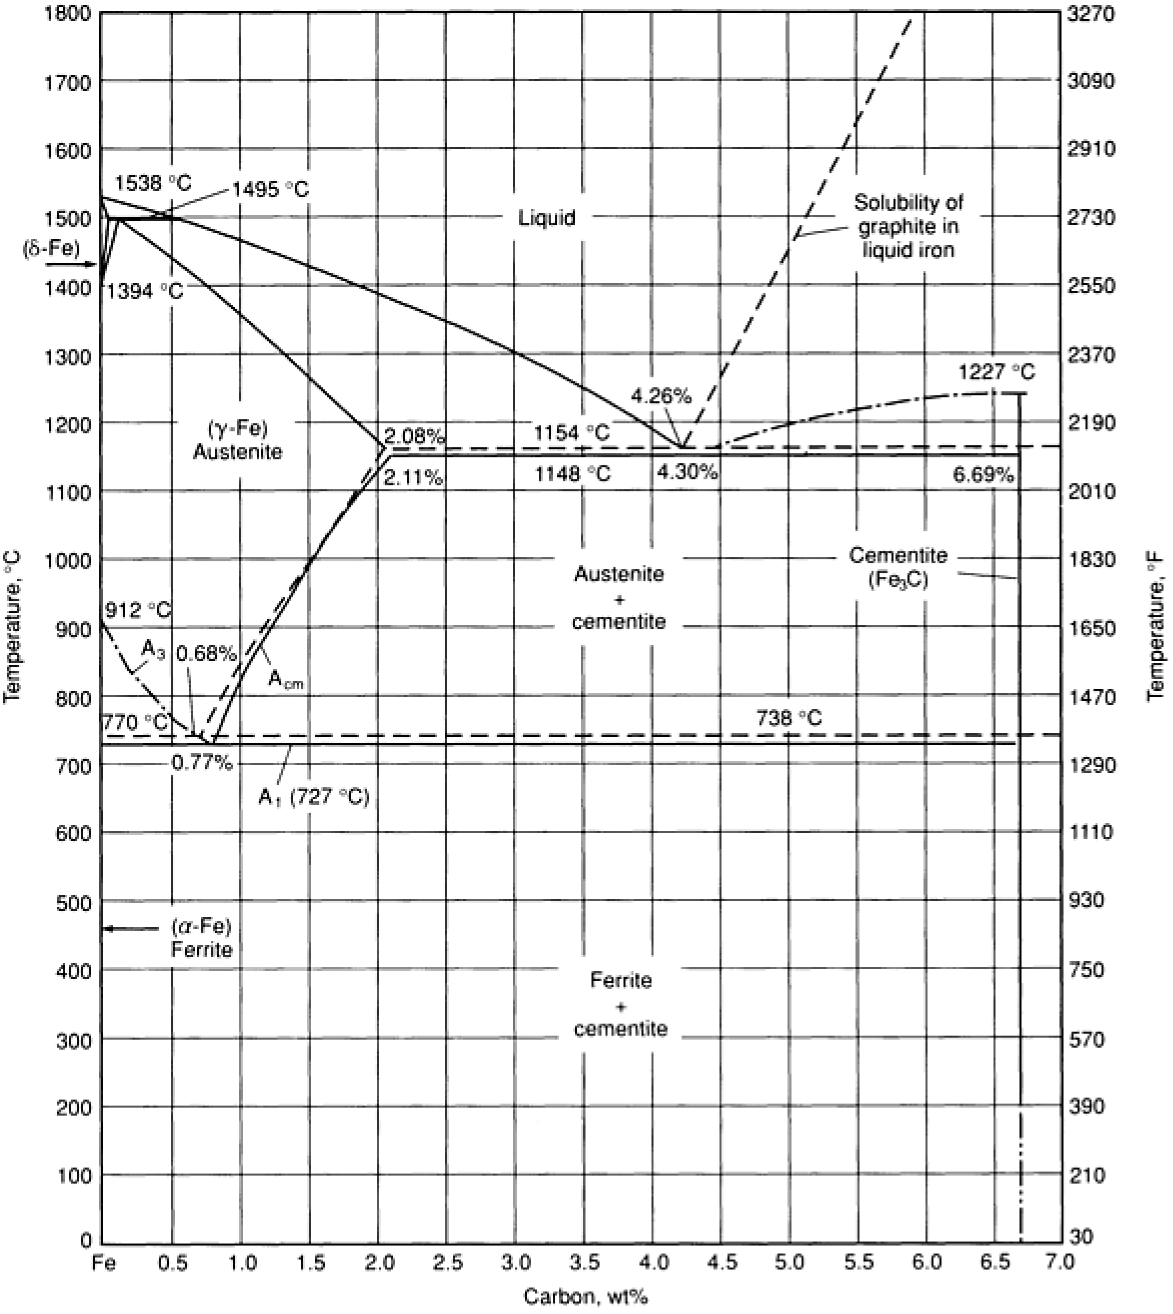

Fig. 1 Iron-carbon equilibrium diagram up to 6.67 wt% C. Solid lines indicate Fe-Fe_3C diagram; dashed lines indicate iron-graphite diagram. Source: Ref 1

Several phases of iron-carbon are shown in Fig. 1: austenite, ferrite, γ-iron, and cementite. These are all equilibrium phases. Austenite exists at elevated temperatures (>727 °C, or 1341 °F). Carbon is an austenite stabilizer and is more soluble in austenite (2.11 wt%) than in ferrite (0.22 wt%). As temperature is reduced from 1148 °C (2098 °F), the solubility of carbon in austenite decreases and carbon is rejected as iron carbide (Fe_3C) or cementite. Two phases (cementite and austenite) exist together as shown in the phase diagram. At 727 °C (1341 °F), austenite converts to ferrite and considerable carbon is rejected from solution as carbide and the two phases (ferrite and cementite) exist together.

Fortunately for engineers, carbon rejection is a very sluggish process and, with rapid enough cooling from the austenite region, a supersaturated solution of carbon in iron results. The lattice strain caused by the excess carbon produces a phase change to body-centered tetragonal (bct), a distorted cubic structure, with very high hardness. This structure, not shown on the equilibrium diagram, is known as martensite. Martensite is desirable as a highly wear-resistant steel phase. Martensite requires rapid cooling such as that achieved by quenching. Slower cooling rates will produce other

microstructures having equally useful engineering properties. These microstructures include bainite (a martensitelike structure) and pearlite (a lamellar structure of ferrite sandwiched between cementite plates). The hardness of these microstructures, especially martensite and bainite, is significantly influenced by carbon content. Figure 2 shows hardness as a function of carbon content for martensite.

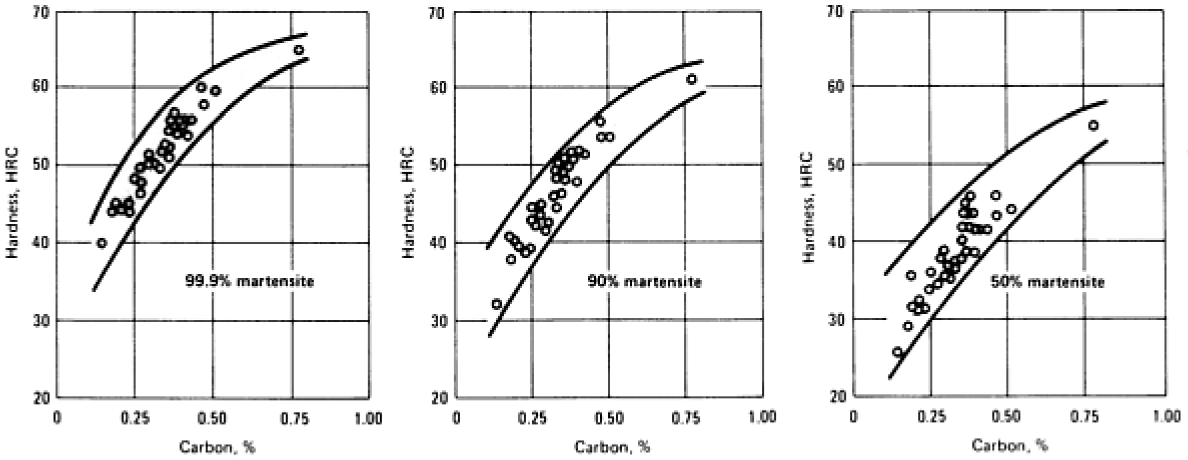

Fig. 2 Plot of hardness versus carbon content for steels containing varying amounts (99.9, 90, and 50%) of untempered martensite in their microstructures

The above metallurgical factors make it possible for a wide variety of steels to be produced by varying the amounts of carbon (Table 1) and by using different heat treatments (Table 2). This makes steel a very versatile engineering material.

Not only is there a large variety of steels from which to choose, but within those grades of steels, various heat treatments are possible, resulting in a greater variety of microstructures. The microstructure of steel can have a significant effect on wear resistance (Table 3). Microstructure can also influence corrosion resistance, toughness, dimensional stability, residual stresses, and fatigue resistance.

Steel Transformation Diagram

When carbon steel is heat treated by quenching from a high temperature, the resulting room-temperature microstructures are not those shown in the equilibrium diagram. Instead, a temperature-time-transformation diagram (TTT) diagram is used to describe these changes. A typical diagram for AISI 1095 steel is shown in Fig. 3. The left side of the diagram shows the temperature in both centigrade and fahrenheit. The right side of the diagram shows the hardness of the steel at room temperature. Note that the maximum hardness attainable for this steel is 66 HRC. The first heavy curved line in the chart represents the time at which transformation begins. In hypoeutectoid steels, this initial transformation consists of the separation of proeutectoid ferrite. This is followed by the separation of ferrite and carbide in the form of pearlite. The beginning of the pearlite formation is represented by the second heavy curved line. Below the knee of the curve ($\leq$540 °C, or 1000 °F), the transformation product is bainite, a phase similar in morphology to martensite but not quite as hard. If the solid curved line is not crossed before the martensite start temperature (M_s) horizontal dashed line, martensite is the product of austenite decomposition. This diagram shows that a very rapid quench is required to produce martensite (that is, one must go from 885 °C, or 1625 °F, past the knee in <1 s--a quench rate of approximately 360 °C/s, or 650 °F/s). Bainite can be obtained by rapid quenching to a temperature just below the knee and holding at that temperature until the transformation is complete, followed by a quench to room temperature.

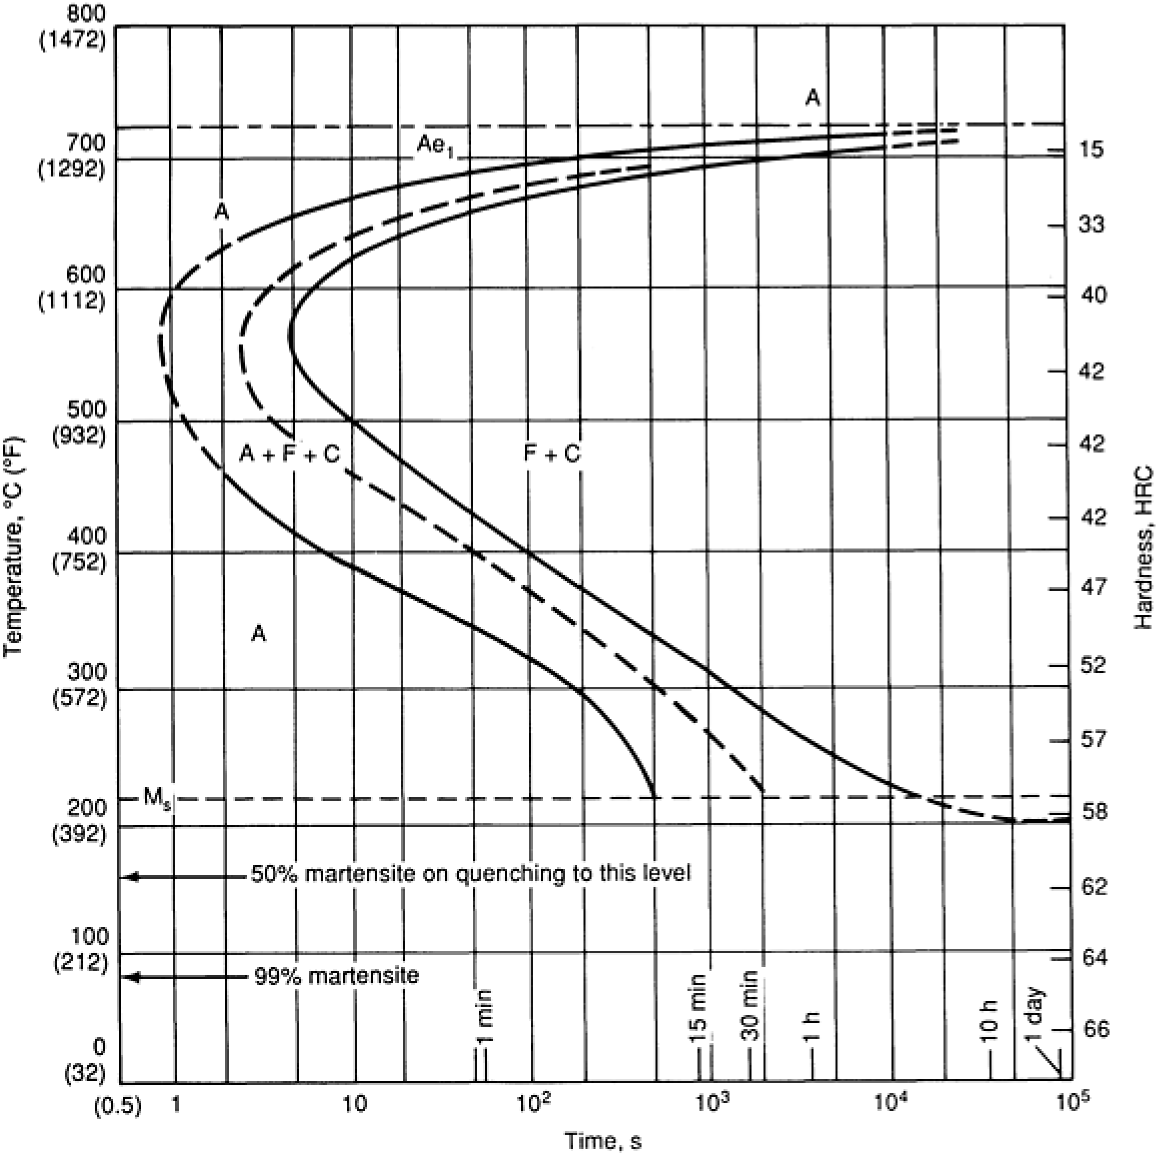

Fig. 3 Time-temperature-transformation diagram for SAE 1095 eutectoid carbon steel (0.9C-0.3 Mn). Austenitized at 885 °C (1625 °F); grain size, 4 to 5. Ae_1, equilibrium transformation temperature

A variety of microstructures can be obtained by controlling the quench processes. Martensite is the hardest phase and provides the highest wear resistance in the absence of any fracture-initiating conditions. If a tougher material is desired, bainite is the best wear-resistant phase. Of course, tempering (that is, heating the martensite to an elevated temperature below the austenitizing temperature and holding to reduce the lattice strain) is a process that can be used to increase the ductility and toughness of martensite. The maximum martensitic hardness attainable in a steel is a function of the carbon content (Fig. 2).

Wear Properties of Carbon Steel

Hardness as a Function of Carbon Content. Under the abrasive conditions found in mining and construction operations, wear rates of steel can be related to hardness and carbon content. For example, wear tests were conducted on steel rods used on a vibrating screen at an ore crushing plant. These screens were equipped with rods 6.5 mm ($\frac{1}{4}$ in.) or 4.8 mm ($\frac{3}{16}$ in.) in diameter, 585 mm (23 in.) long, and equally spaced in several rows across the rod deck of vibrating screens used to size -25 mm (-1 in.) siliceous ore into ±9.5 mm (±$\frac{3}{8}$ in.) sizes. The wear rate of all test rods was compared with that of 1070 high-carbon steel that was oil quenched and tempered to 44 HRC. To ensure that each type of

steel would be exposed to the same abrasion, rods were alternated in groups of five across the screen. Wear rates based on the loss of weight for the different steels and hardnesses are shown in Fig. 4. Although the 0.30C-13Cr stainless steel showed the best resistance to wear, 1080 steel austempered to 57 HRC was found to be more cost effective.

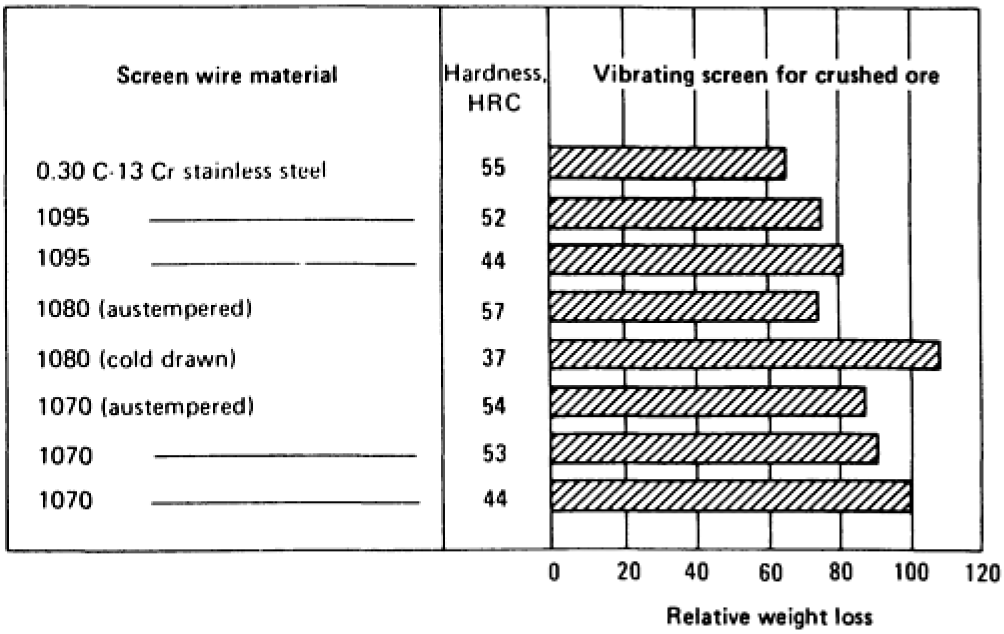

Fig. 4 Effect of hardness and carbon content on the abrasive wear of selected steel rods used in an ore crusher

Improving Wear Properties of Mild Steels. Mild steel demonstrates poor wear resistance and resistance to surface damage during dry sliding. The use of mild steel in sliding surface contact requires surface treatment, such as hardening or coating, and the selection of a "compatible" mating material such as bronze or babbitt. Where hard minerals come in contact with steel, wear is very rapid unless the steel surface is hardened or coated with a very hard material.

Corrosion Resistance Improved by Altering Microstructure. Steel is subject to accelerated wear in a corrosive environment. Unprotected steel is also susceptible to fretting damage or the formation of oxidized wear debris between two contacting surfaces in low-amplitude oscillating motion. A wide variety of microstructures is possible in the heat treatment of steel or cast iron. Wear properties can be related to specific microstructures.

Steel Selection Based on Relative Costs

When selecting a steel based on its wear-resistance properties, the total cost of the steel and its heat treatment must be considered. The following steels, which may have suitable wear-resistance properties in specific applications, are listed in order of increasing total costs:

- Low-carbon steels, such as 1020, not heat treated
- Simple high-carbon steels, such as 1095, not heat treated
- Directly hardened carbon or low-alloy steels, either through-hardened or surface-hardened by induction or flame process
- Low-carbon or low-alloy steels that are surface-hardened by carburizing, cyaniding, or carbonitriding
- Medium-carbon chromium or chromium-aluminum steels that are hardened by nitriding
- Directly hardened high-alloy steels, such as D2 high-carbon high-chromium tool steel (1.50C-12Cr), that contain particles of free carbide
- Precipitation-hardening stainless steels (mainly for applications involving elevated temperatures and corrosive environments, as well as excessive wear)
- Specialty steels produced by powder metallurgy (P/M) or mechanical alloying techniques

- Alloy carbides bonded by steel matrices

Other ferrous materials, such as high-manganese austenitic steels and various classes of cast irons, are also widely used for wear-resistance applications.

Depth of Hardened Regions

Skids, grinding rods, chute liners, and similar parts may be considerably reduced in section before replacement is necessary. In such parts, a more expensive deep-hardening steel may be more economical than a shallow-hardening steel. For example, a 64 mm ($2\frac{1}{2}$ in.) diameter bar with a surface hardened of 50 HRC may be made of either a water-quenched 1040 or an oil-quenched 5160 steel. However, by the time the bar has been worn to three-fourths of its original diameter (~48 mm, or $1\frac{7}{8}$ in.), the 1040 steel will have a surface hardness of ~25 HRC and thus would wear at a much faster rate than the 5160 steel, which has a hardness of ~37 HRC at the same location (Ref 2).

Toughness

Wear resistance tends to increase with hardness, but it decreases as toughness increases. This is an important relationship in applications that require both wear resistance and impact resistance.

The correlation between wear resistance and toughness for a variety of ferrous alloys is shown in Fig. 5. The scatter arises, at least in part, from microstructural effects. For example, point 22B refers to AISI 4340 steel, quenched and tempered at a high temperature of ~650 °C (~1200 °F) to produce fine carbides in a ferrite matrix. Point 22A represents the same steel, except normalized to produce fine pearlite; point 22C represents a quenched sample tempered at 205 °C (400 °F), a relatively low tempering temperature. Steels in the lower band of Fig. 5 combine toughness with wear resistance; these are mainly the austenitic manganese steels. The data in Fig. 5 indicate that, for most ferrous alloys, there is a trade-off between wear resistance and toughness. In some alloys, altering the carbon content is a simple method for adjusting these properties.

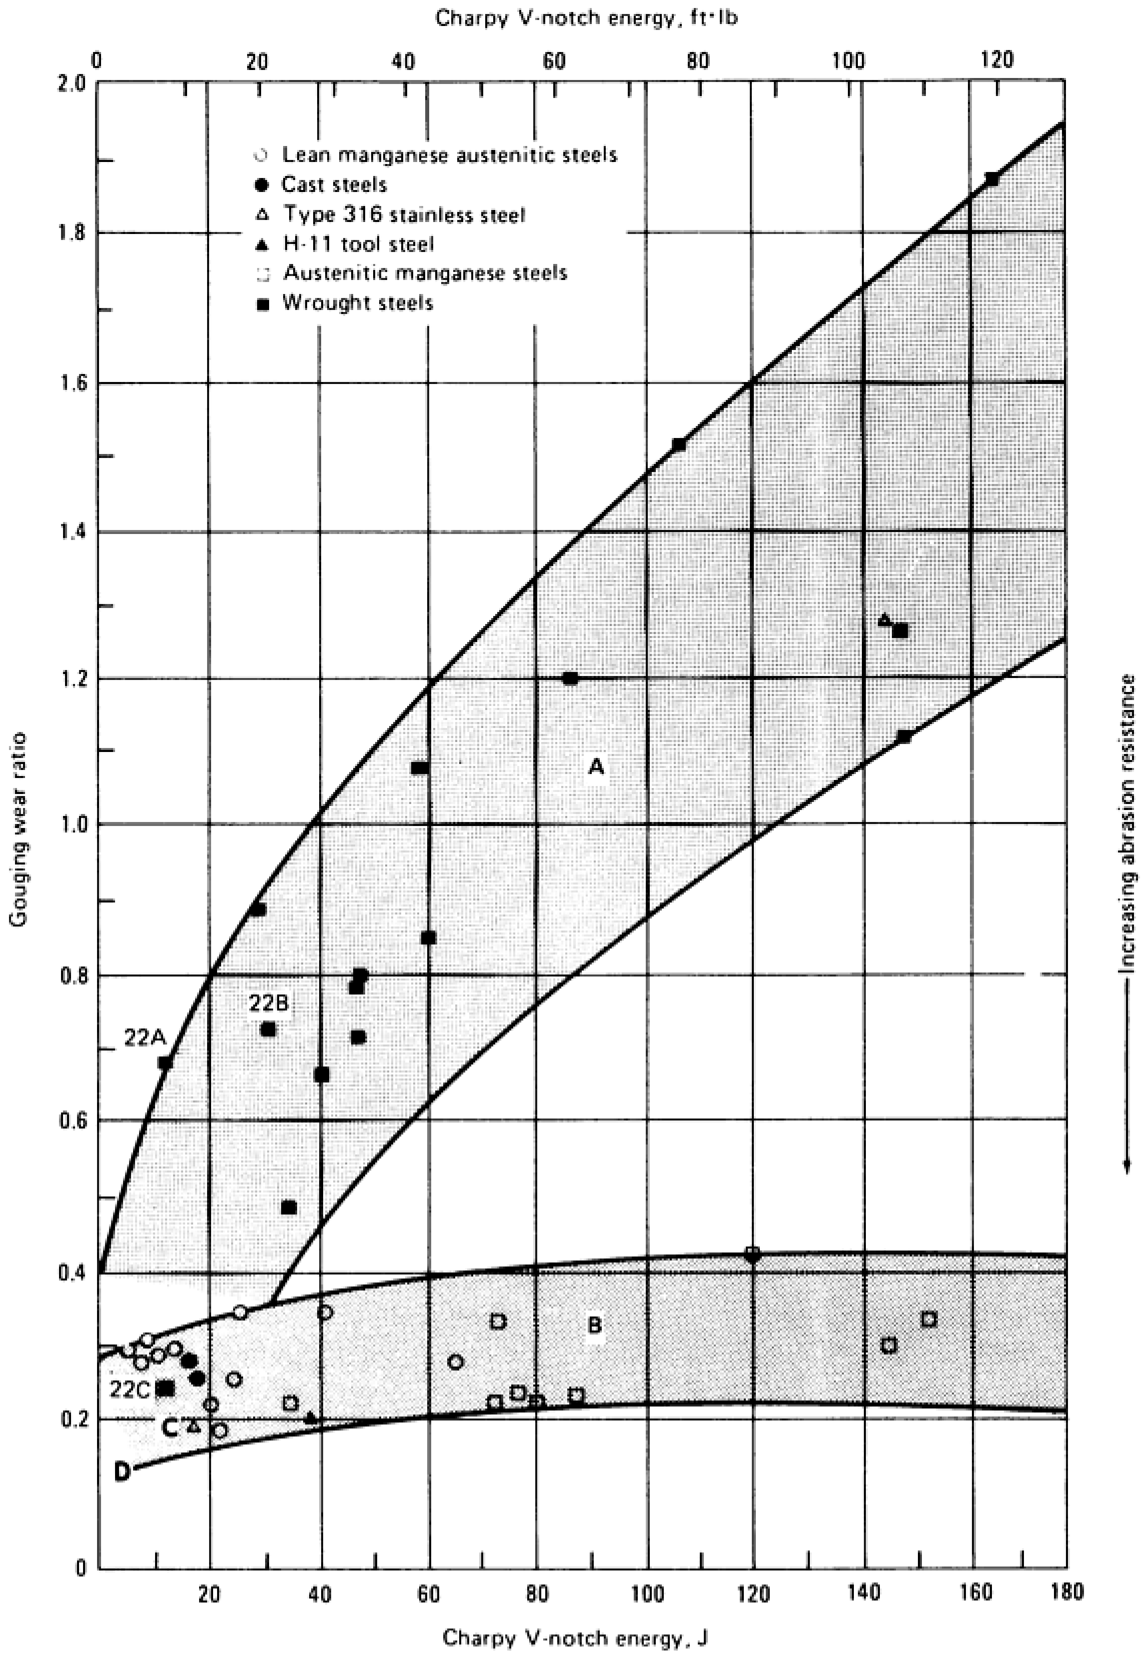

Fig. 5 Relationship between resistance to gouging abrasion and toughness of selected materials. Area A, wrought and cast low-alloy steels; area B, austenitic manganese steels; area C, variety of heat-treated steels; area D, high-chromium white cast irons. Source: Ref 3

Carbon Content

The wear resistance of ferritic steel is improved by hardening, either throughout the section or superficially. The maximum hardness depends on the carbon content of the steel and the amount of martensite (that is, efficiency of quenching) (Fig. 2)

Standard hardness measurements may indicate that a martensitic steel is largely transformed, although it may retain some austenite. Exposure to ultralow temperatures, followed by tempering, can help complete the transformation to martensite and improve wear resistance. Because martensite is a metastable structure, it begins to transform to more stable structures as the temperature is increased. Consequently, martensitic steels are not suitable for wear resistance at elevated temperatures (>200 °C, or 390 °F) or for applications in which the heat of friction can raise the temperature significantly. Special alloy steels, such as tool steels or martensitic stainless steels, are appropriate for service at higher temperatures. The thermal instability of martensite should also be considered during finishing operations (such as grinding) when a heat-affected zone (HAZ) could be produced at the surface. The resultant tempering effects could be localized or general; in either case, wear resistance is likely to be reduced.

Carbon content also affects hardness and wear resistance through the formation of various simple and complex carbides. Wear properties depend on the type, amount, shape, size, and distribution of carbides present, in addition to the properties of the matrix (for example, hardness, toughness, and stability). Despite this complexity, a correlation for relative wear content is possible.

Relation of Hardness to Microstructure

The frequent use of bulk hardness as a guide to abrasive wear resistance is supported by the data shown in Fig. 6 for annealed unalloyed metals. These data were obtained using an abrasive cloth (two-body abrasion) with an abrasive hardness much greater than that of the metal samples. The data points are approximate; the experimental scatter of the measurements is not shown.

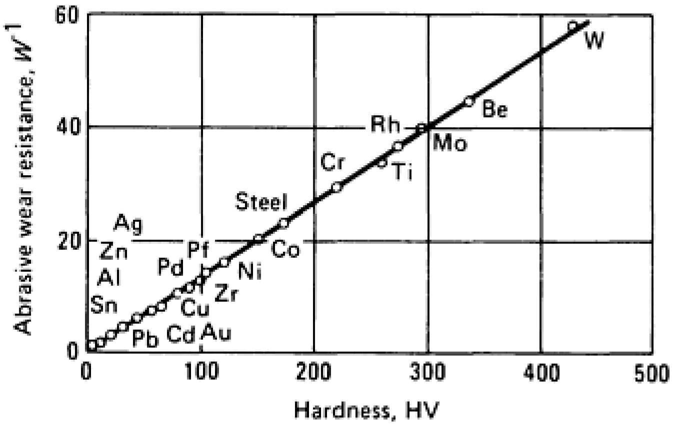

Fig. 6 Abrasive wear resistance versus hardness for annealed unalloyed metals and steel. Source: Ref 4

Corresponding correlations with other properties related to hardness (such as elastic modulus) have also been presented. In all cases, if the metals are unalloyed, a simple correlation is obtained for controlled tests of two-body abrasion. Different crystal structures would be expected to yield different correlations, but the data in Fig. 6 do not show such an effect.

Care must be exercised in extending the simple hardness correlation to metals containing impurities or solutes, or to more complicated alloys. Figure 7 shows how wear resistance relates to hardness for various types of materials. The linear plot shown for pure metals in Fig. 6 is repeated as the steep line in Fig. 7. Another straight line describes brittle ceramics reasonably well. The differences in bonding type may account for these two distinct lines.

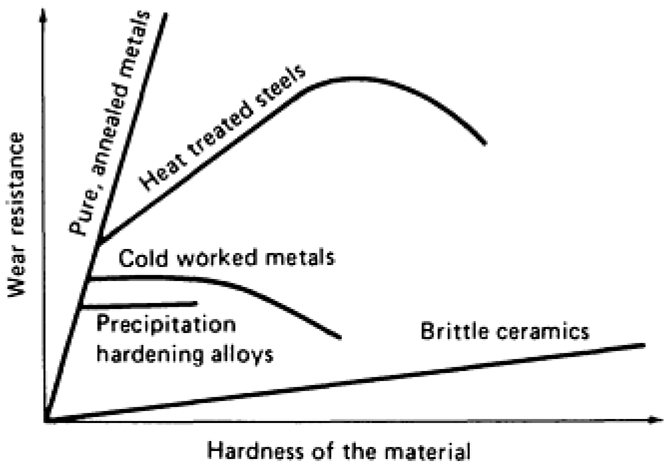

Fig. 7 Plot of wear resistance versus hardness for selected materials (metals, alloys, and ceramics) having various microstructures. Source: Ref 5

Between the curves for pure metals and brittle ceramics are curves for heat-treated steels, cold-worked metals, and precipitation-hardening alloys of varying hardnesses. For a typical precipitation-hardening alloy, large increases in hardness provide very little improvement in wear resistance. The same is true of simple cold working alloys (assuming no complicating phase changes), except that wear resistance actually decreases at high hardness levels. Heat-treated steels show initial improvement in wear properties as hardness increases, but eventually the correlation is reversed. It is possible that the reduced wear resistance at high hardness for cold-worked metals and heat-treated steels is related to the reduction in fracture toughness. Zum Gahr (Ref 6) has evaluated the effect of low fracture toughness on reduced abrasion resistance of metal alloys. He suggests that during abrasion a critical load can be reached by a given abrasive particle, above which fracture toughness becomes a significant factor in the abrasive wear process. Although carbon steels are not likely to fall into the category of materials for which fracture toughness related abrasive wear is a problem, the effect of heat treatment and carbon content on fracture toughness should be kept in mind. As the carbon content of carbon steel increases, the maximum martensitic hardness attainable by quenching increases and fracture toughness decreases. If one tries to use very hard untempered martensite in a part, the chances of the microfracture dominating wear in abrasive wear increases.

Pearlitic steels are inexpensive materials and above a certain hardness level exhibit reasonable wear resistance. Clayton (Ref 7) demonstrated in pin-on-ring experiments that a hardness of >250 HV 30 (Vickers hardness of >250 measured under a load of 30 kgf applied for 10 to 15 s, the normal loading time) wear resistance increased by almost an order of magnitude (Fig. 8). Note that specific wear, which is defined as the volume removed per total sliding distance, has units of mm^3/mm. Wear resistance, which is the reciprocal of specific wear, has units of mm/mm^3 or mm^{-2}.

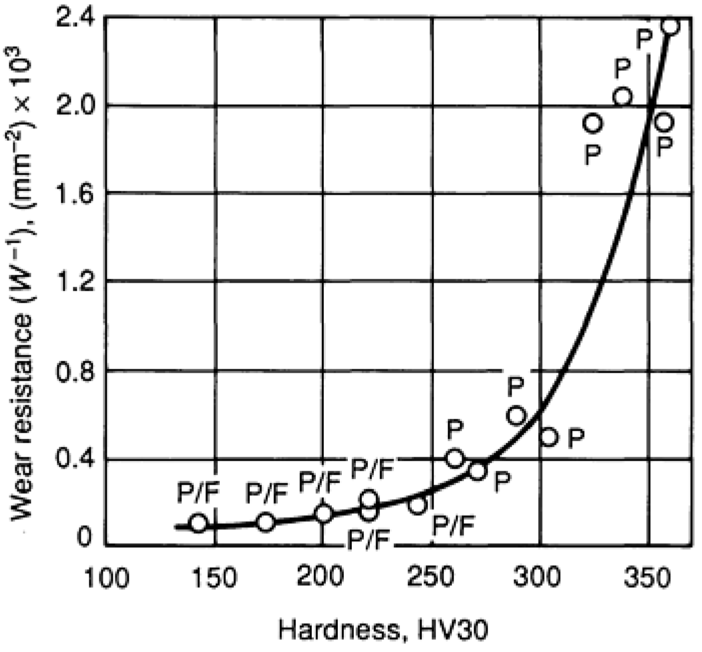

Fig. 8 Dry pin-on-ring test used to evaluate effect of microstructure on the wear resistance and the hardness of pearlitic steel pins. Test parameters: pressure, *P,* 34.71 MPa (5.033 ksi); velocity, *v,* 0.4 m/s (1.3 ft/s); atmosphere, dry air. P, pearlite; P/F, pearlite and ferrite. Source: Ref 6

In lubricated block-on-ring wear experiments with pearlitic carbon steel where deformation wear was the principal wear mode, pearlite was observed to minimize the depth of extreme plastic deformation (Ref 8). During heavy working, the interlath spacing in pearlite will decrease and the ferrite will work harden. Thus, the hardness of pearlite increases with decreased lamellae spacing (Fig. 9) and the structure tends to resist recrystallization (Ref 9). The result is a thinner zone of heavy working and a smaller volume of metal extruding out of the contact zone.

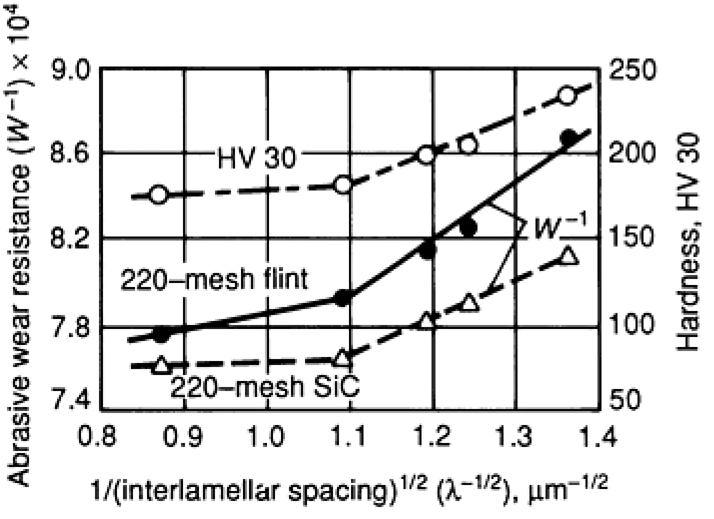

Fig. 9 Abrasive wear resistance and bulk hardness of 0.7% C steel as a function of pearlite interlamellar spacing. Abrasion data obtained using pin abrasion test apparatus with pressure, *P,* of 710 kPa (105 psi); two different 220-mesh abrasives (flint [96 to 99% Si] and silicon carbide) used in separate tests. Source: Ref 6

Under boundary lubrication conditions, where heavier loads are possible than under dry conditions, a pearlitic structure with tight interlamellar spacing in the pearlite phase is appropriate to minimize the depth of shear instability. Shear instability (Ref 10) below the contact surface is the source for deformation wear.

Austenitic steels with varying manganese content show wear resistance to be a function of manganese content. The resistance depends on the transformation of the unstable austenite to martensite (that is, the hard wear-resistant phase). Manganese tends to promote the retention of room-temperature austenite in carbon steel. The retained austenite is unstable and will transform to martensite under heavy deformation. The room-temperature austenite becomes more stable as the manganese content of the alloy is increased. Pin-on-disk experiments performed by Jost and Schmidt (Ref 11) showed that the amount of austenite transformation decreased with increasing manganese content. Figure 10 shows an almost linear increase in wear resistance with decreasing concentration of manganese in the alloy.

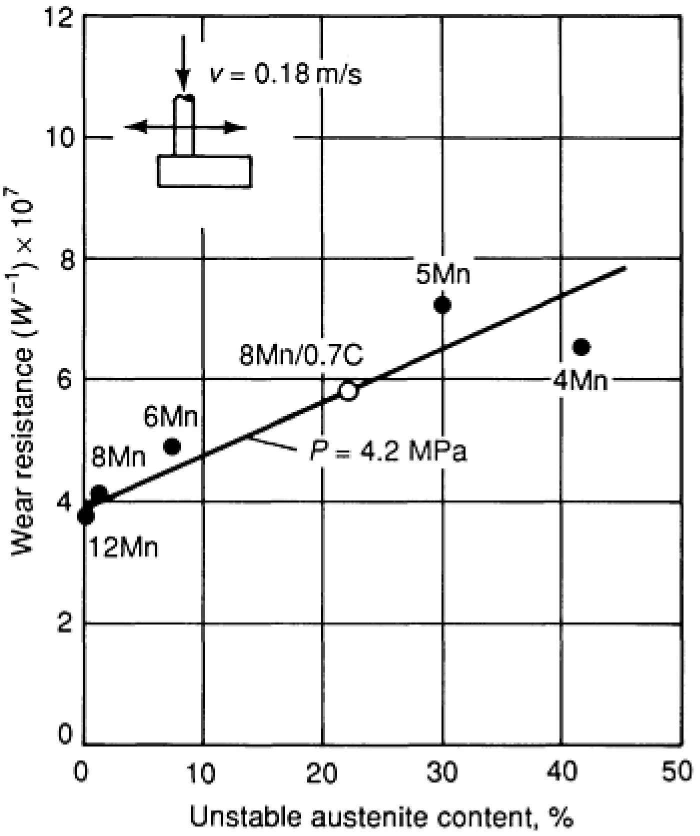

Fig. 10 Plot of wear resistance versus unstable austenite content as a function of manganese content. Pin-on-disk test specimens had 4 to 8% Mn content Fe-Mn-C steel pins rubbed against a steel disk. Test parameters, pressure, 4.2 MPa (610 psi); velocity, 0.18 m/s (0.59 ft/s). Source: Ref 6

Wear of Stainless Steels

John H. Magee, Carpenter Technology Corporation

Introduction

STAINLESS STEELS are primarily used to resist corrosive attack in environments that are as mild as kitchen sinks or as severe as piping used in the chemical process industry. They are broadly defined as steels that contain at least 10.5% Cr.

A wide range of corrosion resistance can be achieved by increasing the chromium content and adding other elements, especially nickel. In addition, high tensile yield strength (>1400 MPa, or 205 ksi) can be accomplished through martensite formation, precipitation hardening, or cold work. Because of the broad definition used, stainless steels are further divided into five families, each with a unique microstructure, alloying element additions, and range of physical, mechanical, and corrosion properties.

The selection of a particular type of stainless steel for an application involves the consideration of such factors as the corrosion resistance of the alloy, mechanical properties, fabricability, and cost. However, for applications such as pumps, valves, bearings, fasteners, and conveyor belts, where one contacting metal surface moves relative to the other, the wear and galling resistance of the metals in contact should also be considered in the selection process.

Stainless steels are characterized as having relatively poor wear and galling resistance, but are often required for a particular application, because of their corrosion resistance. Therefore, finding the most effective alloy to withstand wear and galling can be a difficult problem for design engineers. Lubricants and coatings are often used to reduce wear, although lubricant use is precluded in may applications, such as high-temperature environments, in which they can break down, or food and pharmaceutical processing equipment, which require sanitation.

Additionally, a critical part, such as a valve in a power plant, must resist galling or seizing, because it can shut down or endanger the entire plant (Ref 1, 2).

This article discusses each stainless steel family, specifically in terms of wear resistance. Information on wear and galling, laboratory wear and galling tests, and the associated data from these tests is presented. Applications and design considerations are also discussed.

Classification of Stainless Steels. In the United States, grades of stainless steels are generally designated by one or more of these methods: the American Iron and Steel Institute (AISI) numbering system, the Unified Numbering System (UNS), and proprietary name of designation. In addition, designations have been established by most of the major industrial nations. Of the two institutional numbering systems, AISI is the oldest and most widely used. Most of the grades have a three-digit designation; the 200 and 300 series are generally austenitic stainless steels, whereas the 400

series are either ferritic or martensitic. Some of the grades have a one- or two-letter suffix that indicates a particular modification of the composition.

The UNS system is a broader-based system that comprises a list of metal alloys, including stainless steel. This system includes a considerably greater number of stainless steels than AISI, because it incorporates all of the more recently developed stainless steels. The UNS designation for a stainless consists of the letter S, followed by a five-digit number. For those alloys that have an AISI designation, the first three digits of the UNS designation usually correspond to an AISI number. When the last two digits are 00, the number designates a basic AISI grade. Modifications of the basic grades use two digits other than zeroes.

Table 1 provides the compositional limits for select stainless steels, listed by UNS and AISI type designations and separated into the basic families. Where AISI type designations are not available, common trade names are listed in parentheses. These names, the third commonly used identification of stainless steels, have often become the popular means of identifying a particular alloy. A complete listing of all stainless alloys available is provided in Ref 3.

Families of Stainless Steels

On the basis of microstructure, there are five major families of stainless steels: ferritic, austenitic, martensitic, precipitation-hardenable (PH), and duplex (austenite and ferrite).

Ferritic stainless steels are so named because their body-centered-cubic (bcc) crystal structure is the same as iron at room temperature. These alloys are magnetic and cannot be hardened by heat treatment. In general, ferritic stainless steels do not have particularly high strength. Their annealed yield strengths range from 275 to 350 MPa (40 to 50 ksi), and their poor toughness and susceptibility to sensitization limit their fabricability and the usable section size. Their chief advantages are their resistance to chloride stress-corrosion cracking, atmospheric corrosion, and oxidation, at a relatively low cost.

Ferritic stainless steels contain between 11 and 30% Cr, with only small amounts of austenite-forming elements, such as carbon, nitrogen, and nickel. Their general use depends on their chromium content.

The low-chromium (11%) alloys (S40500 and S40900) have fair corrosion and oxidation resistance and good fabricability at low cost. They have gained wide acceptance for use in automotive exhaust systems.

The intermediate-chromium (16 to 18%) alloys (S43000 and S43400) are used for automotive trim and cooking utensils. These alloys are not as readily fabricated as the lower Cr alloys, because of their poor toughness and weldability.

The high-chromium (19 to 30%) alloys (S44200 and S44600) are used for applications that require a high level of corrosion and oxidation resistance. These alloys often contain either aluminum or molybdenum and have a very low carbon content. Their fabrication is possible because of special melting techniques that can achieve very low carbon, as well as very low nitrogen contents. Stabilizing elements, like titanium and niobium, can be added to prevent sensitization and to improve as-welded properties.

Austenitic stainless steels constitute the largest stainless family, in terms of number of alloys and usage. Like the ferritic alloys, they cannot be hardened by heat treatment. However, their similarity ends there. The austenitic alloys are nonmagnetic, and their structure is face-centered-cubic (fcc), like high-temperature (900 to 1400 °C, or 1650 to 2550 °F) iron. They possess excellent ductility, formability, and toughness, even at cryogenic temperatures. In addition, they can be substantially hardened by cold work.

Although nickel is the chief element used to stabilize austenite, carbon and nitrogen are also used, because they are readily soluble in the fcc structure. A wide range of corrosion resistance can be achieved by balancing the ferrite-forming elements, such as chromium and molybdenum, with austenite-forming elements.

Austenitic stainless steel can be subdivided into two categories: chromium-nickel alloys, such as S30400 and S31600, and chromium-manganese-nitrogen alloys, such as S20100 and S24100. The latter group generally contains less nickel and maintains the austenitic structure with high levels of nitrogen. Manganese (5 to 20%) is necessary in these low-nickel alloys to increase nitrogen solubility in austenite and to prevent martensite transformation. The addition of nitrogen also increases the strength in austenitic alloys. Typical chromium-nickel alloys have tensile yield strengths from 200 to 275 MPa (30 to 40 ksi) in the annealed condition, whereas the high-nitrogen alloys have yield strengths up to 500 MPa (70 ksi).

As previously mentioned, austenitic alloys can be substantially hardened by cold working. The degree of work hardening depends on alloy content, with increasing alloy content decreasing the work-hardening rate. Figure 1 depicts the higher work-hardening rate of type 301 (7% Ni) versus type 305 (11.5% Ni), which is primarily due to its lower nickel content. Austenitic stainless steels that have a low alloy content, such as S20100, S20161, S30100, and S30400, often become magnetic because of the transformation to martensite when sufficiently cold worked or heavily deformed in machining or

forming operations. The rapid work hardening of S20161 is a major advantage in sliding wear. In S30430, copper is intentionally added to lower the work-hardening rate for enhanced headability in the production of fasteners.

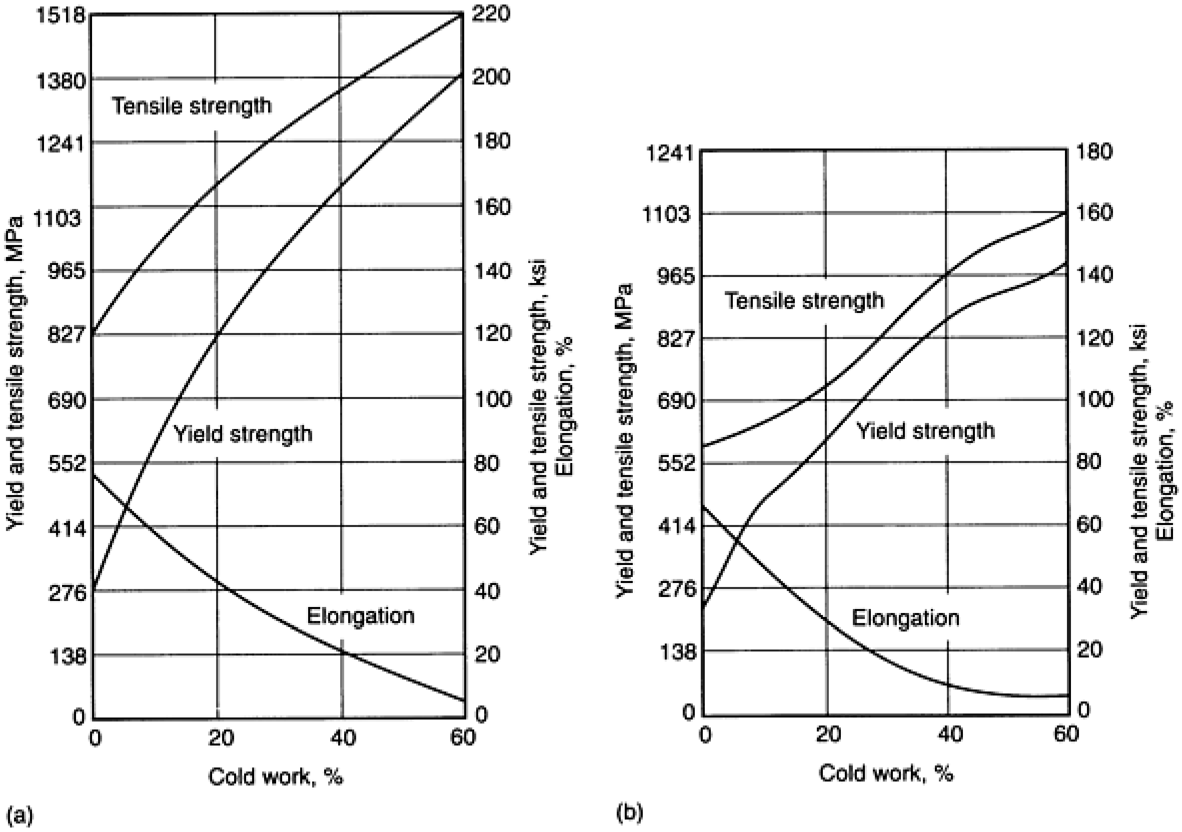

Fig. 1 Effect of cold working on mechanical properties of stainless steels. (a) Type 301. (b) Type 305. Source: Ref 4

Another property that depends on alloy content is corrosion resistance. Molybdenum is added to S31700 and S31600 to enhance corrosion resistance in chloride environments. High-chromium grades (S30900 and S31000) are used in oxidizing environments and high-temperature applications, whereas a high-nickel grade (N08020) is used in severe reducing acid environments. To prevent intergranular corrosion after elevated-temperature exposure, titanium or niobium is added to stabilized carbon in S32100 or S34700. Also, lower-carbon grades (AISI L or S designations), such as S30403 (type 304L), have been established to prevent intergranular corrosion.

Martensitic stainless steels are similar to iron-carbon alloys that are austenitized, hardened by quenching, and then tempered for increased ductility and toughness. These alloys are magnetic, and their heat-treated structure is body-centered tetragonal. In the annealed condition, they have a tensile yield strength of about 275 MPa (40 ksi) and are generally machined, cold formed, and cold worked in this condition.

The strength obtained by heat treatment depends on the carbon content of the alloy. Increasing carbon content increases strength, but decreases ductility and toughness. The most commonly used alloy in this family is S41000, which contains about 12% Cr and 0.1% C. This alloy is tempered to a variety of hardness levels, from 20 to 40 HRC. Both chromium and carbon contents are increased in alloys S42000, S44002, S44003, and S44004. The first of these contains 14% Cr and 0.3% C and has a hardness capability of 50 HRC. The other three alloys contain 16% Cr and from 0.6 to 1.1% C. These alloys are capable of 60 HRC, and a tensile yield strength of 1900 MPa (280 ksi). The amount of primary carbides increases with increased carbon content in these three alloys.

Wear resistance for martensitic stainless steels is very dependent on carbon content. S44004 (1.1% C) has excellent adhesive and abrasive wear, similar to tool steels, whereas S41000 (0.1% C) has relatively poor wear resistance. The key

to adhesive wear resistance is a high hardness. Abrasive wear resistance requires both high hardness and primary carbides.

Molybdenum and nickel can be added to martensitic stainless steel to improve corrosion and toughness properties. However, the addition of these elements is somewhat restricted, because higher amounts results in a microstructure that is not fully martensitic.

PH stainless steels are chromium-nickel grades that can be hardened by an aging treatment. These grades are classified as austenitic (such as S66286), semi-austenitic (such as S17700), or martensitic (such as S17400). The classification is determined by their solution-annealed microstructure. The semi-austenitic alloys are subsequently heat treated, so that the austenite transforms to martensite. Cold work is sometimes used to facilitate the aging reaction. Various alloying elements, such as aluminum, titanium, niobium, or copper, are used to achieve aging. They generally form intermetallic compounds, but in S17400, fine copper precipitates are formed.

Like the martensitic stainless steels, PH alloys can attain high tensile yield strengths, up to 1700 MPa (250 ksi). However, these alloys have superior ductility, toughness, and corrosion resistance, compared with the martensitic alloys. These properties are related to their higher chromium, nickel, and molybdenum contents, as well as their restricted carbon (0.040 max.) levels. The low carbon content of the martensitic PH stainless steels is especially critical for toughness and good ductility. However, this low carbon content reduces the wear resistance of these alloys.

Duplex stainless steels are chromium-nickel-molybdenum alloys that are balanced to contain a mixture of austenite and ferrite, and are magnetic, as well. Their duplex structure results in improved stress-corrosion cracking resistance, compared with the austenitic stainless steels, and improved toughness and ductility, compared with the ferritic stainless steels. They are capable of tensile yield strengths ranging from 550 to 690 MPa (80 to 100 ksi) in the annealed condition, which is approximately twice the strength level of either phase alone.

The original alloy in this family was the predominantly ferritic S32900. The addition of nitrogen to duplex alloys, such as S32950 and S31803, increases the amount of austenite to nearly 50%. In addition, nitrogen improves aswelded corrosion properties, chloride corrosion resistance, and toughness. The improvement in toughness is probably related to the higher amount of austenite present, which makes it possible to produce heavier product forms, such as plates and bars.

Physical and Mechanical Properties of Stainless Steels

The physical and mechanical properties of stainless steels are quite different from those of aluminum and copper alloys. However, when comparing the various stainless families with carbon steels, many similarities in properties exist, although there are some key differences. Like carbon steels, the density of stainless steels is $\sim$8.0 g/cm^3, which is approximately three times greater than that of aluminum alloys (2.7 g/cm^3). Like carbon steels, stainless steels also have a high modulus of elasticity (200 MPa, or 30 ksi), which is nearly twice that of copper alloys (115 MPa, or 17 ksi) and nearly three times that of aluminum alloys (70 MPa, or 10 ksi).

Differences between these materials are evident in thermal conductivity, thermal expansion, and electrical resistivity, as well. Figure 2 shows the large variation in thermal conductivity between various types of materials: type 6061 aluminum has a very high thermal conductivity, followed by aluminum bronze, 1080 carbon steel, and then stainless steels. For stainless steels, alloying additions, especially nickel, copper, and chromium, greatly decrease thermal conductivity.

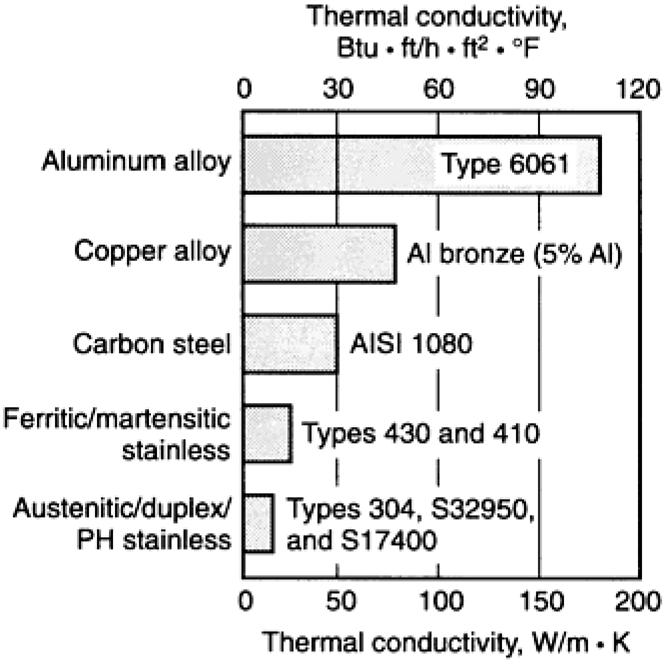

Fig. 2 Comparison of thermal conductivity for carbon steel, copper alloy, aluminum, and stainless steels. Source: Ref 5, 6

Thermal expansion (Fig. 3) is greatest for type 6061 aluminum alloy, followed by aluminum bronze and austenitic stainless alloys, and then ferritic and martensitic alloys. For austenitic stainless alloys, additions of Ni and Cu can decrease thermal expansion. Stainless steels have high electrical resistivity (Fig. 4). Alloying additions tend to increase electrical resistivity. Therefore, the ferritic and martensitic stainless steels have lower electrical resistivity than the austenitic, duplex, and PH alloys, but higher electrical resistivity than 1080 carbon steel. Electrical resistivity of stainless steels is ~7.5 times greater than aluminum bronze and nearly 20 times greater than type 6061 aluminum alloy (Ref 5, 6).

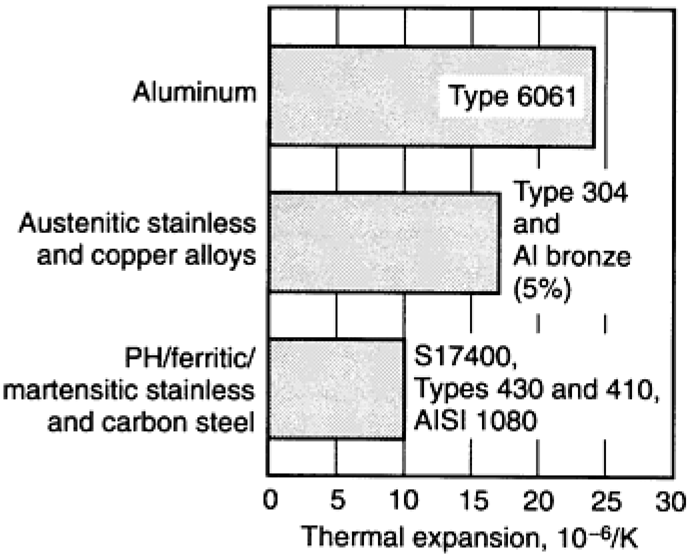

Fig. 3 Comparison of thermal expansion for carbon steel, copper alloy, aluminum, and stainless steels. Source: Ref 5, 6

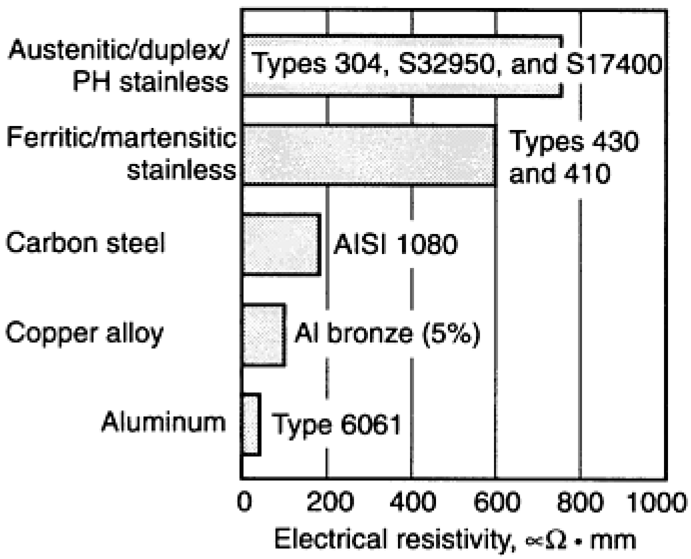

Fig. 4 Comparison of electrical resistivity for carbon steel, copper alloy, aluminum, and stainless steels. Source: Ref 5, 6

Table 2 lists tensile properties and toughness for selected stainless alloys representing the five families. The four grades listed under austenitic alloys have relatively low yield strength, compared with the heat-treatable alloys, but have the highest tensile ductility and toughness. The latter two alloys, S20161 and S21800, were specifically developed to have superior resistance to galling and metal-to-metal wear for stainless steels. Alloy N08020 is a high-nickel (33%) stainless alloy for use in harsh corrosive environments.

Table 2 Properties of selected stainless steels relative to various ferrous and nonferrous alloys

Source: Ref 5, 6

The ferritic stainless steels (type 405 and 409) listed have tensile yield strengths similar to the austenitic grades, but lower values for ultimate tensile strength, ductility, and toughness. However, strength, ductility, and toughness are still excellent, compared with other materials, such as type 6061 aluminum and aluminum bronze. The duplex stainless alloy (S32950) listed has twice the tensile yield strength of the austenitic and ferritic grades, and approximately half the toughness. Again, its toughness is far superior to heat-treat-hardened alloys.

The martensitic alloys listed in Table 2 have a large variation in strength, ductility, and toughness. In the annealed condition, their properties are similar to the ferritic alloys, with strength increasing and ductility decreasing with increasing carbon content. The higher carbon-containing alloys, type 420 and type 440C, are generally tempered at a low temperature (330 °C, or 625 °F max.) to maximize their strength. On the other hand, type 410 is tempered over a wide temperature range, from 260 to 650 °C (500 to 1200 °F). The tensile properties of type 410 are similar to carbon steel (AISI 1080).

The martensitic PH alloys, such as S45500 and S17400, have higher annealed strength and lower ductility than the martensitic alloys, and are aged at temperatures ranging from 480 to 620 °C (895 to 1150 °F). Their strength is dependent on the hardener (Ti, Nb, Cu), the amount of hardener, and the aging temperatures used. Toughness is either similar to superior to the martensitic alloys at a given strength level.

Wear and Galling

Types of Wear

The types of wear described below include abrasive, fretting, corrosive, fatigue, and adhesive wear.

Abrasive wear involves the plowing of localized surface contacts through a softer mated material. The wear is most frequently caused by nonmetallic materials, but metallic particles can also cause abrasion (Ref 7). Generally, a material is seriously abraded or scratched only by a particle harder than itself. Abrasive wear is commonly divided into three types: low stress, high stress, and gouging.

Low-stress abrasion (scratching) is defined as wear that occurs due to relatively light rubbing contact of abrasive particles with the metal. Wear scars usually show scratches, and the amount of subsurface deformation is minimal. Consequently, the surface does not work harden appreciably. Parts such as screens, chute liners, blades, and belts that are exposed to sand slurries or abrasive atmospheres could experience low-stress abrasion. Many machine components such as bushings, seals, and chains that operate in dust will wear by low-stress abrasion (Ref 8).

High-stress abrasion is wear under a level of stress that is high enough to crush the abrasive. Considerably more strain hardening of the metal surface occurs. The abrasion or ore grinding balls is an example of high-stress abrasion in the mining industry. Other examples include abrasion experienced by rolling-contact bearings, gears, cams, and pivots.

Gouging Abrasion. The term gouging abrasion is used to describe high-stress abrasion that results in sizable grooves or gouges on the worn surface (Ref 9). It occurs on parts such as crusher liners, impact hammers in pulverizers, and dipper teeth handling large rocks. Strain hardening and deformation are the dominant factors.

For ferrous materials, abrasion resistance is highly dependent on three metallurgical variables: microstructure, hardness, and carbon content. The inherently hard martensitic structure is preferable to the softer ferritic and austenitic structures. This is especially significant in low-stress abrasion, where little subsurface deformation occurs. When high-stress abrasion is encountered, alloys with high work-hardened hardness values have improved wear resistance, when compared with alloys with low work-hardened hardness values. Although austenitic stainless less steels will work harden more readily than the other stainless families of alloys, martensitic stainless alloys are preferred in applications where high-stress abrasion is encountered, because of their higher hardness by heat treatment. Increased carbon content, regardless of structure, favors better abrasive wear resistance, and so does an increased volume of carbides, as long as their hardness is not exceeded by that of the abrasive medium.

For stainless steels, knowledge of low-stress abrasion resistance is important, because abrasive particles can be found in applications where stainless steels are used. Austenitic stainless steels with a high work-hardening rate could be used where gouging abrasion is a problem and toughness is required. However, austenitic manganese steels, such as Hadfield Mn steel, are more resistant. Generally, stainless steels are considered for abrasive wear conditions when the environment is corrosive or when elevated temperature are encountered.

Fretting wear is material loss that is due to very small amplitude vibrations at mechanical connections, such as riveted joints. This type of wear is a combination of oxidation and abrasive wear. Oscillation of two metallic surfaces produces tiny metallic fragments that oxidize and become abrasive. Subsequent wear proceeds by mild adhesive wear in combination with abrasive wear.

Fretting wear is influenced by contact conditions, environmental conditions, and material properties and behavior. These factors may interact to influence both the nature and the extent of fretting damage. For example, the influence of an environmental factor depends on its accessibility to the metal contact area. Only if the environmental conditions have ready access to fretting damage sites, then environmental factors will strongly influence fretting.

Key parameters in fretting include load, frequency, amplitude of fretting motion, number of fretting cycles, relative humidity, and temperature. Fretting wear rate is virtually independent of amplitude up to a critical value. Beyond that, the wear rate increases almost linearly with the amplitude. The effect of frequency has been studied on mild steel. Up to 30 Hz, the fretting wear decreases with increasing frequency, while wear is not affected above 30 Hz. A threshold number of cycles appears to be required for the onset of steady-state fretting wear rate. This is marked by the appearance of microspall pits, which indicate that a surface fatigue mechanism is operative. The environmental factors, that is, relative humidity and temperature, generally favor the use of stainless steels, because of their superior corrosion and thermal properties.

Corrosive wear involves an interaction between the wear surface and the corrosive reagent. Corrosion in aqueous media is an electrochemical action that results in material removal by dissolution, whereas wear involves material removal that is due to physical interaction between surfaces under relative motion. When these two processes are combined, the material loss may be significantly accelerated, because of synergistic behavior. The wear-corrosion process involves the disruption and removal of the oxide film, leading to exposure of active metal surface to the environment, dissolution or repassivation of the exposed metal surface, interaction between elastic fields at asperities in contact with the environment, and interaction between plastically deformed areas and the environment. The exact nature of the wear-corrosion process is very dependent on the specific metal/corrosive reagent (Ref 10).

Corrosive wear can occur in the mining industry, where abrasive wear combines with a wet corrosive environment. Abrasion-resistant alloy steels can be ineffective in this application, whereas stainless steels often perform well. In these conditions, carbon steel readily forms iron oxide, which is removed by the sliding and bumping of moving coal/ore (Ref 11). If the rust is repeatedly removed, then there will be continuing loss of metal thickness.

In South Africa, a ferritic grade (3Cr12) provides a cost-effective solution to corrosive wear problems in chutes, liners, and conveyor belt equipment used in ore handling. This alloy is a modified type 409 stainless steel. In the United States, type 304 has been widely used in coal-handling equipment such as chutes, bins, hoppers, and screens, because of its good corrosion resistance. Another reason for the popularity of type 304 is the great improvement over alloy steels with regard to "slideability." Type 304 retains a smooth surface finish, whereas abrasion-resistant alloy steels rust, which causes material buildup and lowers flow rate. Coal hopper cars lined with type 304 can be discharged three times faster than unlined cars, because of improved slideability (Ref 12).

Corrosive wear is clearly a situation in which the use of stainless steels is attractive, because of their ability to resist the removal of their oxide film.

Fatigue wear, or contact fatigue, occurs when a surface is stressed in a cyclic manner. This type of wear can be found in parts subjected to rolling contact, such as ball bearings and gears. The fatigue wear rate of metals is affected by surface conditions, such as finish, residual stress, hardness, and microstructure. Surface treatments such as nitriding, carburizing, and shot peening, which increase surface hardness and improve residual stress distribution, are performed to prevent fatigue wear.

Cavitation, a combination of corrosive wear and fatigue wear, occurs when a liquid is subjected to rapidly alternating changes in pressure, during which bubbles form. Subsequent equalization of pressure causes the bubbles to collapse at the liquid-metal interface, resulting in cavitation wear. High-velocity pumps, hydraulic turbines, and fluid flow valves are applications where cavitation is a concern (Ref 13).

Because of the corrosive aspect of cavitation, austenitic stainless steels that work harden rapidly can be used satisfactorily. A cobalt-base hardfacing alloy, such as Stellite 6B, is used to achieve the best resistance.

Adhesive wear occurs when two metallic components slide against each other under an applied load where no abrasives are present. This type of wear is called "adhesive" because of the strong metallic bonds formed between surface asperities (that is, surface high spots) of the materials. Wear results from the shear failure of the weaker of the two metallic mating surfaces. One theory postulates that subsurface crack nucleation and growth follow asperity shearing and flattening (Ref 14).

When the applied load is low enough, the surface oxide film characteristic of stainless steels can prevent the formation of metallic bonds between the asperities on the sliding surfaces, resulting in low wear rates. This form of wear is called mild wear, or oxidative wear, and can be tolerated by most moving components. When the applied load is high, metallic bonds will form between the surface asperities, and the resulting wear rates are high. The load at which there is a transition from mild to severe wear is called the transition load.

Adhesive wear is more prevalent in parts where a lubricant cannot be used. Examples include chain-link conveyor belts, fasteners, and sliding components in a valve. For stainless steels, hardness affects adhesive wear resistance. For martensitic alloys, a minimum hardness of 53 HRC is required for excellent wear resistance. For austenitic stainless alloys, the work-hardened hardness is critical, as are alloying additions that increase the stability of the oxide film. These factors tend to increase the transition load required for severe wear to occur.

Galling

Galling can be considered a severe form of adhesive wear. With high loads and poor lubrication, surface damage can occur on sliding metal components. The damage is characterized by localized macroscopic material transfer, that is, large fragments or surface protrusions that are easily visible on either or both surfaces. This gross damage is usually referred to as galling, and it can occur after just a few cycles of movement between the mating surfaces. Severe galling can result in seizure of the metal surfaces.

The terms scuffing and scoring are also used to describe similar surface damage under lubricated conditions. Scuffing is the preferred term when the damage occurs at lubricated surfaces, such as the piston ring-cylinder wall contact. Scoring typically describes damage that takes the form of relatively long grooves (Ref 15).

Materials that have limited ductility are less prone to galling, because under high loads surface asperities will tend to fracture when interlocked. Small fragments of material may be lost, but the resultant damage will be more similar to scoring than to galling. For highly ductile materials, asperities tend to plastically deform, thereby increasing the contact area of mated surfaces; eventually, galling occurs.

Another key material behavior during plastic deformation is the ease with which dislocations cross slip over more than one plane. In fcc materials, such as austenitic stainless steels, dislocations easily cross slip. The rate of cross slip for a given alloy or element is usually indicated by its stacking-fault energy. Dislocation cross slip is hindered by the presence of stacking faults, and a high stacking-fault energy indicates a low number of impeding stacking faults and an increased tendency to cross slip and, hence, gall. Table 3 lists the stacking-fault energies of four fcc elements. Nickel and aluminum have poor galling resistance, whereas gold and copper have good galling resistance. Austenitic stainless steels with high work-hardening rates will have relatively low stacking-fault energies, and have been shown to have less tendency to gall.

Table 3 Stacking-fault energies of some common metals

Metals	Stacking-fault energy, eV gs/cm^2
Gold	30
Copper	40
Nickel	80
Aluminum	200

Source: Ref 15, p 183

Materials that have a hexagonal close-packed (hcp) structure with a high *c/a* ratio have a low dislocation cross slip rate and are less prone to galling. This explains why cobalt-base alloys and cadmium-plated alloys resist galling while titanium alloys tend to gall.

Factors Affecting Wear and Galling

The factors that affect wear and galling can be design, lubrication, environmental, and material related. Component design is probably the most critical factor. When stainless steels are required, proper design can minimize galling and wear. Similar applications, like valve parts, can often result in wear-related problems for one company or be of very little concern for another, despite their use of the same alloy.

When stainless steels are used in sliding surface applications, a key consideration is reduction of contact stress. The load on the parts should be minimized, and contact area should be maximized. Design tolerance of the parts should be tight with sufficient clearance because tightly fit parts will be more prone to wear and galling. Lubricants should be used where possible, because they are very effective at reducing contact stress. However, the design should ensure that lubrication can be effectively applied. Often, lubricants are ineffective because of poor design, which renders the parts inacessible to lubrication.

Another important factor is the surface roughness of the parts. Highly polished surfaces (<0.25 μm, or 10 μin.) or very rough finishes (>1.5 μm, or 60 μin.) increase the tendency for wear and galling. It is theorized that very smooth surfaces lack the ability to store wear debris, because of the absence of valleys between asperities, which means the asperities will have greater interaction. Also, lubricants will tend to wipe off the smoother surface. Too rough a finish results in interlocking asperities, which promote severe tearing and galling.

A final design option is surface treatments, such as nitriding, carburizing, hard-face coatings, ion implantation, and shot peening. These treatments are effective at reducing wear and galling, provided that the part configuration or the added cost is acceptable.

Wear and galling can also be affected by the environment. Stainless steels are selected instead of carbon steels when the environment requires either oxidation or corrosion resistance. Alloy selection is dependent on the specific environment that the parts will encounter in service. Thus, laboratory and field tests of candidate alloys are highly recommended. Once again, component design is a critical factor in reducing corrosive wear.

In the mining industry, proper design of equipment can reduce corrosive wear, thereby increasing service life. Sharp bends in flames and pipelines should be avoided, and the angle of discharge from belts or chutes should be minimized. Another consideration is the possibility of galvanic corrosion, which can occur where dissimilar metals are connected in the presence of an electrolyte. An example would be the use of carbon steel fasteners to join stainless components. The dissimilar metal combination, plus the adverse surface area ratio between the fastener and the surrounding surface, will accelerate the corrosion of the carbon steel.

The proper design of equipment should allow for the drainage of pipes, flumes, and tanks during shutdown, as well as spillage or hosedown water within the plant. Examples of proper versus improper design of coal-handling equipment are shown in Fig. 5.

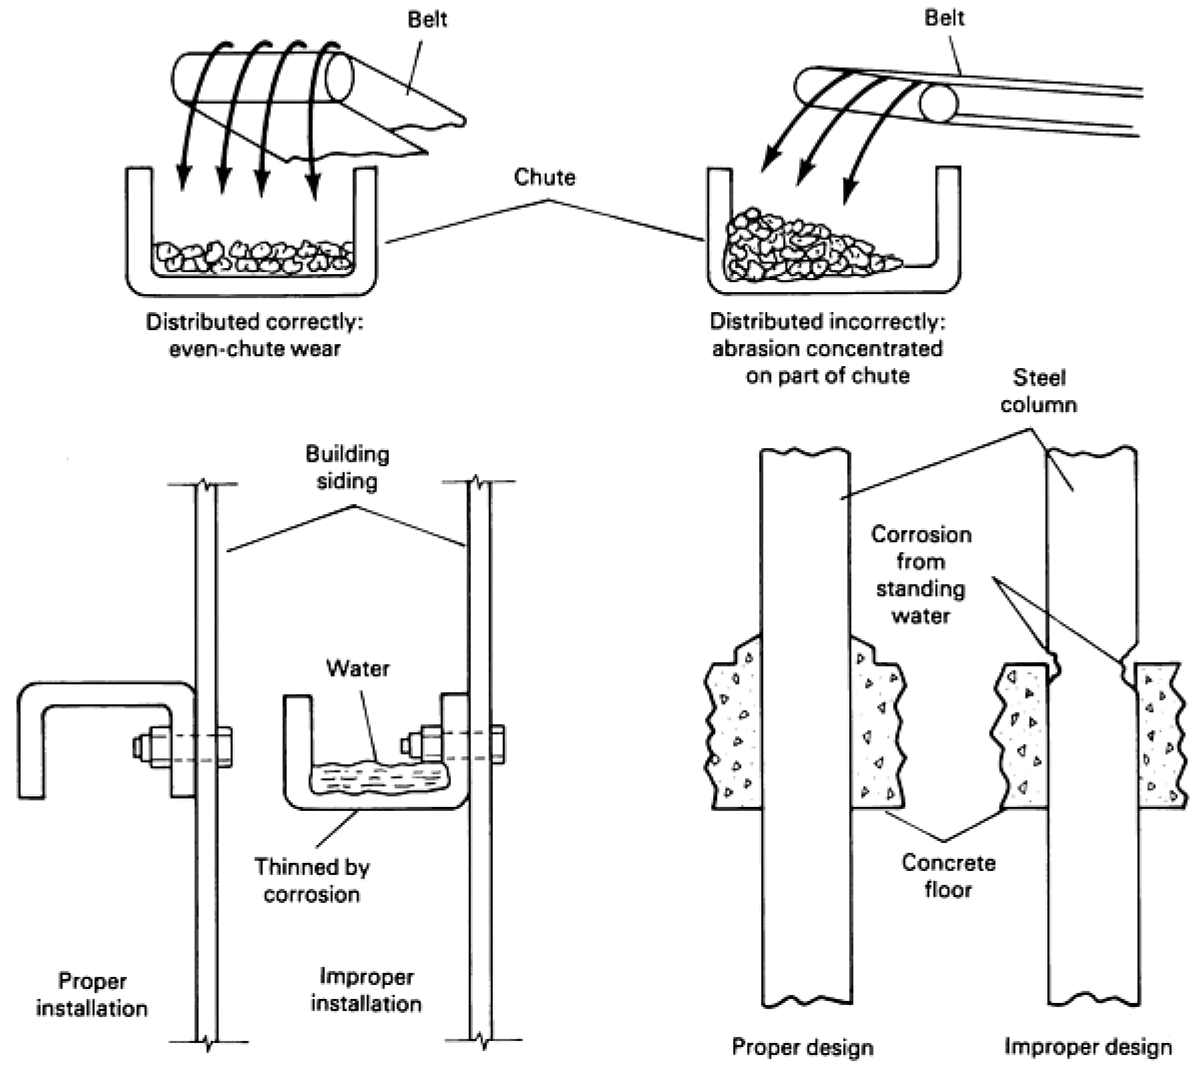

Fig. 5 Effect of design on susceptibility to corrosive wear. Source: Ref 11

Material selection is dependent on the type of wear encountered. To resist adhesive wear, a high work-hardened hardness in an austenitic alloy and a stable oxide film can have excellent results. For hardenable stainless steels, high carbon content (0.3% minimum) to increase hardness (53 HRC minimum) is critical. Thus, martensitic PH alloys with their low carbon content, but high hardness, tend to have poor wear resistance. Because ferritic stainless steels cannot be hardened by heat treatment nor readily work hardened, they may also have poor metal-to-metal wear resistance.

The comments on adhesive wear apply to galling resistance, except that the martensitic PH alloys with high hardness, which is achieved by using a low aging temperature (480 °C, or 895 °F), can have improved galling resistance. Elements that form inclusions in steel, such as sulfur, tin, bismuth, and lead, can affect the sliding behavior of the mated materials. These inclusions act as solid lubricants. Thus, the sulfur-bearing stainless steels, such as types 303 and 416, have better galling resistance, but poorer adhesive wear resistance than their non-sulfur-bearing parent alloys, types 304 and 410. Another alloy example is Waukesha 88, which contains a tin- and bismuth-bearing second phase that results in excellent galling resistance, despite the high nickel content of the alloy (Ref 16).

Hardness and microstructure are critical to abrasive wear resistance. Unlike adhesive wear resistance, which favors austenitic alloys with a high work-hardening rate, abrasive wear resistance favors the hard martensitic matrix structure versus the softer austenitic or ferritic structure. This is especially significant in low-stress abrasion, where little subsurface deformation occurs. Also, high-carbon alloys with primary carbides have better wear resistance. Thus, martensitic alloy S44004 has good resistance to abrasion, whereas low-carbon martensitic PH alloy S17400 has poor abrasion resistance. For gouging abrasion, Hadfield Mn steel is used, because strain hardening and impact resistance are critical.

To resist fretting, thermal wear, and corrosive wear, corrosion and oxidation resistance become critical. The type of stainless steel to be used depends on the environment, with austenitic stainless steels favored in severe environments. A key factor for resisting these types of wear is the alloying addition, because silicon, aluminum, and chromium improve the corrosion and oxidation resistance of a particular alloy regardless of stainless family.

Wear and Galling Tests Commonly Used for Stainless Steels

Dry sand/rubber wheel test is an ASTM standard test (Ref 17) used to determine the resistance of metallic materials to low-stress (scratching) abrasion. The test involves the abrading of a test specimen with a grit of controlled size and composition (that is, rounded grain quartz sand). The abrasive is introduced between the test specimen and a rotating wheel with a chlorobutized rubber tire or rim of a specified hardness. The test specimen is pressed against the rotating wheel at a specified force by means of a lever arm while a controlled flow of grit abrades the test surface. The rotation of the wheel is such that its contact face moves in the direction of the sand flow. A schematic diagram of the test apparatus is shown in Fig. 6. The test duration and force applied by the lever arm vary depending on the relative wear resistance of the materials evaluated. For stainless steels, the test duration is one-third that of the more abrasion-resistant tool steel alloys such as D2. Specimens are weighed before and after the test, and the loss in mass is recorded. Abrasive wear is generally reported in terms of volume loss (in cubic millimeters) by dividing mass loss by the density of the alloy.

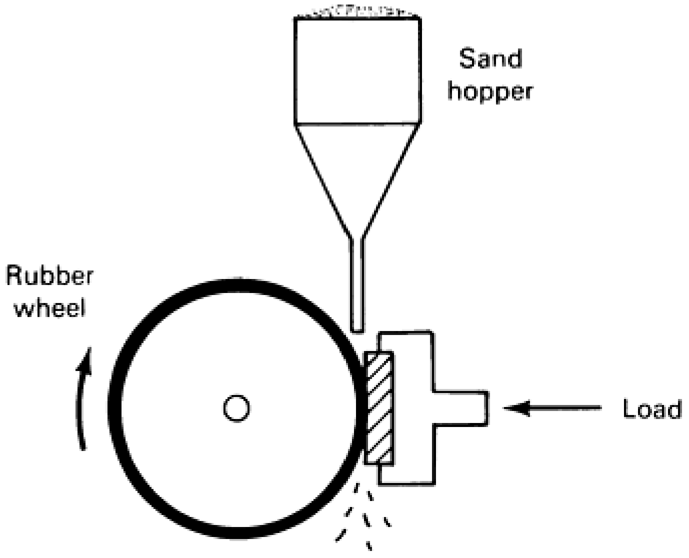

Fig. 6 Dry sand abrasion test apparatus. Source: Ref 18

Corrosive wear testing commonly involves hub and ball mill tests. The apparatus used for the hub test, which is low-stress abrasive test, is shown in Fig. 7. The slurry container has three hubs, each of which holds eight specimens, which are driven through slurry, as shown in Fig. 8.

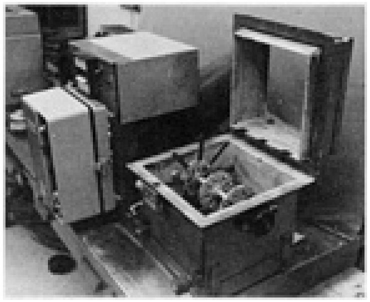

Fig. 7 Hub wear test machine. Source: Ref 12, p 3

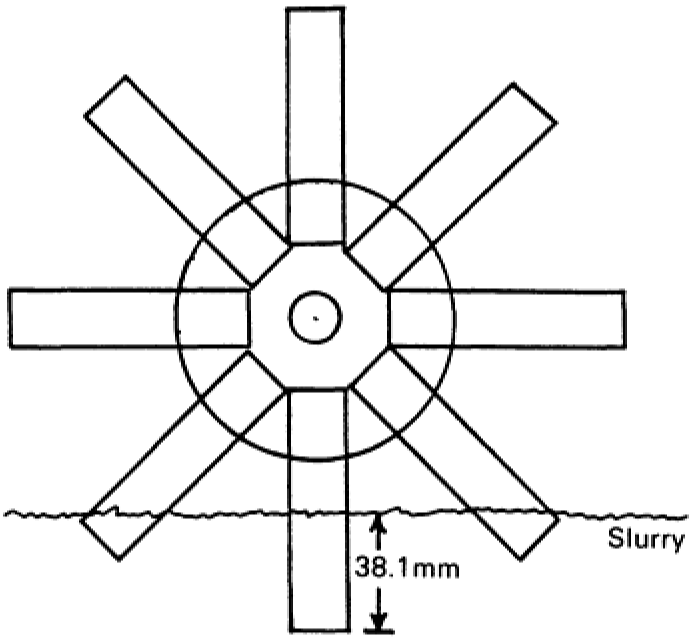

Fig. 8 Specimen arrangement on hub. Source: Ref 12, p 3

Slurries can differ, depending on the application that needs to be simulated. Often, alloys are evaluated both wet (corrosive slurry) and dry to demonstrate the effect of corrosion on corrosive wear. Specimens are weighed before and after the test, and volume loss is determined by dividing the weight loss by the alloy density.

The ball mill test is used extensively by the U.S. Bureau of Mines and in Canada to determine corrosive effects found in nickel mines. For this test, a 5.3 L (1.4 gal) porcelain jar serves as the ball mill, and the specimens are free to tumble in the corrosive slurry. Tests are performed for a particular time period, such as 8 h, after which the weight loss is determined and volume loss is calculated. The samples are then tested for additional time periods, using fresh slurry for each period. At the conclusion of the test, corrosive wear versus time is plotted for the alloys being evaluated.

Block-on-ring is an ASTM standard test (Ref 19) for determining the resistance of materials to sliding wear. The test utilizes a block-on-ring friction and wear testing machine to rank pairs of materials according to their sliding wear characteristics under various conditions. Rotational speed and load can be varied to correspond to service requirements. In addition, tests can be run with various lubricants, liquids, or gaseous atmospheres.

The test consists of a block specimen loaded against a ring specimen at a given speed for a given number of revolutions (Fig. 9). Block scar volume is calculated from the block scar width and depth, and ring scar volume is calculated from ring weight loss. The friction force required to keep the block in place is continuously measured during the test with a

load cell and is then recorded. The choice of test parameters is left to the user (with the exception of sliding distance, which is specified because wear does not usually vary linearly with distance in this test).

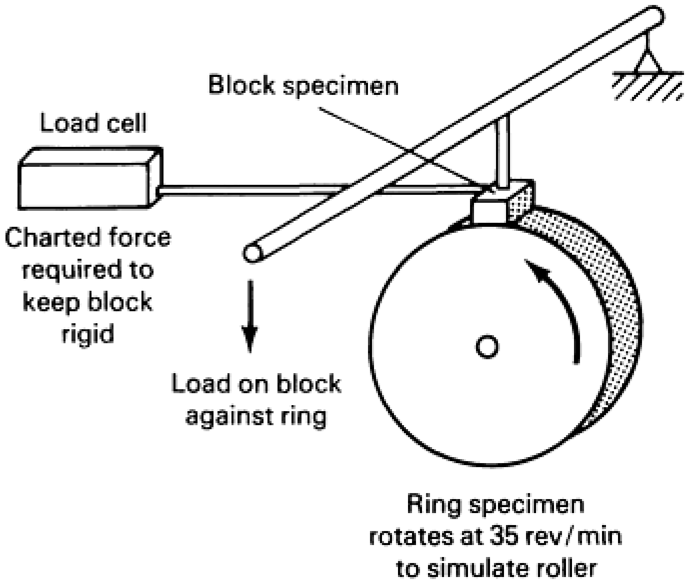

Fig. 9 Key components of a block-on-ring test apparatus. The coefficient of sliding friction, μ_{sf}, is calculated using the equation μ_{sf} = (friction force)/(applied load). Source: Ref 2

Crossed-cylinder is an ASTM standard test (Ref 20) for determining the resistance of metallic materials to metal-to-metal wear. This test ranks the adhesive wear resistance of materials and evaluates the compatibility of different metal couples. It is the most commonly used test for evaluating metal-to-metal wear resistance of stainless steels.

The test configuration consists of two cylindrical specimens that are positioned perpendicular to each other. One sample is rotated at a specified test speed while the other sample is kept stationary. The stationary specimen is pressed against the rotating specimen at a specified load by means of a lever arm and attached weights. The setup results in deadweight loading. A photograph of the test apparatus is shown in Fig. 10. Elevated-temperature tests have also been performed using the crossed-cylinder apparatus. The test duration, number of cycles, and rotational speed are varied depending on the relative wear resistance of the mated materials. The amount of wear is determined by weighing the specimen before and after the test. Weight loss is converted to volume loss by dividing the density of the material. Volume loss is determined for both the stationary and rotating specimens, and the total volume loss is recorded. When dissimilar materials are being tested, it is recommended that each alloy be tested in both the stationary and rotating positions.

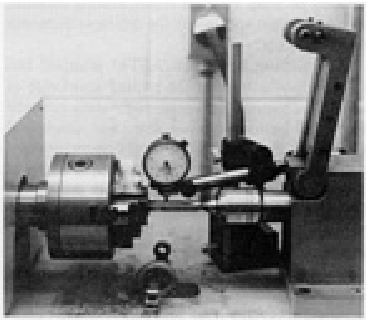

Fig. 10 Typical crossed-cylinder test apparatus. Source: Ref 21

Pin-on-disk is an ASTM standard test for determining the wear of material during sliding (Fig. 11). The coefficient of friction can also be determined using this test. For the pin-on-disk wear test, two specimens are required: one specimen is a pin with a radiused tip that is positioned perpendicular to the other specimen, which is usually a flat circular disk. A ball, rigidly held, often is used as the pin specimen. The test machine causes either the disk specimen or the pin specimen to revolve about the disk center. In either case, the sliding path is a circle on the disk surface. The plane of the disk may be oriented either horizontally or vertically. The pin specimen is pressed against the disk at a specified load, usually by means of an arm or lever and attached weights. Wear results are reported as volume loss (in cubic millimeters) for the pin and disk separately. When two different materials are tested, it is recommended that each material be tested in both the pin and disk positions.

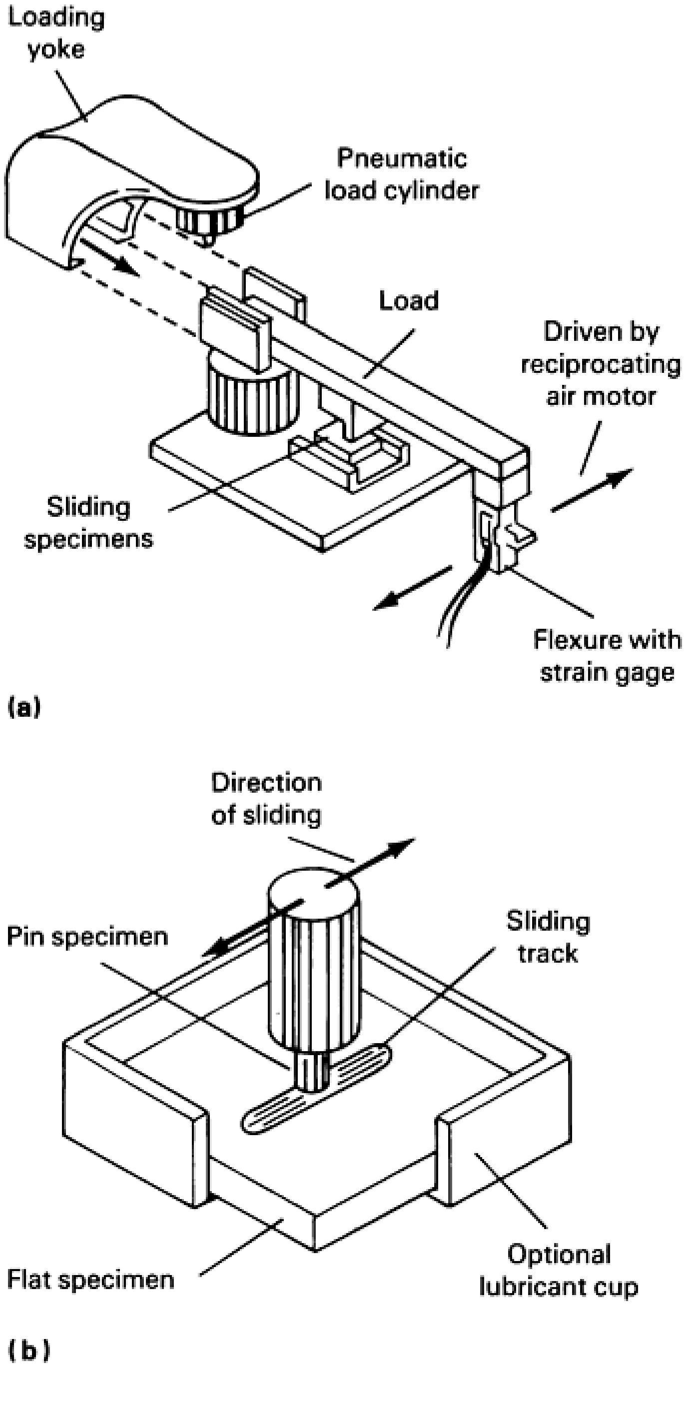

Fig. 11 Pin-on-disk wear test apparatus. (a) Key components of the device. (b) Close-up showing pin motion relative to flat when subjected to load. Source: Ref 2

The amount of wear is determined by measuring appropriate linear dimensions of both specimens before and after the test, or by weighing both specimens before and after the test. Linear measurements of wear are converted to wear volume by using appropriate geometric relationships, while mass loss is converted to volume loss by dividing mass loss by the appropriate density values for the specimens. Wear results are usually obtained by conducting a test for a selected sliding distance, load, and speed. Graphs of wear volume versus sliding distance using different specimens for different distances can be plotted.

The galling test is an ASTM standard test (Ref 22), which ranks the galling resistance of material couples. This test, commonly referred to as the button-on-block test, was developed during the 1950s and is the most commonly used procedure to test the galling resistance of stainless steels. Although it is generally performed on bare metals, nonmetallics, coatings, solid lubricants, and surface-modified alloys can be tested as well.

The test method uses available laboratory equipment that is capable of maintaining a constant compressive load between two flat specimens, such as hydraulic or screw-fed compression testing machines. A specimen with a 13 mm (0.5 in.) diameter section, referred to as the button, is slowly rotated one revolution (360°) relative to the other specimen under a specified compressive load. The test surfaces are ground so that the surface roughness range is from 0.4 to 1 μm (15 to 40 μin.) and the specimens are flat to ensure 100% contact between the mated surfaces.

The surfaces are examined for galling after sliding. The criterion for whether galling occurs is the appearance of the specimens, based on unassisted visual examination. Galling is characterized by at least one of the contacting surfaces exhibiting torn or raised metal. If the specimens have not galled, then a new button is tested on a new block location at an increased load. This procedure is continued until galling occurs. Similarly, if galling does occur on the first test, then lower loads are evaluated until no galling occurs. The galling test set-up is shown in Fig. 12.

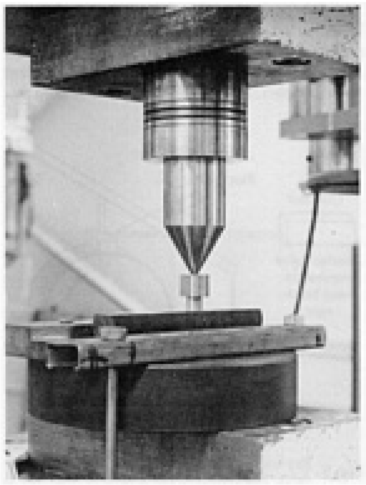

Fig. 12 Button-on-block galling test. Source: Ref 23

The loads applied correspond to a contact stress for the 13 mm (0.5 in.) diameter button. The stress midway between the highest nongalled test and the lowest galled test is referred to as the threshold galling stress. The higher the threshold galling stress, the more resistant the mated materials are to galling. Galling resistance can be determined for a particular selfmated material or dissimilar-mated materials. For the latter, it is recommended that each alloy be evaluated as button and block specimens.

To simulate repeated part performance under service conditions, such as those existing with sliding valve parts, the button specimen can be rotated multiple revolutions, in which the direction is reversed after each 360° revolution, instead of just rotating it once. Because of the increased severity of the multiple-rotation method, threshold galling stresses will be significantly lower than those of the single-rotation test.

To test highly resistant alloys, such as cobalt base Stellite 6B, a similar button-on-block test is used. The button is rotated through a 120° arc ten times at three different loads. Surface profilometry is then used to assess the degree of damage (Ref 24).

Another test that is similar to the button-on-block test is the ring-on-ring test, which uses ring specimens, rather than solid button/block samples. The test is used to assess galling resistance for tubular products related to oil production (Ref 25).

Galling of threaded parts, such as 9 m (30 ft) drill collars, is evaluated by a make/break test. The test procedure involves making a box/pin connection at a specified torque, breaking the connection, and recording the breakout torque. The procedure is repeated a given number of times, and the threads are periodically examined for galling. Unlike the button-on-block test, which simply tries to rank materials, this test simulates the actual service connections that are made for drill collars in the oil-drilling industry. Tests that simulate the specific application are very beneficial, but are usually quite expensive to perform. Thus, the button-on-block test can be used as a screening test to choose the best candidate alloy for a more specific test tailored to the service conditions of a particular application.

Wear Data for Stainless Steels

Abrasive/Corrosive Wear. The low-stress abrasion resistance of stainless steels can be determined by using either the dry sand abrasion or the hub test. Dry sand abrasion data (Table 4) clearly show that austenitic stainless steels have poorer wear resistance than the harder martensitic alloys, whose increased carbon content increases wear resistance. Type 410, which has 0.1% C, has wear resistance similar to the best austenitic alloys, whereas the wear resistance of type 440C is three to four times greater than the austenitic alloys. The abrasive wear resistance of type 440C is inferior to D2, an abrasive wear resistant tool steel. Test results shows that D2 has a volume loss of 32 mm^3, which is similar to type 440C, when the test time for D2 is tripled.

Table 4 Abrasive wear resistance of stainless steels

Alloy	Rockwell hardness	Volume loss, mm^3
Austenitic		
Type 304	85.5 HRB	113.1
S21061	95.0 HRB	139.6
S21061	26.5 HRC	138.2
S21800	93.0 HRB	127.2
S24100	95.5 HRB	94.9
S28200	97.0 HRB	88.3
Martensitic		
Type 410	44.0 HRC	94.0
S42010	51.0 HRC	67.5
Type 420	52.0 HRC	59.4
Type 440A	56.0 HRC	56.3
Type 440C	56.0 HRC	33.5
Type 440C	58.0 HRC	32.1

Note: Based on dry sand/rubber wheel abrasion test, ASTM G 65, procedure B, 133 N (30 lbf), 10 min duration.

When a wet abrasive slurry is present, stainless steels experience greater wear than under dry conditions. However, their wear resistance is superior to martensitic carbon steels. Figure 13 compares five alloys under dry and wet slurry conditions in the hub test. Under dry conditions, the stainless alloys evaluated had similar or greater wear than Hadfield Mn steel and AISI 4340. However, when evaluated in a wet slurry of 5% NaCl plus 0.5% acetic acid, the stainless alloys were more resistant. Similar trends are shown in various wet environments, such as distilled water, synthetic nickel mine water, and synthetic seawater (Fig. 14, 15, 16) using the ball mill test.

Stainless steels have superior corrosive wear resistance in coal-handling equipment. Service life is greatly improved, compared with carbon steels (Fig. 17). In the mining industry, corrosion is the primary factor in the deterioration of equipment. Figure 18 shows the effect of chromium content on atmospheric corrosion resistance. Without chromium, corrosion rates are at least ten times greater than stainless steels.

Tests under service conditions have been performed on stainless steels, abrasion-resistant steels, and carbon steels. Tests were performed for up to 5.3 years, and the reduction of thickness determined. Results of two studies show the superiority of stainless steels, compared with nonstainless alloys (Table 5). In general, type 304 is superior to type 410. However, alloy selection is dependent on the particular coal-handling equipment.

Table 5 Wear rates for test plates in drag conveyor bottoms

Material	Loss in μm/10^9 g (mils/million tons) of coal conveyed	Test time, months
125 × 9.5 mm (5 × $\frac{3}{8}$ in.)		
Type 304 stainless steel	0.67 (24)	27
Type 410 stainless steel	0.73 (26)	27
Type 316 stainless steel	0.90 (32)	27
Abrasion-resistant steel	1.01 (36)	15
Mild steel	1.65 (59)	15
9.5 mm ($\frac{3}{8}$ in.) by 0 thermal dryer product		
Type 304 stainless steel	0.045 (1.6)	25
Type 316 stainless steel	0.053 (1.9)	25
Type 410 stainless steel	0.100 (3.6)	25
Abrasion-resistant steel	2.3 (83)	6
63.5 × 6.35 mm (2.5 × 0.25 in.)		
Type 304 stainless steel	0.07 (2.6)	47
Type 410 stainless steel	0.11 (3.9)	47
Wrought iron	2.5 (89)	23
Mild steel	3.0 (107)	23
Crushed middlings conveyor		
Type 304 stainless steel	0.17 (6)	48
Abrasion-resistant steel	7 (250)	(failed in 18 months)

Adhesive Wear. The metal-to-metal wear resistance of stainless steels can be determined by using the crossed-cylinder wear test. Unlike low-stress abrasion resistance, austenitic stainless steels generally have superior resistance, compared with martensitic stainless alloy (Table 6). The excellent wear resistance of type 201, type 301, S20161, and S21800 can be attributed to a high work-hardening rate. Additionally, the latter two alloys have a high silicon content, which not only increases the work-hardening rate, but results in a more adherent oxide film, thereby preventing the transition from mild oxidation wear to severe wear. Like abrasive wear resistance, a high hardness value is critical for martensitic stainless steels in order to achieve good adhesive wear resistance. For type 440C, high hardness (56 HRC) results in exceptional metal-to-metal wear resistance, whereas for type 440C (26 HRC), volume loss is high. Generally, high volume loss is characteristic of these alloys, even at 50 HRC.

Table 6 Adhesive wear resistance of stainless alloys

Alloy	Rockwell hardness	Volume loss, mm^3

(a) Procedure A.

When different materials are mated together under load, wear testing is important for proper alloy selection. A general misconception for metal-to-metal wear and galling resistance is that a large difference in hardness between the two mated alloys is beneficial. Wear data suggest that alloys with good adhesive wear, such as type 440C (57 HRC) and S21800 (92 HRB), are excellent alloy selections, regardless of the hardness of the other alloy (Table 7).

Table 7 Wear compatibility of dissimilar-mated stainless steels

Alloy	Volume loss, mm^3						
	Type 304 (99 HRB)	**Type 316 (91 HRB)**	**S17400 (43 HRC)**	**S24100 (95 HRB)**	**S20910 (99 HRB)**	**S21800 (95 HRB)**	**Type 440C (57 HRC)**
Type 304	16.4	. . .	. . .	. . .	. . .	. . .	. . .
Type 316	13.5	16.4	. . .	. . .	. . .	. . .	. . .

Source: Ref 28

The best stainless alloys have superior adhesive wear resistance, compared with aluminum (type 6061), abrasion-resistant steel (Astralloy-V), and AISI 4130 carbon steel. However, they are less resistant than Hadfield MN steel, D2 tool steel, and Stellite 6B, a hardfacing alloy (Table 8). These rankings can change when environmental factors such as corrosion, oxidation, and temperature are considered. For example, these three factors will have a much greater effect on alloys that contain little, if any, chromium. Even Stellite 6B, which does contain chromium, has reduced adhesive wear resistance at elevated temperatures (Table 9), unlike type 304 and S21800.

Table 8 Relative ranking of adhesive wear resistance of wrought materials

Wrought material	Rockwell hardness	Weight loss, mg/1000 cycles	
		at 105 rev/min	**at 415 rev/min**
D2 tool steel	61 HRC	0.46	0.34
AISI 4337	52 HRC	0.73	0.48
Stellite 6B	48 HRC	1.00	1.27
Hadfield Mn steel	95 HRB	1.25	0.41
Al (10.5%) bronze	87 HRB	2.21	1.52
Type 6061-T6 aluminum	59 HRB	17.06	21.15
AISI 4130	47 HRC	9.44	6.80
Astralloy V steel	46 HRC	213.58	8.22
Stainless alloy Type 440C	57 HRC	3.81	0.54
S21800	95 HRB	2.79	1.58
Type 201	90 HRB	4.95	4.68

(a) Cobalt-base hardfacing alloy.

The galling resistance of stainless steels can be determined by using the button-on-block test. Higher threshold galling stress indicates better resistance to galling. All five families of stainless steels are susceptible to galling.
